Gait dysfunction and falls are extremely common in the LBDs; the causes are probably multifactorial and related to motor symptoms, attentional impairments and autonomic dysfunction. Transient losses of consciousness occur in patients with LBDs where they are found mute and unresponsive for several minutes but do not obviously display any focal neurological signs. These may relate to autonomic mechanisms such as orthostatic hypotension or carotid sinus sensitivity although they may be an extreme expression of fluctuating attention and arousal.

CLINICAL DIAGNOSIS

The availability of clear, internationally recognized consensus criteria for both PDD[16] and DLB[3,5,6] provides a rigorous scaffold on which clinicians can formulate their diagnosis; however, this places an onus on the clinician to:

- Take a detailed history from both the patient and a reliable informant, which is inclusive of the severity of impairment in daily living activities;
- Compile a problem list which will aid management decisions;
- Perform a mental state examination as well as cognitive testing which encompasses multiple domains;
- Carry out a full neurological examination;
- Arrange for appropriate investigations such as brain imaging or assessment of dopaminergic function.

DIFFERENTIAL DIAGNOSIS

Aside from the difficulties of diagnostically separating PDD from DLB there are a number of other differentials that should be considered. Often the question for PD versus PDD is: when does the dementia become clinically evident? To address this, the movement task force[57] provided a five-point guideline that recommends there should be:

1. a clear diagnosis of PD according to Queen's Square Brain Bank criteria;
2. the PD develops before the onset of dementia;
3. there is a global decline in cognitive efficiency (Mini-Mental State score <26);
4. cognitive deficiency is sufficient to impair daily life;
5. impairment occurs in more than one cognitive domain (e.g. attention, executive, visuo-constructive or memory).

For both PDD and DLB, other atypical Parkinson syndromes such as MSA, progressive supranuclear palsy, and corticobasal degeneration should be considered in the differential. However, for DLB the main differential diagnosis is other dementias, in particular AD; up to 65% of autopsy-confirmed DLB cases also meet the clinical NINCDS-ADRDA criteria for probable or possible AD[58]. Vascular dementias frequently present with fluctuations in cognition, which can cause diagnostic confusion with DLB. Although rare, Creutzfeldt–Jakob disease should be considered, particularly if myoclonus is evident.

DLB has often been re-elaborated as 'delirium with Lewy bodies'; therefore, intermittent delirium is another important differential; the diagnosis of DLB should therefore only be considered after appropriate clinical investigation to exclude infective, metabolic, medication or other related causes has been carried out. Occasionally DLB may present atypically, initially, as a late-onset delusional disorder or a depressive psychosis. Development of cognitive decline or parkinsonism should raise suspicions of DLB as the underlying cause.

INVESTIGATIONS AND POTENTIAL BIOMARKERS

Electroencephalography

Although not specific, the EEG in LBDs can show generalized slowing with transient temporal sharp waves; indeed, this EEG pattern is incorporated into the supportive features described in the DLB consensus criteria.

Imaging

Generalized atrophy as well as white matter changes occurs in LBDs. However, their presence does not help clinically in making the differential diagnosis. Nevertheless, in DLB there appears to be a relative preservation of hippocampal and medial temporal lobe volume on MRI, which can help differentiate it from AD[59]. Functionally, occipital hypoperfusion has been noted in LBDs in single photon emission computerized tomography (SPECT)/positron emission tomography (PET). However, while specificity in SPECT/PET is often greater than 80% for distinguishing DLB from Alzheimer's, sensitivities tend to be lower. For example, Lobotesis *et al*.[60] noted a sensitivity of only 68%. An important recent development for the diagnosis of DLB is the visualization of presynaptic dopaminergic deficits in the striatum using ^{123}I-radiolabelled 2β-carbomethoxy-3β-(4-iodophenyl)-N-(3-fluoropropyl)nortropane (FP-CIT, trade name DaTSCAN). This technique demonstrates high sensitivity (78%) and specificity (90%) in identifying probable DLB versus non-DLB dementia[61]. However, although the current regulatory approval for FP-CIT imaging is in distinguishing probable DLB from AD, this discrimination can often be adequately made on clinical grounds alone. Rather, a longitudinal study has suggested that FP-CIT appears to be much more useful in determining clinically uncertain, i.e. 'possible', cases[62]. In this study of 19 people with an initial diagnosis of possible DLB who subsequently were diagnosed with probable DLB 1 year later, 12 had had abnormal FP-CIT scans at baseline (63% sensitivity).

Another potentially useful imaging modality is that of cardiac scintigraphy with ^{123}iodine metaiodobenzyl guanidine (^{123}I-MIBG); this provides a measure of the degree of postganglionic sympathetic cardiac innervation and it has been used to discriminate PD from other motor disorders such as MSA[63]. Additionally, ^{123}I-MIBG uptake is markedly reduced in DLB in contrast to non-demented PD patients[64] and AD patients, and it has been advocated as a means of improving sensitivity in discriminating DLB from AD, particularly if SPECT perfusion imaging is equivocal[65].

Cerebrospinal Fluid and Plasma Markers

There is increasing interest in the use of cerebrospinal fluid (CSF) and serum markers in the diagnosis of dementias. CSF levels of

alpha-synuclein species and p-tau, as well as a large number of other neurochemicals, have all been mooted as potential markers of LBDs (see Mollenhauer and Trenkwalder for further elaboration[66]), in particular the differentiation of DLB from AD. However, study results have been mixed, with poor replication between studies, variable sensitivities and specificities with frequent overlap in concentration levels between disease groups (e.g. DLB versus AD), and a lack of neuropathological confirmed diagnoses. Recently, serum proteomic array methods, which identify multiple potential diagnostic protein markers, have been used to diagnostically separate DLB from AD[67], and RNA expression patterns in blood have been suggested to be helpful in the diagnosis of early PD[68].

Genetics

A large number of genes have been associated with rare forms of familial PD; for example, *LRRK2, PINK1, SNCA* and *PARK2*, to name a few. As noted previously, GBA mutations appear to be strongly associated with the development of PD and LBDs. However, aside from this, specific gene linkages to PDD and DLB are less clear although a gene–dose effect with triplication of the associated alpha-synuclein gene (*SNCA*) has been suggested to give rise to familial variants of DLB and PDD whereas duplication is associated only with motor PD[69]. However, sporadic LBDs have not been found to be associated with over-expression of alpha-synuclein genes. Butylcholinesterase allelic variants in conjunction with the presence of APOE $\varepsilon 4$ alleles have been suggested, in individuals who will go on to develop LBDs, to increase the likelihood than they will express the DLB clinical phenotype rather than PDD phenotype, i.e. dementia before the onset of parkinsonism[70].

Conclusion

Biomarkers are useful in early diagnosis, separation of the disease from other differentials, understanding the natural history of the disease and providing objective biological correlates of treatment response. However, while a number of modalities, including fluid markers and genetics, are potentially promising, they will require significant further research before they are clinically useful. Currently, best evidence probably exists for imaging markers, in particular, FP-CIT SPECT.

COURSE, PROGNOSIS AND PSYCHOSOCIAL EFFECTS

The annual decline in cognitive and motor function scores in DLB and PDD patients is about 10%[35]. The survival duration from symptom onset (either parkinsonism or dementia) to death is between five and eight years in DLB and PDD patients depending upon the population studied[71,72]. However, some patients display a much more rapid disease course and adverse predictors may include older age at onset, greater neuropsychiatric symptom severity (hallucinations and depressive symptoms), cognitive fluctuations and the presence of co-morbid Alzheimer pathology. Conversely, a long latency between parkinsonism onset and dementia onset in PDD patients has been suggested to predict longer survival after dementia onset.

The psychosocial impact of LBDs is high: cognitive, neuropsychiatric and motor impairments cause significant difficulties for patients and their caregivers. Nursing home placement is often a frequent outcome and is particularly common when psychotic symptoms are present. One study which examined quality of life indices in DLB patients suggested that DLB patients had lower quality of life scores and used more resources than AD patients; indeed, almost 25% of DLB patients included had negative scores on the EQ-5D utility index, a level which has been defined as a state worse than death[73]. Determinants of poor quality of life in DLB patients included the presence of apathy, delusions, poor activities of daily living and absence of a caregiver; cognitive scores had no impact.

MANAGEMENT

Initial diagnosis of AD is often straightforward; in contrast, awareness of LBDs among clinicians and the general public is often very limited and this has previously led to patients being misdiagnosed, given incorrect information and treated inappropriately. Fortunately, the establishment of the consensus criteria, diagnostic neuroimaging and an increasing evidence base for the symptomatic treatment of LBDs has improved this situation. Furthermore, dissemination of knowledge is also now being supported by organizations such as the Lewy Body Dementia Association (www.lewybodydementia.org) and Lewy Body Society (www.lewybody.org).

Overall, LBDs are complex conditions in which there are multiple management issues including those of early diagnosis, treatment of cognitive impairments, assessment and management of neuropsychiatric and behavioural symptoms as well as treatment of parkinsonism, autonomic dysfunction and sleep disorders[3]. Treatments include pharmacological therapy, but non-pharmacological approaches, psychoeducation to patients and family about the various neuropsychiatric symptoms and a multidisciplinary approach to management which encompasses occupational therapy, good nursing care, and social and carer groups are also very important. Table 58.5 provides a summary of the management approach. However, currently there is insufficient data for evidence-based guidelines for PDD and DLB management although it should be noted that the Third Consortium report by McKeith and colleagues does provide the first authoritative recommendations based on expert consensus for the latter condition[3].

NON-PHARMACOLOGICAL TREATMENTS

Systematic evaluation of non-pharmacological interventions in LBDs is lacking. In the case of visual hallucinations, clear explanations as to their origin to patients who still have insight and the caregivers can be helpful. Hallucinations also appear to be exacerbated by visuoperceptual disturbances, which can be secondary to eye disease or environmental issues; cataract removal, improved illumination and removal of patterned furnishings (e.g. carpets, curtains) that can provoke illusionary experiences all may be helpful. In addition, low levels of arousal and cognitive fluctuations appear to respond to enhanced environmental novelty and improved social interaction.

PHARMACOLOGICAL TREATMENTS

Management of Cognitive Impairments

The profound cholinergic deficits which occur in the central nervous system of patients with LBDs have provided the scientific rationale that restoration of acetylcholine may help ameliorate some of the cognitive and neuropsychiatric dysfunction that occurs in LBDs. Three ChEis – donepezil (Aricept), rivastigmine (Exelon) and galantamine (Reminyl) – which block the breakdown of acetylcholine within the synapse and thus prolong its effect postsynaptically have been used

Table 58.5 Symptom management in LBDs

General management
Provide psychoeducation to patient and relatives, including explanation of the intrinsic features of LBDs including cognitive effects (attention and cognitive fluctuations), neuropsychiatric symptoms such as hallucinations, and any associated motor symptoms
Establish from the patient and carer which symptoms are most problematic, impair quality of life and need active treatment
Consider firstly what non-pharmacological and social care interventions can be implemented e.g. environmental stimulation for fluctuations; care package and occupational therapy assessment for cognitive and motor impairments
Specific treatment
Cognitive impairment
Perform baseline assessment of cognitive function; this may need to be done on several occasions given the tendency to fluctuate in LBDs
Review medication chart; stop any unnecessary drugs with a propensity to anticholinergic or sedative effects
Consider, provided there are no contraindications, a gradual introduction of a ChEi; response should be evident within several weeks. This may include specific improvements in test scores, but also be alert to more global improvements in activities of daily living and attention
Memantine, in addition, or as an alternative, should also be considered
Neuropsychiatric symptoms
Treat symptoms only if they are causing distress and/or are functionally impairing; for example, many patients are able to tolerate their visual hallucinations without the need for active treatment
Review any antiparkinson medication; gradually reduce and, if possible, stop the medications in the following order: anticholinergics, amantadine, direct dopamine agonists, COMT inhibitors and L-dopa
ChEi, in addition to their cognitive benefit, may help ameliorate neuropsychiatric symptoms such as visual hallucinations, delusions, and apathy
If psychotic symptoms persist, consider a cautious trial of an antipsychotic:
Warn both patient and carers about the potential for severe adverse reactions
Start low and go slow
Review antipsychotic use regularly, looking for side effects; be alert that most neuroleptic reactions occur in the first two weeks and it may be appropriate to admit patients during this period for monitoring
If parkinsonism is worsened or occurs for the first time (in the case of some DLB patients) stop the antipsychotic
Do not prescribe the antipsychotic for prolonged periods. Regularly re-assess the need for the drug; can alternative interventions be applied now the situation is containable?
Depression may respond to SSRIs or SNRI. Avoid antidepressants with major anticholinergic effects (e.g. tricyclics) as this can adversely affect cognition and cause confusion
Clonazapam may help noctural hallucinations and RBD
Motor symptoms
Balance the need for treatment of motor dysfunction versus the potential for exacerbation of neuropsychiatric symptoms; use the minimal antiparkinson medication required for benefit
Autonomic dysfunction/orthostatic hypotension
Discontinue any unnecessary antihypertensives. Orthostatic hypotension may respond to the addition of midodrine or fludrocortisone

in LBDs treatment. There is some evidence for all three medications with regard to improvement in global cognitive function, attentional function and activities of daily living, although to date, only the efficacy of rivastigmine has been examined in large, robust placebo control trials in DLB and PDD patients[74,75] and as such it is the only ChEi which is currently licensed for treatment in PDD. Nevertheless, there is no evidence to suggest that any one ChEi is better than another[76]. Generally the treatment effect size for cognitive impairment appears to be larger in LBDs than AD and this probably reflects the greater cholinergic deficit seen in the former[77].

Overall, ChEis are reasonably tolerated in patients with LBDs; notable side effects include gastrointestinal disturbance, urinary frequency, insomnia, leg cramps, hypersalivation and lacrimation. Given the reciprocal interplay between dopamine and acetylcholine in the striatum, one might expect an exacerbation of motor symptoms with ChEi treatment; surprisingly a dose-dependent worsening only occurs in a minority of patients[78].

There is limited data for the long-term effect of ChEi treatment in LBDs although benefits appear to be sustained for up to two years[79,80]. However, there is no data with regard to any potential disease modifying effects.

Memantine, which has a low side effect profile, may also be useful treatment in LBDs; a recent study in PDD and DLB patients by Aarsland *et al*. noted some improvement in a clinical global impression of change scale and improved speed on attentional tasks in patients receiving memantine for 24 weeks in comparison to placebo, and within the memantine receiving group there was a 1.4 point improvement in MMSE scores[81].

Management of Neuropsychiatric Symptoms

Visual hallucinations are the most frequently occurring symptom in LBDs and they are often accompanied by delusions, agitation and behavioural disturbance. As noted above for cognition, ChEis have

also been shown to be effective in open-labelled studies for treating visual hallucinations although placebo-controlled data is available only for rivastigmine[74,75]. Symptom reduction in frequency and intensity seems to be, in part, mediated by improvements in attentional function. Conversely, the presence of visual hallucinations predicts a better cognitive response to ChEi, perhaps as a result of greater cholinergic deficits in those individuals who experience them[82].

ChEi should be considered first line; however, if they are ineffective it is sometimes necessary to consider the use of an atypical antipsychotic. Clozapine or quetiapine have been advocated in the literature as preferred agents. However, clozapine has notable side effects (e.g. agranulocytosis) and needs regular blood monitoring. Clinical trial data for quetiapine is equivocal; one study noted that while quetiapine did not worsen parkinsonism, it did not have any demonstrable benefits with regard to agitation or psychosis in DLB or PDD patients[83].

However, there are substantial risks associated with antipsychotic use. Aside from the high risk of severe neuroleptic reaction, the Food and Drugs Administration in 2008 issued an alert that both typical and atypical antipsychotics are associated with increased mortality in older patients with dementia related psychosis[84]. Additionally both risperidone and olanzapine have warnings about increased risk of cerebrovascular disease[85]. Overall, therefore, a high level of caution needs to be applied to the use of antipsychotics in LBDs.

Treatment of depression and apathy in LBDs is empirical as there is no clear evidence base. Preferred agents include SSRIs and SNRIs with the avoidance of tricyclics given their anticholinergic propensity. Apathy and drowsiness may respond to ChEis, and some have advocated the use of modafinil or methylphenidate although there is no evidence to support the effectiveness of these agents.

Low dose clonazepam before bed may be helpful in the management of associated REM behaviour disorder (RBD) in LBDs[86].

Management of Parkinsonism

It is well established that antiparkinsonian medications can exacerbate psychotic symptoms in LBDs and often there needs to be a clinical compromise between a relatively mobile and active patient with psychosis and one who is non-psychotic but immobile. In PDD, it is often necessary to have some level of anti-parkinsonian medication given the greater motor impairments that occur in this condition relative to DLB. Medications should be used at the lowest dose possible, and anticholinergic, antiglutaminergic and direct dopamine agonists should be avoided if possible. In DLB, only a third of patients show significant motor response to L-dopa; therefore treatment of parkinsonism should only be instituted if motor symptoms interfere with function.

Prion Diseases

Brian S. Appleby

Division of Geriatric Psychiatry and Neuropsychiatry, The Johns Hopkins Hospital, Baltimore, USA

PRION THEORY AND BIOLOGY

Cellular Prion Protein

The native cellular prion protein (PrP^c) is located throughout the human body, predominantly in the brain and gut. PrP^c is a glycosyl phosphatidyl inositol-linked glycoprotein that is anchored on lipid rafts. The tertiary structure of PrP^c is primarily composed of α-helixes with few β-sheets. The prion protein gene (*PRNP*) was identified in 1986 and its identification has led to the development of *PRNP* knock-out mice, which do not appear to behave differently from wild-type mice. However, PrP^c null mice exhibit impaired synaptic inhibition and it has been proposed that PrP^c has stress-protective functions. Divalent cations including copper, zinc and manganese have also been shown to bind to PrP^c, though the significance of this is unclear. There has been emerging evidence that PrP^c may be associated with Alzheimer's disease and psychiatric illnesses as part of the stress diathesis.

Pathological Prion Protein

In contrast to the native prion protein, the pathological prion protein's (PrP^{res}) structure is primarily composed of β-sheets that aggregate and form amyloid plaques. The high β-sheet content of PrP^{res} leads to its partial resistance to proteinase K, resulting in proteinase-resistant protein fragments (i.e. $PrP^{'res'}$) called prions, which stands for '*pr*oteinaceous *in*fectious particle.'

There are three aetiologies of PrP^{res}: (i) sporadic, (ii) genetic and (iii) acquired. Although the exact mechanism for the formation of sporadic PrP^{res} is unknown, it is widely believed to be the result of a posttranslational mutation. This has recently been demonstrated using *in vitro* protein misfolding cyclic amplification (PMCA) techniques[1]. PrP^{res} can also be generated *de novo* by mutations within the prion protein gene (*PRNP*). Lastly, PrP^{res} can be acquired from an outside source and introduced into the body, precipitating the formation of additional PrP^{res}.

Prion Theory (The Protein-Only Hypothesis)

Prions are transmissible agents that lack the nucleic acids that bacteria and viruses use to infect other organisms. In lieu of nucleic acids, the transmissibility of prions is accomplished via an autocatalytic mechanism, a theory coined the 'protein-only hypothesis' (Figure 59.1). This process was first postulated by the mathematician J. S. Griffith in 1967[2] and was later described by Stanley Prusiner, who was subsequently granted a Nobel Prize for his work[3]. PrP^{res} interacts with PrP^c, using itself as a template to change the conformation of PrP^c into another PrP^{res} protein. Mouse studies have found that the presence of PrP^c is a requirement for the conversion process to occur. As evidence of this fact, PrP^c-null mice do not develop prion disease when they are inoculated with PrP^{res}, as the conversion process does not occur without the PrP^c substrate.

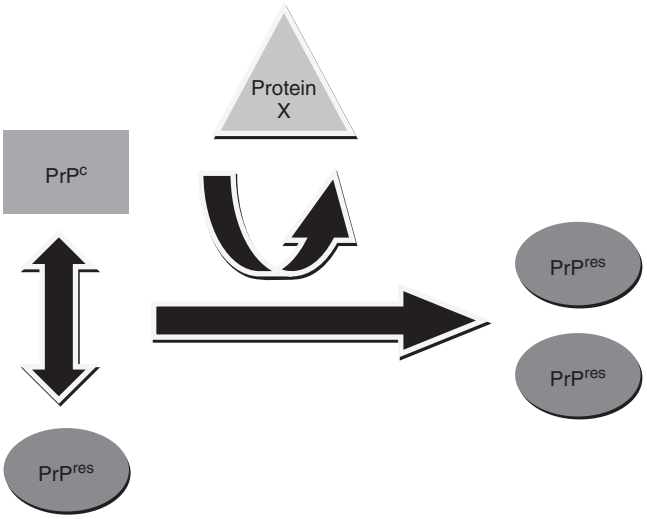

Figure 59.1 The prion conversion process. PrP^{res} replicates via an autocatalytic mechanism. PrP^{res} uses PrP^c as a substrate for the production of further PrP^{res} proteins. An uncharacterized protein (protein X) is postulated to facilitate the transformation process

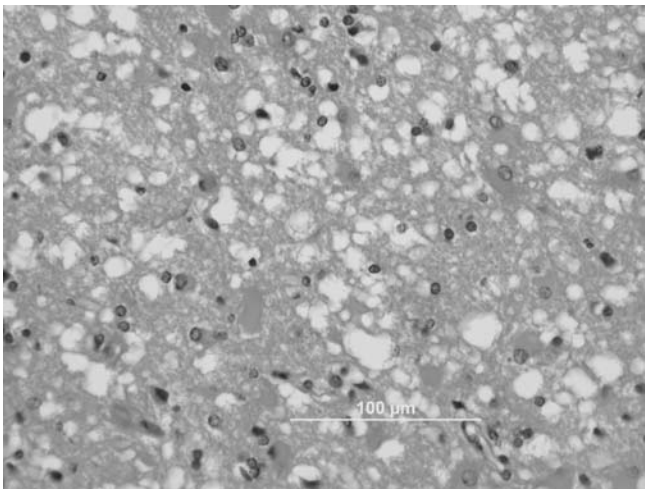
HUMAN PRION DISEASES

Kuru

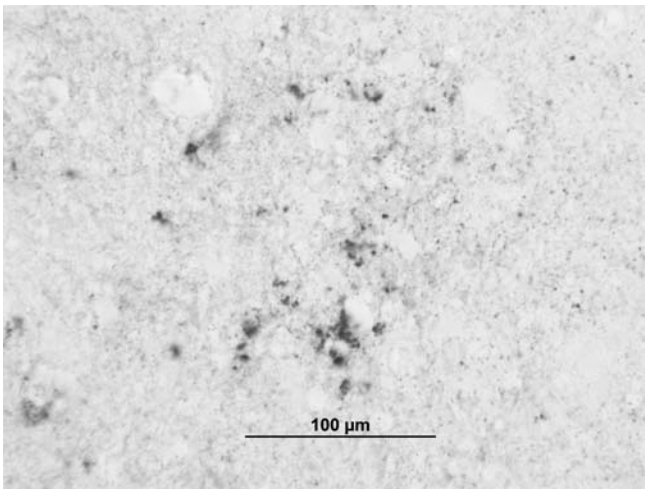
Human prion diseases, or transmissible spongiform encephalopathies (TSEs), were initially described in detail by Nobel Prize laureate Carlton Gajdusek through his research on kuru[4]. Believed to be a 'slow virus', kuru was an endemic illness in the Fore tribe of Papua New Guinea. Kuru was characterized by rapidly progressive ataxia, oculomotor impairment, myoclonus and dementia with death typically occurring within two years of the illness onset. Gajdusek

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd



later found that kuru was transmitted among the tribe via its cannibalistic rituals of consuming their deceased, particularly their brains. Tribal members who consumed brain matter of relatives with kuru were exposed to the illness and incubated it for several years, sometimes decades, until they eventually developed the illness. It is generally accepted that the kuru epidemic has since subsided and no longer exists.

Creutzfeldt–Jakob Disease



The most common human prion disease is Creutzfeldt–Jakob disease (CJD), which was first described by two neuropsychiatrists, Hans Gerhard Creutzfeldt[5] and Alfons Maria Jakob[6]. Both Creutzfeldt and Jakob described patients with a rapid neurodegenerative illness who had a spongiform appearance of their brain at postmortem analysis. CJD is recognized at autopsy by the neuropathological triad of astrogliosis, spongiform changes and neuronal death (Figure 59.2a). Immunostaining with monoclonal 3F4 antibodies also shows prion deposition within the brain (Figure 59.2b). Abnormal prion proteins can also be detected by pre-treating brain homogenate with proteinase K and performing Western blot analyses that typically detect proteinase-resistant protein fragments (PrP^{27-30}).

CJD is a rare cause of dementia. The worldwide incidence of CJD is one per million people per year and is slightly higher in females than in males, although the age-adjusted incidence is slightly higher in males. CJD is rare in blacks for unclear reasons, but ascertainment problems may be one reason for the low incidence. Researchers have discovered a genetic propensity towards the development of CJD in relation to the codon 129 polymorphism of the *PRNP* gene. Individuals who are homozygous (Met-Met or Val-Val) at codon 129, especially Met-Met, are more likely to develop CJD. The *PRNP* codon 129 polymorphism is also associated with differences in clinical presentations and survival times.

CJD can be divided by aetiological subtypes. There are three main aetiologies of CJD: (i) sporadic CJD (sCJD), (ii) genetic CJD (gCJD), and (iii) acquired forms of CJD. The latter group includes the iatrogenic transmission of CJD (iCJD) and human transmission of bovine spongiform encephalopathy (BSE) called variant CJD (vCJD). In addition to different aetiologies, these subclasses of CJD also demonstrate different demographic, clinical, diagnostic, neuropathological

and molecular characteristics. Table 59.1 lists the characteristics of the CJD subtypes[7,8].

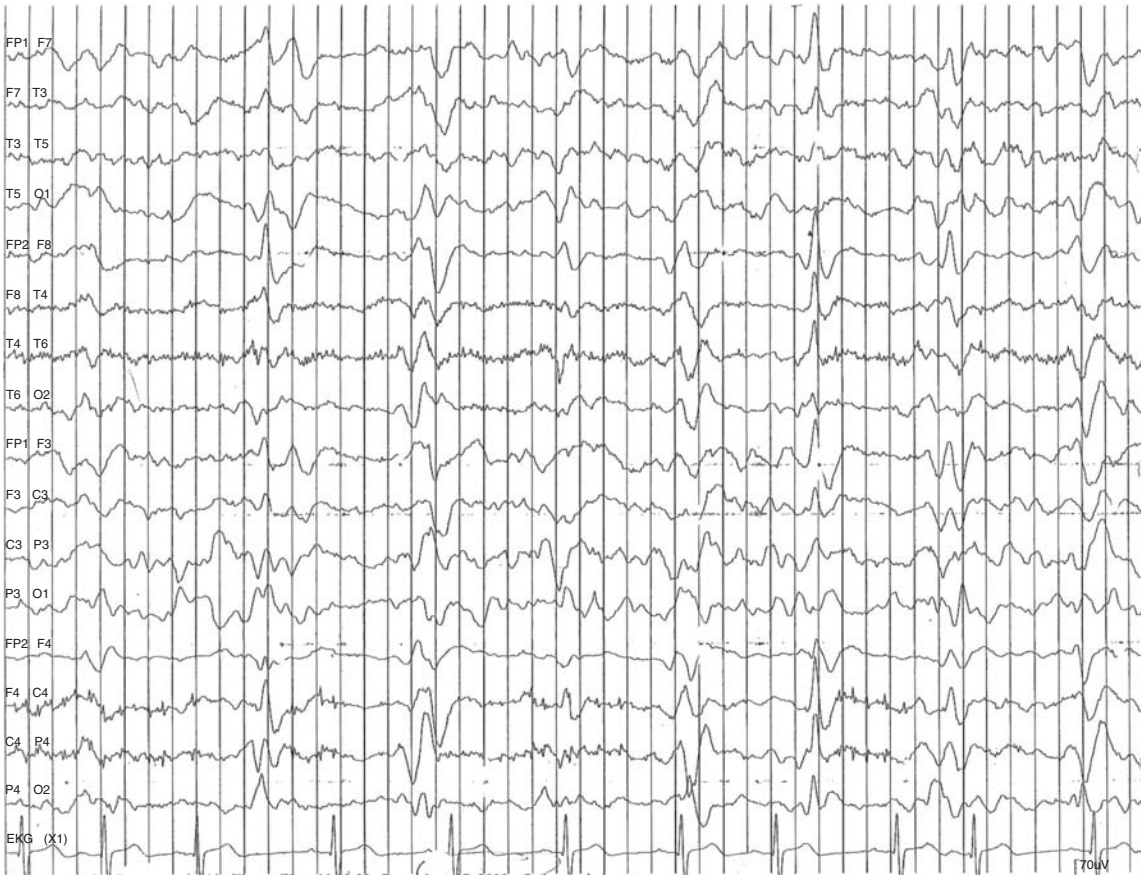
Sporadic Creutzfeldt–Jakob disease

The exact aetiology of sCJD is unknown, but is largely believed to be a consequence of a posttranslational mutation of PrP^c. Comprising 85% of all human prion diseases, sCJD is the most common human prion disease. The age of onset follows a bell-shaped curve with a mean age of onset of 61 years (Figure 59.3). The average survival time is four months and a very small percentage of individuals survive for more than two years. Although the cardinal symptoms of sCJD are dementia, ataxia, myoclonus, akinetic mutism and visual disturbances, the clinical presentation is widely variable and can include many different neuropsychiatric symptoms (Table 59.2)[9].

Table 59.3 Diagnostic test results in sporadic CJD

Diagnostic test	*Characteristics*
EEG	Periodic sharp wave complexes
CSF analyses	+14-3-3 protein
Brain MRI (DWI/FLAIR)	Hyperintensity in the basal ganglia and/or cortical ribbon

A definitive diagnosis of CJD is only possible via neuropathological examination; however, various diagnostic tests can aid with an antemortem diagnosis (Table 59.3). CJD is a diagnosis of exclusion; hence, all other possible aetiologies should be considered and ruled out first. An electroencephalogram (EEG) may help to arrive at a diagnosis should it show the classic periodic sharp wave complexes (PSWCs) that are characteristic of CJD (Figure 59.4). A lumbar puncture must always be performed to exclude other causes of encephalopathy but the cerebrospinal fluid (CSF) can also be examined for the presence of the 14-3-3 protein, a native neuronal protein that is a marker of neuronal cell death. Although a sensitive diagnostic test, the 14-3-3 protein is non-specific and can be detected in the



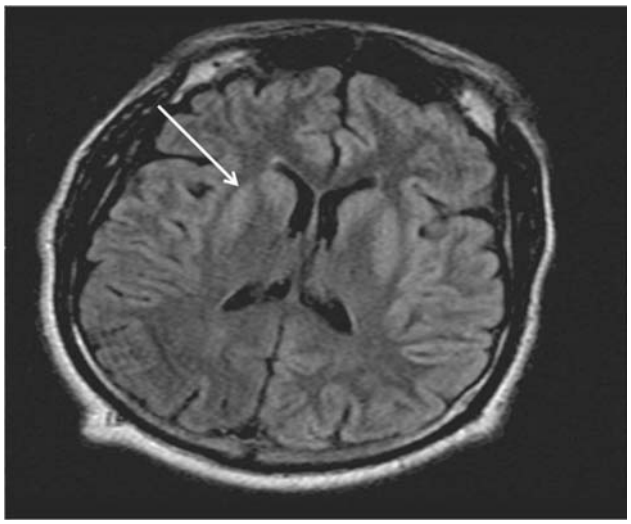


Figure 59.4 Electroencephalogram (EEG) of a sporadic Creutzfeldt–Jakob disease patient. The diffuse and synchronous periodic sharp wave complexes (PSWCs) seen in this EEG are characteristic of CJD

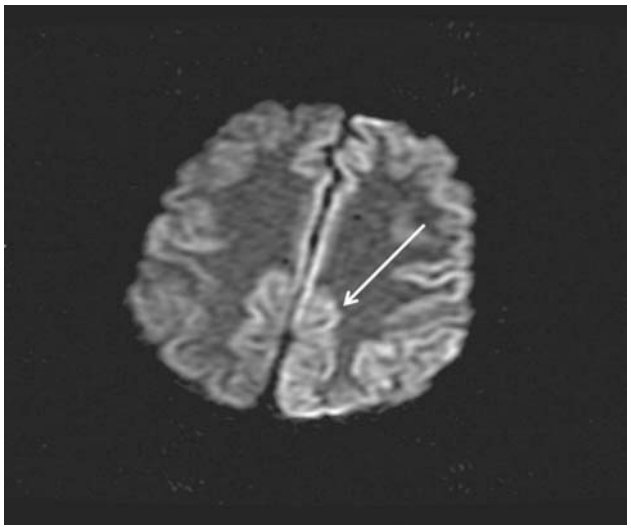

CSF of patients with multiple sclerosis, transverse myelitis and brain tumours. The presence of 14-3-3 in combination with tau is highly specific for a diagnosis of sCJD. Brain magnetic resonance imaging (MRI) can also be helpful in establishing a diagnosis of CJD. Hyperintensity in the cortical ribbon and/or basal ganglia are frequently observed on diffusion weighted and FLAIR image sequences, as shown in Figure 59.5.

Genetic Creutzfeldt–Jakob disease

Genetic CJD accounts for approximately 15% of human prion diseases and it is caused by a pathological mutation in the prion protein gene (*PRNP*) that results in the production of PrP^{res}. To date, over 30 different mutations in the *PRNP* gene are known to result in prion diseases. The majority of mutations are autosomal dominant point mutations, but insertion and deletion mutations have also been described. All mutations demonstrate near complete penetrance by the ninth decade of life. The age of onset is usually mid-life (Figure 59.3) and disease duration is typically longer than other prion diseases and can be several years in duration. Clinical and neuropathological phenotypes vary and are determined by the mutation site, codon 129 polymorphism, and PrP^{res} type[10]. Diagnostic test results also differ between mutation types. The most common gCJD haplotype is E200K-129M. Other common mutations and their characteristics are listed in Table 59.5.

(a)

(b)

Figure 59.5 Brain magnetic resonance imaging of a patient with Creutzfeldt–Jakob disease. (a) Basal ganglia hyperintensity is seen on FLAIR sequences and (b) hyperintensity in the cortical ribbon is seen on diffusion-weighted imaging

Iatrogenic Creutzfeldt–Jakob disease

Iatrogenic CJD is pre-empted by the transmission of prions through several possible medical interventions[11]. Table 59.4 lists the known risk factors for iCJD, including cadaveric dura grafts, gonadotrophins, corneal transplants, neurosurgical depth electrodes and neurosurgical instrument contamination. Direct contact with the central nervous system is necessary for transmission to occur in the majority of cases. Very low levels of prion proteins have been detected in the blood and urine of CJD patients, though the amounts are not significant enough to cause transmission with the exception of vCJD. There have been four recognized cases of vCJD transmission via blood transfusions; three died of CJD and one was pre-symptomatic at the time of death. There has been no known blood-borne transmission of the other prion diseases. Because of iCJD, cadaveric dura mater grafts and corneas are no longer used and neurosurgical instruments undergo extensive autoclaving procedures to prevent the transmission of prions. The ages of onset and survival times are variable given the groups' varied demographic features.

Variant Creutzfeldt–Jakob disease

Although it is the most publicized form of CJD, vCJD is quite rare. Fewer than 300 total cases have been described to date, nearly exclusively in European countries (e.g. UK, France, Spain, Italy and the Netherlands). Variant CJD is caused by ingesting foodstuffs tainted with a form of prion disease found in cows, termed bovine spongiform encephalopathy (BSE). During the 1990s, Bob Will and colleagues at the UK National Creutzfeldt–Jakob Disease Surveillance Centre noted an increased incidence of CJD in younger people, who also exhibited atypical neuropathological features at autopsy. Individuals with vCJD tended to be in their 20s or 30s (Figure 59.3) and had amyloid plaques in their brains, termed 'kuru plaques'[12]. Individuals with vCJD primarily presented with psychiatric (e.g. mood and anxiety disorders) and sensory symptoms and their illness duration was typically longer than sCJD. Until December 2008, all cases of vCJD

Table 59.4 Risk factors for iatrogenic Creutzfeldt–Jakob disease

Risk factors
Dural mater grafts
Cadaveric gonadotrophins (e.g. hGH, hCG)
Corneal transplants
Neurosurgical depth electrodes
Neurosurgical instrument contamination

Table 59.5 Clinical characteristics and EEG findings of familial prion diseases by mutation

PRNP genotype	*Clinical characteristics*	*EEG findings*
E200K	Rapidly progressive dementia, ataxia and myoclonus	PSWCs
V210I	Memory impairment, behavioural changes, and ataxia	PSWCs
D178N-129V	Cognitive impairment, depression and irritability	Lack of PSWCs
D178N-129M (fatal familial insomnia)	Insomnia, dysautonomia, pyrexia and dementia late in illness	Loss of sleep architecture
P102L (Gerstmann–Sträussler–Scheinker disease)	Gait and limb ataxia, nystagmus and dysarthria	Slowing

have been homozygous for methionine at codon 129 (129Met-Met), which led many to believe that the *PRNP* codon 129Met-Met genotype was necessary for the development of vCJD. Many researchers cautioned that, similar to iCJD, the codon 129 polymorphism may affect incubation period and that other polymorphisms may also be at risk, though they may display a prolonged incubation period. With the discovery of the first codon 129 Met-Val vCJD case in December 2008[13], many are concerned that there may be another cluster of vCJD cases from the 1990s BSE exposure.

Fatal Familial Insomnia

Fatal familial insomnia (FFI) is a hereditary prion disease first described by Pierluigi Gambetti and colleagues[14]. FFI is caused by the D178N-129M mutation of the *PRNP* gene in contrast to one of the more common gCJD mutations, D178N-129V (Table 59.5). The different haplotypes differ in their codon 129 polymorphism of the mutant allele, resulting in different clinical and neuropathological phenotypes. FFI typically occurs in mid-life with the onset of progressive insomnia, fatigue, dysautonomia (e.g. labile blood pressure and pulse, pyrexia) and hypervigilance. Dementia typically does not manifest until late in the disease. EEGs and sleep studies show a characteristic loss of sleep architecture, including the absence of sleep spindles and K complexes. The neuropathology of FFI also differs from conventional CJD in that spongiform changes are found predominantly in the thalamus. There have also been several cases of sporadic fatal insomnia (sFI) described in the literature.

Gerstmann–Sträussler–Scheinker Disease

Gerstmann–Sträussler–Scheinker disease (GSS) is the least common heritable prion disease and it is caused by several different mutations in the *PRNP* gene, the P102L mutation being the most common[15] (Table 59.5). The initial symptoms of GSS include global cerebellar impairment (e.g. limb and gait ataxia, dysmetria, scanning speech). The survival time of individuals with GSS can be several years in duration. The unique pathological prion protein, Pr^{7-8}, is also a characteristic feature of GSS.

SAFEGUARDS

Despite the name 'transmissible spongiform encephalopathies,' prion diseases are not infectious in the usual clinical environment. Only universal precautions are necessary when providing routine care to individuals with prion diseases. Prion precautions, which consist of special autoclaving and sterilization procedures, are necessary when there is exposure to the central nervous system. Scenarios in which prion precautions would be necessary include neurosurgery, post-mortem examinations, and general surgery in individuals who have a family history of familial prion disease and suspected vCJD. In the United States, individuals who have a relative who has been diagnosed with a prion disease or those who spent time in the UK during the 1990s cannot give blood.

In relation to the zoonotic forms of acquired prion disease, care must be taken when handling central nervous system tissue of any mammal. Consuming brain matter, which is considered a delicacy in some cultures, is a high-risk activity for acquiring prion diseases. Not all animal prion diseases are transmissible to humans. Scrapie, a prion disease in sheep, has not been demonstrated to cross the animal–human species barrier. Some prion diseases in other species, such as cows, have shown the potential for human transmission. Because of vCJD, national governments and agricultural regulatory agencies should prohibit the return of 'downer cows' into the feed. Genetic forms of BSE have recently been discovered, strongly discouraging any re-feeding of animals as they have the potential to be presymptomatic carriers of prion disease. Chronic wasting disease (CWD), a prion disease that is rampant in cervids (e.g. deer and elk), has recently become a concern in the US. Researchers have estimated that up to 30% of deer in certain locales are incubating CWD. Although cervid to human transmission of CWD has not been demonstrated in the laboratory, hunters are encouraged to have their game tested for CWD prior to its consumption.

TREATMENTS

Unfortunately, human prion diseases are invariably fatal with no current treatment or cure. Several investigational treatments have been and are currently being explored. Carsten Korth, a psychiatrist who trained in Stanley Prusiner's laboratory, discovered the antiprion effects of chlorpromazine and other phenothiazine antipsychotics that led to the two largest clinical trials in prion diseases to date[16]. Korth uncovered that many compounds with antiprion activity were based on tricyclic structures with an aliphatic side chain at the middle ring moiety. Chlorpromazine, imipramine and quinacrine were among these compounds, quinacrine having approximately 10-fold greater antiprion activity compared to the others. This discovery led to two major trials of quinacrine for the treatment of CJD: PRION-1, a UK trial with negative results, and a quinacrine trial at the University of California at San Francisco (UCSF), the results of which have not been published. Besides quinacrine, several other compounds are being investigated as potential treatments for prion diseases, including intraventricular pentosan polysulphate (PPA) and doxycycline. Both compounds exhibit antiprion activity *in vitro*, although human

studies have demonstrated that neither drug will likely be a cure. Future studies are planned to examine the use of antiprion protein antibodies, gene therapy and iRNA.

Until better treatments are available for individuals with prion disease, the clinician is left with the all-important symptomatic treatment of the disease. Certain symptoms can be particularly upsetting to the patient and the family. Myoclonus, especially startle myoclonus, can greatly decrease quality of life, yet can be easily managed with behavioural interventions (e.g. decreased touching, turning and decreased sensory input in general) and benzodiazepines or anticonvulsants. Both drugs can also address seizures, which are sometimes present in the end stages of the illness. Insomnia can also be treated with benzodiazepines. Visual hallucinations and paranoid delusions are common due to visual impairments and disorientation in the setting of a relatively normal level of alertness. These symptoms can be treated with antipsychotics, with a preference towards quetiapine and clozapine due to the high prevalence of extrapyramidal symptoms in this patient population. Pyrexia, another end-stage symptom, can be managed with cold compresses and acetaminophen. Finally, hospice care is usually recommended, which includes palliative care as well as treating pain and agonal breathing with morphine or other opiates.

PRION DISEASES AND OTHER PROTEIN-MISFOLDING DISORDERS

Prion diseases posit a unique situation for studying protein-misfolding disorders, also known as proteinopathies. Proteinopathies are diseases caused by the formation of an abnormal isomer of a native protein. Through toxicity and/or loss of function mechanisms, proteinopathies cause neurodegenerative diseases including Alzheimer's disease (amyloid beta), frontotemporal dementia (tau), Parkinson's disease (alpha-synuclein) and Huntington's disease (huntingtin). Most of the above illnesses have familial forms caused by gene mutations (e.g. PS-1 and -2, APP, MAPT, TDP-43 and PGRN), but the majority of cases are of sporadic aetiology. Basic science research typically focuses on transgenic animal models, which may ignore the disease mechanisms that are responsible for the majority of these populations. Prion diseases are unique in that they are sporadic, familial and transmissible. Whereas transgenic mice can also be used to study prion diseases, PrP^{res} can be used to inoculate normal animals, causing them to become ill without any genetic modification. Hence, prion diseases are a unique proteinopathy because PrP^{res} is both necessary and sufficient to cause disease in a normal population. Prions also aggregate and form amyloid plaques, a process called nucleation. Other proteinopathies follow this pattern: amyloid-beta forms amyloid plaques in Alzheimer's disease, tau proteins aggregate into neurofibrillary tangles in frontotemporal dementia, and alpha-synuclein forms Lewy bodies in Parkinson's disease and dementia with Lewy bodies. Protein misfolding cyclic amplification (PMCA), as used in prion diseases, can also be used to study other protein misfolding disorders, which may share similar features such as abnormal chaperone activity. Although one of the rarest protein misfolding disorders, much more is known about prion diseases than most of the other proteinopathies. Prion diseases thus serve as an opportunity to study these diseases from a much different, and perhaps easier, perspective. Additionally, the prion protein gene (*PRNP*) is routinely listed in the top 20 genes implicated in Alzheimer's disease and the native prion protein has recently been shown to inhibit beta site APP-cleaving enzyme (BACE-1), an enzyme associated with Alzheimer's disease.

Alcoholic and Other Toxic Dementias

Eileen M. Joyce

Professor of Neuropsychiatry, UCL Institute of Neurology, Queen Square, London, UK

ALCOHOLIC DEMENTIA

The concept of a dementia consequent upon the neurotoxic effects of long-term alcohol abuse developed from clinical observations of a gradual deterioration in personality and intellect in many alcoholics. Subsequent research suggested that this is age related, is milder in degree than other forms of dementia and constitutes 11–24% of all demented patients[1,2]. To put this in further perspective, of the estimated 18 million alcoholics in the USA, approximately 40% will have mild cognitive impairment which is potentially reversible with abstinence, but a further 10% will have persisting severe cognitive impairment requiring institutional care, comprising patients mainly with dementia and amnesia[3,4].

Amnesia in alcoholics is known as the Wernicke-Korsakoff syndrome. This is the result of thiamine malnutrition which causes subcortical periventricular vascular lesions in diencephalic structures, the mamillary body and thalamus, known to be critically involved in new memory formation[5]. Alcoholic dementia was originally thought to be distinct from the Wernicke-Korsakoff syndrome and due to the direct neurotoxic effect of alcohol on the cerebral cortex. Horvath[6] prospectively examined 100 chronic alcoholics presenting clinically with a dementia syndrome and concluded that alcoholic dementia was different from the Wernicke-Korsakoff syndrome and that other non-amnesic organic syndromes exist in alcoholics characteristic of frontal, parietal or global cortical damage. Cutting[7] performed a retrospective case-note analysis of alcoholic patients with cognitive impairment and found two forms of clinical presentation. One consisted of a rapidly developing illness in younger patients with preserved intellect, akin to the traditional Wernicke-Korsakoff syndrome, whereas the other was more characteristic of dementia, being a gradual and global cognitive deterioration in older patients.

Although these studies support the concept of alcoholic dementia as a distinct entity, other evidence suggests a more complex picture with there being several different neuropathological 'routes' to the development of brain damage sufficient to cause the diffuse cognitive impairment recognized clinically as dementia. Torvik and colleagues[8] examined the clinical records of patients who at autopsy had diencephalic lesions characteristic of thiamine malnutrition; that is, Wernicke-type lesions. Seventy five percent of these were considered to be demented in life rather than amnesic and the majority had no additional neuropathological hallmarks of a neurodegenerative dementia. They concluded that the diencephalic lesions of thiamine deficiency can result in the clinical picture of both 'alcoholic dementia' and the Wernicke-Korsakoff syndrome. Victor and Adams[9] then pointed out that 10% of their pathologically proven cases of the Wernicke-Korsakoff syndrome developed cognitive abnormalities insidiously rather than acutely[5] and that cognitive impairment other than amnesia and behavioural abnormalities such as inertia and apathy can be demonstrated in these patients[10]. Thus they argued that, depending on the severity of the non-mnemonic deficits or the mode of presentation, cases of the Wernicke-Korsakoff syndrome may be misattributed as cases of alcoholic dementia. The neuropathological studies of Harper and colleagues[11–13] are in agreement with this view. They found that two thirds of the alcoholics coming to post-mortem in their unit had lesions of thiamine deficiency; of these, only a third had received a clinical diagnosis of the Wernicke-Korsakoff syndrome in life and, in the remainder, the most common diagnosis was dementia.

This evidence points to the conclusion that subcortical lesions caused by thiamine malnutrition can be sufficient to explain both amnesia and dementia witnessed in alcoholics. However, Victor and Adams[9] and Torvik and colleagues[8] did not suggest that *all* cases of alcoholic dementia are unrecognized cases of the Wernicke-Korsakoff syndrome. Both considered that superadded cerebral lesions may explain the dementia-like presentation of a proportion of patients with the Wernicke-Korsakoff syndrome. Because these additional lesions can be attributed to a variety of pathological processes, including chronic hepatocerebral degeneration, communicating hydrocephalus, Alzheimer's disease and ischaemic infarction, they argued that there is no need to invoke a special process of alcohol neurotoxicity. Some studies have supported this hypothesis. For example, Kasahara and colleagues[14] compared young and old alcoholics and found evidence of dementia only in the older group; most of these patients had additional medical diagnoses including hypertension, liver disease and cardiomyopathy and no case of dementia could be accounted for by the direct effect of alcohol alone.

Although these clinical studies suggest that dementia in alcoholics can be caused by factors other than the direct effect of alcohol on brain function, the neuropathological evidence is that alcohol is neurotoxic. The question therefore still remains as to whether this is sufficient to cause cortical damage and frank dementia. Carefully controlled neuropathological studies have frequently found whole brain atrophy involving grey and white matter in chronic alcoholics with and without evidence of thiamine depletion as indicated by the presence or absence of subcortical Wernicke-type lesions[15–18]. This atrophy appears to reflect reductions of white matter volume, neuronal loss in the dorsal frontal association cortex and neuronal

shrinkage in other cortical areas such as the cingulate gyrus and the precentral motor cortex[19–23]. The contribution of liver failure to this neuropathology has been assessed in several studies and the bulk of evidence suggests that cirrhosis alone does not account for the brain atrophy witnessed in alcoholics[16,17,24]. Other findings suggest that thiamine depletion in the context of alcohol ingestion may contribute to this neuropathological picture even when this is insufficient to cause the subcortical lesions of the Wernicke-Korsakoff syndrome.

Thiamine is an essential co-enzyme for three enzyme complexes (pyruvate dehydrogenase, alpha-ketoglutarate dehydrogenase and transketolase) involved in mitochondrial oxidative phosphorylation and a number of cellular synthetic processes. Animal models have shown that lack of thiamine leads to mitochondrial dysfunction and cell death consequent upon oxidative stress, glutamatergic excitotoxicity and inflammatory responses; as these mechanisms are also active in other forms of neurodegenerative dementia, it is possible that thiamine depletion, as well as causing diencephalic vascular lesions, also directly causes cortical cell damage secondary to these actions[25]. Animal models have also shown that alcohol alone can lead to cell damage via oxidative stress[26–28] and that cortical cell death is greater in the presence of both alcohol and thiamine depletion than either factor alone[29].

Thiamine deficiency is common in alcoholics due to a combination of inadequate diet, poor absorption secondary to the effect of alcohol on the gastrointestinal tract and poor cellular utilization due to the direct action of alcohol on intracellular mechanisms[30,31]. Thus it is likely that, even in alcoholics who have not developed Wernicke-Korsakoff syndrome, reduced thiamine availability will be present in a significant proportion and that this contributes to the development of dementia along with alcohol via a joint action on cortical neurones. Evidence that alcohol and thiamine deficiency are synergistic in man also comes from findings that the cortical pathological changes witnessed in alcoholics without evidence of thiamine depletion are similar to but less severe than those with co-existent subcortical Wernicke lesions[16,18,21,24,32–34].

In summary, it can be concluded from these studies that: (i) alcohol itself can cause neuronal damage including cell death; (ii) liver disease *per se* is not a major factor in the aetiology of the neuropathological cerebral changes seen in alcoholics; and (iii) thiamine malnutrition potentiates the neurotoxic effect of alcohol on the brain and it is likely that frank dementia in alcoholics is due to this combined action rather than the effect of alcohol alone.

What is the relationship between alcohol ingestion and the more common, milder cognitive impairment seen in alcoholics? The advent of *in vivo* neuroimaging has enabled clinicopathological correlational studies to clarify the consequences of alcohol consumption on brain function and cognition in alcoholics uncomplicated by liver disease or thiamine depletion. Well-controlled, prospective studies using both CT and MRI have reliably confirmed the presence of cerebral shrinkage in such alcoholics in life involving both cortical grey and subcortical white matter[35–42], which is more pronounced in older patients[43] and more apparent in the frontal lobe[44,45]. One early imaging study highlighted the possibility that women are more vulnerable to the effects of alcohol in that brain atrophy was equivalent in age-matched men and women despite the women having shorter or less severe drinking histories[46]. This remains controversial, however, as some later studies[47,48] but not all[49,50] have replicated this finding.

The development of the MRI modality of diffusion tensor imaging (DTI) has allowed a more detailed assessment of the white matter volume reductions found in postmortem and conventional MRI studies. DTI depends on water diffusion being constrained by cell membranes or myelin sheaths and, when abnormal, may reflect pathology of myelin microstructure. Studies of alcoholics without complications of liver disease or a history of Wernicke's encephalopathy have found that white matter abnormalities are widespread in life, being present in areas not previously detected by conventional MRI[51–53]. DTI data can also be used to examine specific fibre pathways using the technique of tractography. When applied to alcoholics, abnormalities in the frontal forceps, internal and external capsules, fornix, and superior cingulate and longitudinal fasciculi have been detected, and the severity of these abnormalities was found to correlate with lifetime alcohol consumption[54]. In the same study, when matched for alcohol exposure, alcoholic women showed more DTI signs of white matter degradation than alcoholic men in several fibre bundles, suggesting that any sex differences in the vulnerability to alcohol may be neural tissue specific[54].

An important observation is that the percentage of alcoholics with evidence of cerebral damage on brain scans is far in excess of that noted in neuropathological studies[15]. This discrepancy is probably explained by the finding that brain changes are reversible with continuing abstinence[37,41,42,46,55–63], thus indicating that neuroimaging findings may not accurately reflect the permanent neuropathological changes previously described in postmortem studies. However, because some studies have found that neuroimaging changes worsen in patients who continue to drink, and may not be entirely reversible with abstinence in heavier drinkers[56,64,65], and others have found that greater total alcohol consumption is associated with greater decrease in cortical grey matter, particularly in the frontal[62,66] and temporal lobes[62], these neuroimaging abnormalities may represent neurotoxic processes which may ultimately lead to more permanent neuropathology if abstinence is not achieved.

Like dementia, the characteristic cognitive impairment witnessed in uncomplicated alcoholics is diffuse in nature but much milder. Parsons[67], following decades of his own research, concluded that both male and female sober adult alcoholics have deficits on tests of learning, memory, executive functions and speed of information processing which are equivalent to those found in other patients with known brain dysfunction of a mild to moderate nature. Similar findings have repeatedly been demonstrated by others (see[68]). Like neuroimaging studies, controlled neuropsychological studies have shown that cognitive deficits are largely reversible following abstinence[69] although, again, these may not be reversible in those with severe and long-term alcohol abuse[67]. Early studies attempting to relate cognitive and structural changes in alcoholics found weak and inconsistent correlations, the majority of which were explained mainly by age and premorbid IQ[35,36,38,70–72]. However, the use of novel MRI techniques has produced stronger evidence for a link between cognitive impairment on the one hand and brain structural and functional abnormalities on the other. For example, studies have combined structural MRI and MR spectroscopy to demonstrate concomitant brain atrophy and metabolic abnormalities in the context of cognitive deficits, all of which improve together with abstinence[60,61,73]. Precise volumetric analyses have also confirmed the neuropathological finding that the dorsal frontal association cortex is the area most vulnerable to alcohol, in that this undergoes the greatest reduction in volume, but that other areas such as the temporal cortex, insula and cerebellum are also affected, as well as widespread areas of white matter[74]. In the same study, neuropsychological impairments correlated with the grey and white matter volume reductions even in detoxified patients with well-preserved social function[74].

These studies of uncomplicated alcoholics suggest that chronic alcohol ingestion can cause damage to widespread areas of the cerebral cortex and subcortical white matter sufficient to cause cognitive impairment even in people who otherwise appear to be functioning well. Such findings, although reversible with sustained abstinence if caught early enough, seem to herald more permanent brain damage and possibly dementia in those who continue to drink heavily, especially if there is co-existent thiamine depletion. Together with the recent findings of the combined action of alcohol and thiamine deficiency on cortical viability in animal studies[25,29], this underscores the need to suspect and treat thiamine malnutrition even in apparently healthy alcoholics.

OTHER TOXIC DEMENTIAS IN THE ELDERLY

The long-term neuropsychiatric effects of ingestion of drugs of abuse are unclear and probably differ depending on the compound; however, there is little evidence to suggest that these generally cause significant brain damage enough to produce dementia. For example, benzodiazepines, perhaps the most relevant substance in elderly populations, do not produce diffuse cognitive impairment or brain damage[75]. As ageing populations will now include people with other forms of long-term drug abuse or dependence, it is also important to consider other substances. Although there is some evidence that opiate addiction can result in grey matter volume reductions, these studies have been contaminated by including subjects with co-morbid alcohol abuse, and at least one of these suggests that alcohol rather than opiates *per se* was responsible for their findings[76]. There is one notable exception to the lack of strong evidence that substances of abuse cause dementia and that is the phenomenon of toxic leukencephalopathy seen in heroin, cocaine and amphetamine abuse. This usually occurs in the context of an overdose via the intravenous route or by inhalation, and is thought to be due to a direct toxic effect causing impaired intracellular energy metabolism[77–79].

The neuropsychiatric effects of long-term occupational solvent exposure are also relevant to the elderly. Although there is controversy concerning whether solvents *per se* produce long-lasting effects, most studies find evidence for lasting neuropsychological abnormalities[80–82]. Of particular interest is that these studies also found that a combination of long-term solvent exposure and alcohol abuse is a particular risk factor for the development of dementia. Of final relevance to this age group is the identification of bismuth encephalopathy which results from the over-ingestion of bismuth-containing compounds commonly taken for gastric irritation and sold without prescription. Following an acute organic reaction characterized by delirium, seizures and neurological abnormalities, persistent sequelae of diffuse cognitive impairment and cerebral atrophy has been documented[83,84].

Reversible Dementias

Michael Philpot

Mental Health of Older Adults, South London and Maudsley NHS Foundation Trust, Maudsley Hospital, London, UK

INTRODUCTION

The aim of this chapter is to review the causes of 'reversible' dementias, their prevalence, methods of investigation and response to treatment. Given the right circumstances, almost any illness can affect cognition, so the objective is to identify those treatable conditions that most commonly present in this way. The early literature on this subject included numerous case studies or series of 'dementia' that appeared to resolve completely following treatment of the associated physical or psychiatric condition. Undoubtedly many of the patients described were actually suffering from delirium or other organic brain syndromes[1]. Also, the concept of 'reversible' dementia appears at odds with the term 'dementia', denoting an insidiously progressive disorder[2]. This confusion extends to psychiatric disorders such as depression and schizophrenia that may present as 'pseudo-dementia'[3]. Lastly, many patients, indeed probably the majority, with 'real' dementias will have concomitant conditions that, while not being aetiologically related to the dementia, may reduce cognitive function.

AETIOLOGY

The timely investigation of patients presenting with symptoms of dementia is a keystone of many clinical protocols[4–6]. Diagnosis of 'probable' Alzheimer's disease is largely by exclusion of other causes of dementia – including those reckoned to be reversible. A list of what are considered the classic potentially reversible causes of dementia (PRD) is given in Table 61.1. Table 61.2 lists PRD that have been described in the past 10 years – usually in either single cases or small case series. The identification of the latter can depend crucially on how intensively a case is investigated. They include conditions sometimes grouped together as the 'rapidly progressive' dementias[7].

PREVALENCE

Despite the extensive lists in Tables 61.1 and 61.2, the frequency with which PRD occur in everyday clinical practice is an important factor in determining the rigour with which contributory physical disorders or other causes are pursued. The overall prevalence identified in case series or clinic surveys can vary depending on the setting (inpatient, outpatient or community), the medical specialty involved (geriatric psychiatry, geriatrics, neurology or neuropsychiatry) and the disease pattern of the country in which the study is carried out (e.g. neurological infections are more prevalent in developing countries). Early studies generally failed to provide follow-up data to confirm whether the identified PRD were actually reversible or not. Previous reviews[24,25] concluded that approximately 11–12% of patients presenting to a variety of specialist services with symptoms of dementia during the 1970s and 1980s had PRD. Philpot and Burns[24] found that the rate was 18% in patients under the age of 65 years but only 5% in those over 65, an observation that has been supported[26,27]. However, few of the early studies provided follow-up data to confirm recovery. Clarfield[28] has reviewed the literature for studies published between 1987 and 2000 and identified 39 that fulfilled meta-analysis criteria. He found that recent studies were more often community or outpatient based, but that only 9% of cases had PRD. These figures represented a fall in prevalence from a previous review examining studies published in the 1970s and early 1980s when 13% of dementias were potentially reversible[25].

Table 61.3 lists more recent studies of PRD since 2001. The frequency of each underlying cause is compared to Clarfield[28]. Mental disorders (chiefly depression) comprise the most prevalent category, with alcohol-related disorders also being more prominent than in previous reviews. Space-occupying lesions, endocrine/metabolic disease and drug toxicity appear less frequently.

INVESTIGATION PROTOCOLS

A number of organizations have published guidelines for routine investigations used in the assessment of dementia, and the recommendations of three such are listed in Table 61.4[4–6]. Chui and Zhang[39] examined the added value of using investigations routinely. After a thorough clinical assessment, blood tests and neuroimaging results changed management in only 13% and 15%, of cases respectively. Van Crevel *et al*.[40] found that the number of patients requiring investigation to find one case of PRD was approximately 100, and the financial saving on care costs was insignificant. Foster *et al*.[41], in a detailed examination of the cost-effectiveness of brain computed tomography, concluded that scans should only be performed routinely if symptom duration was less than one year, symptoms were rapidly progressive, presentation was atypical or the patient was under 65 years. However, the hard facts of health economics need to be balanced against the imperative to do one's best for the patient, so consensus protocols tend not to specify limiting investigations to particular age groups.

Table 61.1 Classification of potentially reversible dementias (after Lishman[2])

Reversible dementias	*Common clinical examples*
Degenerative	Normal pressure hydrocephalus, Wilson's disease
Space-occupying lesions	Cerebral tumour, subdural haematoma
Infection	Neurosyphilis, chronic meningitis and encephalitis, HIV-associated dementia
Collagen-vascular	Cerebral vasculitis systemic lupus erythematosus, sarcoidosis
Metabolic/endocrine	Liver disease, uraemia, remote effects of carcinoma, hypo- and hyperthyroidism, hypopituitarism, hypo- and hyperparathyroidism, hypoglycaemia, Cushing's disease, Addison's disease
Toxic	Primary alcoholic dementia, Wernicke-Korsakoff syndrome, chronic intoxication with sedative drugs, heavy metals
Anoxic	Chronic obstructive airways disease, sleep apnoea syndrome, chronic carbon monoxide poisoning, post-cardiac arrest, congestive cardiac failure
Nutritional	Anaemia, deficiencies of vitamin B12, folate, thiamine
Psychiatric	Depression, late-onset schizophrenia

Table 61.2 Recently reported reversible dementias

Reversible dementias	*Common clinical examples*
Autoimmune encephalopathies	Anti-NMDA receptor[8], anti-neuronal antibodies (limbic and extralimbic paraneoplastic syndromes)[7], potassium channel antibody-associated[9], non-vasculitic meningoencephalitis[10], Hashimoto's disease[11,12]
Space-occupying lesions	Dural arteriovenous fistulae[13]
Infection	Neurocysticercosis[14], cryptococcal meningitis[15], enteroviral meningo-encephalitis[16], Whipple's disease[17]
Collagen-vascular	Cerebral amyloid inflammatory vasculopathy[18], antiphospholipid syndrome[19], other CNS vasculitides (multiple causes)[7]
Metabolic/endocrine	Paget's disease[20], Cushing's syndrome[21]
Toxic	Steroids[22]
Anoxic	Spontaneous intracranial hypotension[23]

RESPONSE TO TREATMENT IN ORGANIC DISORDERS

A minority of studies identifying the prevalence of PRD actually include follow-up data reporting the response to treatment. Individual retrospective studies from the 1980s (e.g. Byrne[1]) found some improvement in two thirds of patients and complete recovery in 40%. However, Clarfield[25,28] suggested a much less optimistic outcome: 15% of PRD showed some response to treatment, 8% with full recovery, the remainder only partial recovery. Overall, some degree of recovery was shown in only 0.6% of patients with dementia[28]. In more recent studies listed in Table 61.3, treatment outcome was only reported in two studies. Takada *et al*.[33] found that 55% showed some degree of reversibility. Of the 10 patients with neurosyphilis, only one fully recovered: full recovery was also seen in a patient with normal pressure hydrocephalus (NPH) and partial recovery in a patient with a subdural haematoma (SDH). All the potentially reversible cases identified in Sheng *et al*.[38] showed some degree of recovery. However, 63% had functional psychiatric disorders, mainly depression. Clearly, the lack of reversibility revealed by these studies suggests that most of the potentially reversible disorders are actually *concomitant* with real dementia[42]. Treatment of concomitant disorders may have some clinical benefits, improving overall function while not eliminating the underlying cause. Some problems may also be secondary to the dementia itself, e.g. anaemia as a result of malnutrition. The response rates of a selection of disorders are now discussed in more detail.

Vitamin B12 Deficiency

Strachan and Henderson[43] first described dementia in association with B12 deficiency. Treatment with cobalamin brought about complete remission of cognitive impairment. However, there have been mixed results in prospective studies of replacement in patients with dementia and B12 deficiency, some showing improvement[44,45] and others showing little benefit[46–48]. Patients with mild cognitive impairment and B12 deficiency fare better[44,47,48].

Thyroid Dysfunction

The propensity for thyroid deficiency to lead to memory impairment and psychomotor slowing has been known since the nineteenth century[49] and hypo- and hyperthyroidism are among the traditionally accepted causes of PRD[2]. However, a clear reversibility of cognitive impairment sufficient to be considered dementia is rare[28]. Hypo- and hyperthyroidism are found in approximately 0.4% and 0.3% of older people, but subclinical thyroid dysfunction is found five or six times more often[50,51]. There is a complex relationship between this condition and incident dementia. An increased risk of dementia has been associated with subclinical hyperthyroidism[52,53] and hypothyroidism[54], while a U-shaped relationship with thyroid function has also been demonstrated[55]. However, the association found between high free T4, T3 levels and atrophy in the hippocampus and amygdala in otherwise healthy elderly people might suggest a preclinical phase of cognitive impairment[56].

Brain Lesions

NPH is the single most common organic cause of PRD[28]. Hakim and Adams[57] described two patients who presented with dementia, gait disturbance and incontinence in association with ventricular enlargement and normal cerebrospinal fluid (CSF) pressure. Most cases are idiopathic but NPH can follow meningitis, bleed or head injury. The treatment is shunt insertion diverting CSF from the lateral ventricles to the peritoneum. Good outcome in terms of an improvement in cognition can vary from 20% to 80%[58–61]. Features associated with a good prognosis include younger age, shorter duration of symptoms, and whether temporary improvement occurs as a result of pre-operative CSF drainage[59–61].

SDH occur usually as a result of head injuries or anticoagulant drugs but can occur spontaneously. A chronic SDH may present solely with progressive cognitive impairment but this is usually accompanied by fluctuating confusion, drowsiness and headache. Bleeding occurs from the veins between the dura and arachnoid mater and the resulting fluid collection may exert localizing neurological signs[62]. Clots are removed via burr holes and a good prognosis is found in more than half the cases thought to have dementia preoperatively[63,64]. Again, good prognosis is associated with younger age (under 74), milder cognitive impairment and less handicap[64].

The increasing prevalence and incidence of malignant brain tumours with age is well documented in surveillance studies[65–67] and may relate to increasing population in the older age groups[65,67]. Late-onset epilepsy, focal neurological signs or evidence of raised intracranial pressure raise the suspicion of a space-occupying lesion. Elderly patients may be less likely than younger ones to present with headache or seizures, but more likely to present with confusion, aphasia or memory impairment[66]. Dementia is usually associated with slowly growing lesions that can develop without localizing signs, but may be accompanied by mood disorder, personality change, apathy or fatigue[2]. In older patients, slowly growing meningiomas may indeed be largely asymptomatic and 'watchful waiting' with repeat neuroimaging annually may be the best approach[68]. With regard to malignant tumours, although the outcome of surgical and/or radiotherapy treatment can be less favourable than in young patients[66,69], aggressive approach to treatment is still advocated[69].

DEPRESSION AND DEMENTIA

The syndromes of depression and dementia interact in a complex way. Depression may be a risk factor for Alzheimer's disease[70], and is commonly found in association with established dementia[71]. Depression can be a reaction to the early symptoms of dementia[72]. Depression in late life is associated with impaired cognition[73,74]. Impairment is in multiple areas – attention, working memory, visual and verbal memory, and executive function[73] – but slowed information processing might underline all difficulties[74]. For the most part, cognitive dysfunction is relatively mild but in some patients it can be extreme. Although, in practice, it can be difficult distinguishing between these disorders, depressive 'pseudo-dementia' has traditionally been viewed as a treatable condition with a distinct clinical history and symptoms that distinguish it from 'true' dementia[3]. Patients have a relatively short clinical course and a clearly defined onset. They complain of a poor memory, poor concentration or difficulty thinking, emphasize their disability, and communicate distress and low mood. They may frequently answer 'don't know' to direct questions and be slow to respond. There is often a past or family history of depression. For the individual patient, physical investigations including brain imaging[75] and neurophysiological studies[76] are of little use in differentiating between pseudo-dementia and 'real' dementia.

Traditional teaching holds that treatment of the underlying depression with antidepressant therapy results in complete recovery in depressive pseudo-dementia[1–3]. However, some degree of cognitive impairment may persist after treatment[73,77], and longitudinal studies tend to support the view that severe cognitive impairment in depression is a harbinger of true dementia in between 25% and 50% of patients[78–80]. Indeed, elderly patients who develop cognitive impairment during depression are at four to five times increased risk of developing dementia within five years[79,80].

CONCLUSION

Reversible dementias are relatively uncommon but their identification is important from the individual patient's perspective. As investigative techniques improve and new treatments are developed, the range of potentially reversible conditions grows. However, the literature encompasses a polarization of views. Depression aside, the evidence-based view would suggest that given the rarity and poor response to treatment, extensive investigation is unnecessary. The more traditional, patient-centred view, perhaps coloured by the early literature and the fear of litigation, would demand the continued use of routine investigations in the hope of excluding treatable aetiologies, however rare. The introduction of care protocols reached by consensus should guide clinicians and ensure patients have equity of access to appropriate assessment.

Cognitive Domains Affected by Conditions of Ageing and the Role of Neuropsychological Testing

Heather R. Romero, Scott M. Hayes and Kathleen A. Welsh-Bohmer

Joseph and Kathleen Bryan Alzheimer's Disease Research Center, Department of Psychiatry (Div Medical Psychiatry), Department of Medicine (Div Neurology), Center of Cognitive Neurosciences, Department of Psychology, Duke University, Durham, NC, USA

INTRODUCTION

Memory loss and dementia are nearly universal concerns in the ageing sector of our population[1]. In practice, differentiating the normal age changes from those of early Alzheimer's disease can be daunting. Advances in clinical diagnostics and laboratory imaging methodologies facilitate this process[2]; however, there remains no definitive diagnostic biological test for Alzheimer's disease or for other related neurodegenerative conditions. Ultimately, the diagnosis of a cognitive disorder rests on an informed clinical examination. A thorough neurobehavioural examination and more detailed neuropsychological assessment, when indicated, allow the clinician to determine the integrity of various mental processes. Using this information, diagnostic inferences can be made regarding the presence or absence of brain disease and the potential confounding influences of depression, anxiety and other medical factors. The purpose of this chapter is to provide an overview of the cognitive domains assessed by a standard neuropsychological evaluation with focused consideration of the domains specifically affected by normal brain ageing, mild cognitive impairment, Alzheimer's disease and geriatric depression.

PRINCIPAL COGNITIVE DOMAINS IN THE GERIATRIC EVALUATION

When patients present with memory or other cognitive complaints, objective verification of the nature and extent of these problems and the determination of their functional impact are goals of the neuropsychological evaluation. To ascertain this, the evaluation will assess eight major areas of cognitive function along with aspects of mood and personality. The basic areas assessed or 'cognitive domains' include: (i) general orientation and alertness, (ii) attention/concentration, (iii) intellect, (iv) memory, (v) language, (vi) executive functions, (vii) visuoperception/spatial judgement, and (viii) sensorimotor control. A brief discussion of each of these domains and the tests commonly used to measure each are described in the sections that follow. More detailed discussion of the range of instruments available to clinicians can be found in other sources[3].

General Orientation

Orientation is a particularly important function that can be disrupted by a number of medical (e.g. delirium), psychiatric (e.g. depression) and neurological disorders[4]. In assessing general personal awareness, the neuropsychologist will establish the patient's ability to orient to time (e.g. year, date, time of day), place (e.g. current location), personal information (e.g. name, age) and situation (e.g. why they are having a doctor's appointment). Commonly, the examining clinician may use mental status tests in which orientation screening is included, such as the Mini-Mental State Examination (MMSE)[5] or more detailed batteries, such as the Mattis Dementia Rating Scale[6] and the comprehensive memory battery of the Wechsler Memory Scale[7]. Targeted, well-validated measures of orientation, such as the Temporal Orientation Test (TOT)[8], are often selected and preferred by neuropsychologists over mental status screening tests, in order to streamline the evaluation and allow comprehensive evaluation of domains only cursorily measured in a screening metric.

Attentional Functions

The components of attention tapped within the neuropsychological examination include visual and auditory: (i) simple attention span, (ii) selective attention, (iii) vigilance or sustained attention, (iv) divided attention and (v) alternating attention[9]. There are a number of well-validated tests from which to choose when assessing attention and concentration, some of which are now computerized.

Simple attention span, the number of units held in immediate memory, is commonly assessed by tests such as the Digit Span subtest from the Wechsler Adult Intelligence Scale III (WAIS-III)[10] or the Spatial Span test of the Wechsler Memory Scale III[7]. *Selective attention* requires the ability to respond to relevant stimuli while simultaneously inhibiting response to irrelevant, distracting stimuli, such as in speeded target identification tasks (e.g. Symbol Search of the WAIS-III) or the Ruff 2 and 7 Selective Attention Test[10,11]). *Vigilance* requires that stimuli be attended to over a period of time, commonly assessed by computerized continuous performance tests (CPTs), such

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

as the Test of Variables of Attention (T.O.V.A.)[12]. *Divided attention* requires response to multiple competing tasks that occur simultaneously, such as tasks involving the simultaneous performance of both verbal repetition and visual search tasks. *Alternating attention* requires an individual to shift between tasks, such as the Trails B task, which requires switching between number and letters. It should be noted that tests of attention are easily influenced by a number of factors.

Failure on any single attentional test, or any neuropsychological test for that matter, can occur for a myriad of reasons. Consequently, it is important to consider confounds (e.g. sensory or motor limitations) and factors that may modify performance (e.g. educational experience) before drawing conclusions regarding impairments. Typically a neuropsychologist will look for consistency of performance across at least two tests measuring the same cognitive function before drawing an inference of compromised function.

Intelligence

Intelligence is a multifaceted construct that examines capacities of reasoning, problem solving, creative thought and abstraction, measured both verbally and non-verbally. Significant impairments in this domain result in compromised function, a defining feature of dementia. The tests most commonly used for the purpose of assessing intelligence are those of the Wechsler Adult Intelligence Scale IV (WAIS-IV)[13] (and its predecessors, WAIS-III and the WAIS-R), due to the well-established psychometric properties (reliability, validity and clinical utility) and extensive normative information for a broad age range (age 16–89). The WAIS tests also afford a comprehensive survey of a number of complex cognitive processes, including calculation, verbal and non-verbal abstraction, fund of knowledge, comprehension, reasoning and problem solving, spatial judgement, and sensorimotor integration. In situations where administration of an entire intelligence battery may be impractical, shorter versions are available (e.g. Wechsler Abbreviated Scale of Intelligence, WASI[14]). Alternatively, the neuropsychologist may sample specific areas of concern. Subtests of the WAIS, such as Block Design and Similarities, are sensitive indicators of brain disease and are often selected to quickly assess non-verbal and verbal abstraction, respectively.

Learning and Memory

A considerable portion of the neuropsychological evaluation is generally devoted to the in-depth characterization of the different components involved in the learning and retention of new information as depicted in Figure 62.1. The pattern of deficit across these varying learning and memory processes can suggest one medical condition over another. In a standard neuropsychological evaluation of dementia there will be measures of *semantic memory*, the recall of well-learned facts and world knowledge, and *episodic memory*, the rich person-specific memory that records all new occurring daily events. Tests of semantic memory include category or semantic fluency tests, which require the patient to generate items to a category or group items that are related to one another along specific dimensions (living vs. non-living; instruments vs. tools). Other tests tap recall of world knowledge and are built into larger memory batteries[7].

Episodic memory and its component processes of encoding, storing and retrieving new information are determined using tests aimed at verbal and visual learning and memory functions. Acquisition of new information over multiple trials examines the efficacy of encoding whereas assessment of memory retention over short intervals (less than 3 minutes) and extended delay periods (30+ minutes) allow inferences regarding consolidation. Recognition memory allows determinations of the integrity of retrieval when cueing is provided.

Tests commonly used to assess memory are summarized in Table 62.1 and include comprehensive batteries such as the Wechsler Memory Scale (WMS-III)[7]. Targeted verbal learning and memory measures include the California Verbal Learning Test II[15], the Hopkins Verbal Learning Test-Revised[16] and the Rey Auditory Verbal Learning Test (Rey AVLT)[17]. Complementary visual memory tests include the Brief Visuospatial Memory Test-Revised[18] and the Benton Visual Retention Test[19]. An entire listing of all available memory tests is beyond the scope of this review. However, a summary of commonly used metrics in current practice is presented in Table 62.1, and the reader is referred to other comprehensive sources[3].

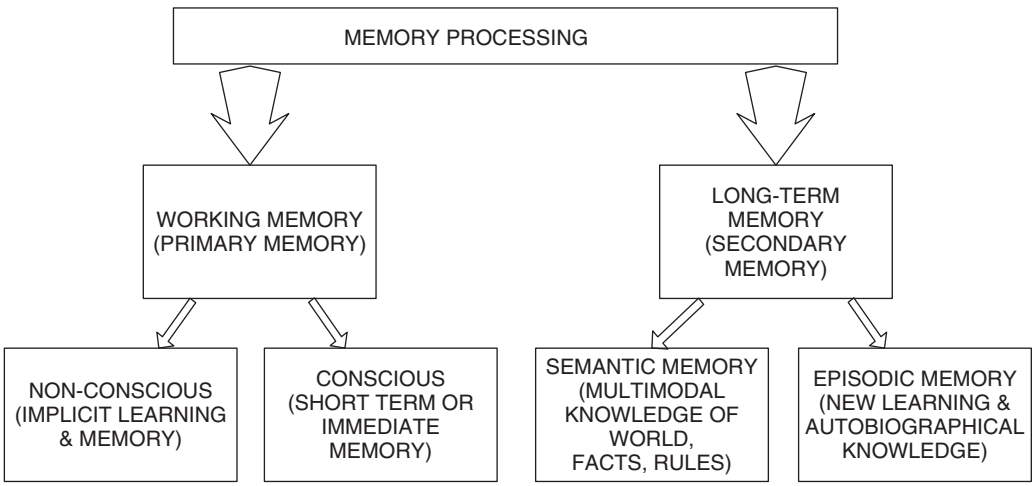

Figure 62.1 Neuropsychological conceptualization of learning and memory organization. Conscious aspects of working memory that require immediate, short-term processing of information and processes of semantic and episodic memory are typically assessed in the geriatric evaluation. Non-conscious learning and memory (e.g. motor memory, habits) are not typically assessed directly in the clinical neuropsychological examination

Table 62.1 Domains and common tests used to measure memory

Domain	*Common tests*
Orientation	Temporal Orientation Test[8]
	Mini-Mental State Examination[5]

Language

Verbal communication in day-to-day life relies on the individual's ability to express and comprehend oral and written speech. Formal neuropsychological evaluation focuses on spoken and written expressive language and on comprehension or 'receptive' language abilities. The Boston Diagnostic Aphasia Exam[20] and the Multilingual Aphasia Exam[21] are two comprehensive batteries of language function commonly used. Administered in their entirety, each aphasia battery takes approximately 30–60 minutes to administer. Unless language disorder is the referral issue, more focused brief testing of specific functions is frequently a preferred approach. Expressive language will be assessed with fluency measures, such as the Controlled Oral Word Association Task (generating words beginning with a specified letter, e.g. 'R'), and with tests of 'semantic fluency' in which participants provide examples to a given category (e.g. sports). The Boston Naming Test, a visual naming procedure, is used to formally assess word-finding difficulty. Impairments in aural and written comprehension, if not detected during the interview, are often assessed with subtests of the Wechsler Adult Intelligence Scale, including Comprehension, Vocabulary, Similarities or Information (see section on Intelligence).

Executive Functions

Executive functions, commonly referred to as higher order cognitive functions, comprise a number of supervisory processes that provide some control over many fundamental cognitive abilities and in the organization of general behaviour. The basic components of executive function include planning and organization abilities, monitoring and inhibition of responses, set shifting and cognitive flexibility, and verbal or non-verbal abstract reasoning. Attention and concentration processes, discussed previously, are also subsumed under the broad category of executive control; however, typically, these very specific functions are assessed separately.

There are a number of neuropsychological measures used to tap executive disorders. Comprehensive, all-in-one batteries of executive abilities include the Delis-Kaplan battery, which examines flexible behaviour, problem solving, judgement, personality and abstraction[22]. Targeted measures of decision making and flexible

behaviour include sorting tasks, such as the Wisconsin Card Sorting Test (WCST), or alternating letter–number sequencing procedures, such as the Trail Making Test. Measures commonly used to examine behavioural control and response inhibition include tests such as the Stroop Color Word test[23]. Finally, assessment of abstract reasoning is commonly accomplished using subtests from the WAIS-III, such as the Similarities and Matrix Reasoning, or tests requiring the development of visual or verbal analogies, such as the Halstead Category Test.

Detection of executive deficits can be extraordinarily difficult, particularly in situations of subtle impairment and within the structured clinical setting, which is unlike the real world, where the patient must determine rules, contingencies and adjust behaviour accordingly. Consequently, in cases of suspected frontal lobe dementia, where executive disorders are prominent, and in neurodegenerative conditions (such as Alzheimer's disease and Parkinson's disease), where executive dysfunction emerges over the course of disease, the combined use of neuropsychological performance-based measures of executive function and informant-based measures of daily function, can be enormously helpful in determining the presence of problems in this domain and can help guide management approaches. Computerized tests of decision making and planning, such as the Cambridge Neuropsychological Tests Automated Battery (CANTAB), can augment the diagnostic process[24]. Self-report and informant-report measures such as the Frontal System Behavioral Examination (FrSBe)[25] or the Behavioral Rating Inventory of Executive Function – Adult version (BRIEF-A)[26] are also useful for assessing personality change and patient insight.

Visuospatial Function

Neuropsychological assessment of visual–spatial function focuses on object perception, spatial appreciation, constructional praxis and complex visual integrative capacities[27]. Object perception is often determined through tests such as the Facial Recogniton Task[28], in which the patient is required to discriminate between faces presented from different views or under different lighting conditions. Spatial perception ability is determined via tests assessing judgement of angular relationships, locations of objects in space and detection of movement. Praxis will be assessed either through the copy of simple (e.g. CERAD battery[29]) and visually complicated geometric figures (e.g. Rey-Ostereith Complex Figure Test[30]) or via three-dimensional constructional tasks (e.g. block design[31]). Integrating visual information into a meaningful whole is often determined with tests such as the Hooper Visual Organization test, which require visual processing and conceptualization[32].

In clinical practice, visuo-spatial problems are often less obvious on screening evaluation than either memory or language disorders. Consequently, incorporation of simple visuo-spatial measures, such as the Clock Drawing test[20], to the neurobehaviour examination can augment the detection and tracking of these disorders and can improve the sensitivity of the Alzheimer's disease diagnosis[33]. The information from a detailed neuropsychological evaluation of visuo-spatial function may be very useful for arriving at recommendations concerning daily activities, such as driving[34].

Sensorimotor Function

The neuropsychological examination of motor function will begin with the enumeration of any obvious motor signs, such as evident hemiplegia, tremor, dyskinesia or chorea. Tests for subtle problems in fine motor control are then typically administered and can be highly instructive in pointing to potential lateralized central nervous system deficits[35]. A number of standardized tests of manual strength and speed are available for quantifying and interpreting sensorimotor functions (Table 62.1). Typically, function with both the dominant and non-dominant hands is assessed using any of a number of metrics, permitting an evaluation of hand grip strength, rapid finger movement or fine motor dexterity (e.g. manipulation of small objects). Easy to administer, the measures are a sensitive indicator of general cognitive integrity and lateralized deficits in the nervous system, and can be useful in tracking disease progression and medication effects, particularly those treatments directly effecting extrapyramidal motor function[36].

Mood and Personality

The assessment of mood and personality begins with a psychological interview, allowing the neuropsychologist to assess the range of symptoms, level of functional impairment and relationship of the problems to the onset of cognitive dysfunction. This interview will then be augmented by objective metrics to determine changes from a pre-existing level and longstanding traits. Patient self-report measures of mood state include the Beck Depression Inventory II (BDI-II) or the Geriatric Depression Scale[37,38]. More detailed measures, such as the Minnesota Multiphasic Personality Inventory 2 (MMPI-2), survey broad psychiatric symptoms and are used in situations where psychiatric or personality issues are considered primary to the complaint[39].

Informant report questionnaires are particularly helpful in dementia as patient insight into their own behavioural change may be impaired. The Neuropsychiatric Inventory (NPI) assesses eight different domains of behaviour affected in brain disease (depression, apathy, anxiety, disinhibition, hallucinations, paranoia, delusions, agitation) from an informed observer perspective[40]. Changes in personality can also be assessed by questionnaires such as the FrSBe, discussed previously, which is an inventory that has both self and informant report forms and focuses on areas such of apathy, disinhibition and executive dysfunction[25].

COGNITIVE PROFILES ASSOCIATED WITH COMMON CONDITIONS OF AGEING

With performance across various cognitive domains established, consideration of the impairment profile and its relationship to underlying neural systems and brain disease is required for diagnosis. In the next section we review the typical neuropsychological profiles of normal ageing, Alzheimer's disease, mild cognitive impairment and geriatric depression.

Normal Cognitive Ageing

The profile of cognitive change due to normal brain ageing can be fairly easily distinguished from impairments due to neurodegenerative conditions, such as Alzheimer's disease, particularly in individuals who are 85 years of age or younger[41]. The neuropsychological findings of ageing reveal a spectrum of modest decline within a number of cognitive domains (Figure 62.2)[42]. Selective losses occur on tests of psychomotor speed and sensorimotor functions. Other functions affected include memory retrieval, attentional capacity, executive function and working memory[43]. Semantic knowledge

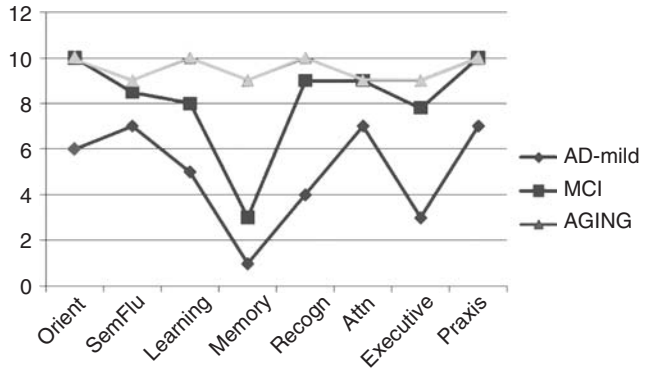

Figure 62.2 Neuropsychological performance in Alzheimer's disease, mild cognitive impairment and normal ageing. Presented are prototypical cognitive profiles of mild-staged Alzheimer's disease (AD), mild cognitive impairment (MCI) and normal ageing when considered relative to the performance of young adults on domains of Orientation, Expressive language (Semantic fluency), Learning, Delayed memory, Recognition memory, Praxis, and Executive function. Compared to young adults, normal older aged adults will demonstrate modest declines on tests of delayed free recall (Memory), word fluency (SemFlu), and higher order executive functions involving flexible behaviour (Executive). These rather modest changes in performance are exacerbated in MCI and AD. Delayed memory is particularly poor and there are also deficits in new learning and recognition memory. Verbal semantic fluency (SemFlu), simple attention, and praxis are also affected by the AD process, but become particularly problematic later in the course of the disease

and crystallized intelligence, which are acquired over the life span, are typically spared from age-related decline. Large cross-sectional comparisons across diverse cohorts aged 18–90 demonstrate monotonic declines across the broad domains noted, beginning as early as age 30; improved function is seen on tests of general knowledge and verbal comprehension[44]. These findings are robust and are confirmed in longitudinal, within-person studies[45]. In fact, within these within-subject comparisons there is evident test–retest improvement in test performance over time (i.e. practice effect)[46]. It has been suggested that the absence of the practice effect on re-evaluation may be an important indicator of an early neurocognitive condition[47], an observation important to consider on repeated evaluation with mental status screens, such as the MMSE.

Alzheimer's disease

In contrast to normal ageing, the cognitive disorder of Alzheimer's disease is characterized, early and throughout the disorder, by a profound impairment in memory consolidation (i.e. effectively storing new information for recall later), making it exceptionally difficult to learn and retain new information. On neuropsychological evaluation this problem is manifest by rapid forgetting of new information, measured with delayed recall procedures administered 10–30 minutes after the individual has already effectively demonstrated ability to successful encode new information on tests of immediate recall[48]. Characteristically, the memory deficit is facilitated very little by structural support, such as recognition cuing. Recall becomes vague, and patients will commit errors on recognition tests, showing a tendency to over-endorse items as recognized targets (i.e. false positive errors[49]). The failure to benefit from cueing in Alzheimer's disease contrasts the memory disorders of normal brain ageing, depression, Lewy body dementia and vascular cognitive impairment. In each of the latter situations, retrieval cueing is beneficial and assists recall[50–52].

Although memory impairment is the prominent clinical sign of Alzheimer's disease, it is not the only deficit characterizing this neurodegenerative dementia. There are also highly characteristic problems in expressive language evident early in the illness. Later, problems in complex problem solving, executive control and abstraction are more clearly evident as well as disorders in visuo-spatial analysis and motor praxis (organization of skilled motor movements – such as writing, drawing, dressing, etc.). As each of these cognitive domains become more impaired, deficits in activities of daily function unfold[29].

On formal neuropsychological evaluation, the early language disorder of Alzheimer's disease is characterized by difficulties on tests of visual confrontation naming and on measures of semantic fluency, assessed by asking the patient to generate exemplars to a category (e.g. household tools, cars). Qualitatively, there may be a vacuous nature to speech output. With an absence of content words in their discourse, patients may resort to 'circumlocution' (i.e. description phrases) rather than easily accessing the precise word needed. Word substitutions and paraphasic errors also become common. Despite these difficulties in expression, comprehension of speech and repetition tend to be spared until later in the illness.

Praxis difficulties, impaired geographical orientation, and visuo-spatial errors may manifest as problems in spatial navigation, judgement of distances and difficulties locating and correctly identifying objects in the environment. On formal neuropsychological testing, these deficits are revealed using tests requiring visual integrative functions, judgement of spatial relationships between objects and form perception[53,54]. Atypical presentations of pronounced and relatively isolated visuo-spatial deficits are noted on occasion in Alzheimer's disease and are common in the Lewy body variant of Alzheimer's disease[53,55]. Similar presentations can also be seen in other progressive dementias, such as posterior cortical atrophy or 'Benson's Syndrome', multisystem atrophy, corticobasal dementia, forms of Creutzfeldt–Jakob disease[56]. In making distinctions between aetiologies, consideration must be given to other salient clinical features including presence or absence of motor signs, history of symptom expression and disease course[52].

Mild Cognitive Impairment

The concept of mild cognitive impairment (MCI) has emerged as a construct describing a transitional stage between normal ageing and the dementia syndrome common in Alzheimer's disease. The original MCI criteria specified: (i) a pronounced and rather isolated deficit in recent memory function, and (ii) preserved activities of daily living capabilities[57]. MCI appears to be a risk factor for later dementia, with a 12% rate of conversion per year compared with 1–2% in normal ageing. The operationalization of this construct has greatly facilitated early Alzheimer's disease identification; however, it has been criticized as too restrictive and not capturing the broad range of subsyndromal symptoms leading ultimately to Alzheimer's disease and to other closely aligned dementias. In addition, the construct has been found in many settings to be diagnostically unstable. Many individuals characterized as MCI in community settings and epidemiological surveys have been reported to revert back to normal function at later observation points, therefore, calling into question the validity of the diagnosis as a prodrome to neurodegenerative dementia[58].

Revised criteria now in use recognize that mild cognitive impairments may be a prelude to a number of different types of dementias, not only Alzheimer's disease[59]. The new criteria have been broadened to include four subcategories of subsyndromal states, each of which share the core criteria of: (i) cognitive complaint, (ii) objective evidence of cognitive deficit beyond expectation for age (variably defined as either −1.0 SD or −1.5 SD below age, education mean), and (iii) activities of daily living are preserved and instrumental functions are either intact or are minimally impaired. With the new criteria, MCI can be dichotomized into an 'amnesic' and 'non-amnesic form', which is further dichotomized into 'single domain' affected vs. 'multiple cognitive domains' impaired. The four resulting subcategories are: 'amnesic MCI', corresponding to the original criteria; 'amnesic- multiple domain MCI', a situation where memory involvement is prominent but another domain (such as executive function or language) is also impaired; 'non-amnesic single-domain MCI', which captures conditions such as an early pronounced visuo-spatial, executive or language-based disorders; and 'non-amnesic multiple domain MCI', which captures multiple deficit disorders in which memory is by and large spared.

The predictive utility of the new subcategories of MCI for Alzheimer's disease and other dementias has yet to be fully demonstrated[60]; however, initial information suggests that the amnesic forms of MCI are predictive of later Alzheimer's disease development[61]. Other non-amnesic forms may be more predictive of other forms of chronic, degenerative disorders, such as vascular dementia[62]. However, there is no universal information on the latter point, and some studies suggest that all categories are equally predictive of later dementia[63,64]. This topic is an evolving area of clinical research, which will be facilitated as the pathobiology of the various chronic diseases and their interactions with one another are better understood.

Geriatric Depression

The neuropsychological profile in geriatric depression reveals highly specific cognitive disturbances in general cognitive efficiency. The entire profile of performance may be suppressed or there can be deficits confined to tests of executive processes of attention, working memory and processing speed[65,66]. On detailed characterization, specific impairments are commonly detected in selective attention, sustained attention, organization, set shifting, initiation and response inhibition. Visuo-spatial deficits and deficient memory performance are also possible; however, unlike the disorder of Alzheimer's disease these impairments tend to result from executive and processing speed deficits, rather than being a problem in spatial ability or memory consolidation. Very poor acquisition of new information in the context of shifting attention leads to memory complaints and subsequent impairment on tests of delayed free recall. However, when memory tasks are more structured and less reliant on executive abilities, delayed recall improves in the depressed patient, sometimes to the normal level, underscoring the role of the initial processing deficits.

Treatment of depression can lead to some reversibility of cognitive deficits and improved function[67]. Persisting cognitive impairment following adequate treatment may be due to underlying neuropathology, which is contributing to both depression symptoms and cognitive deficits, such as cerebrovascular disease or neurodegenerative conditions[68]. Careful evaluation of mood is therefore essential both for differential diagnosis of memory disorder and also for optimizing patient outcomes.

SUMMARY AND CONCLUSIONS

By understanding the common profiles of neurocognitive dysfunction typical of the major disorders of ageing, such as Alzheimer's disease and geriatric depression, the examining physician is given valuable information that complements the more abbreviated mental status assessment. In enhancing the detection of dementia cases in everyday clinical practice, the application of targeted measures of episodic memory (recall after a delay) and executive function (flexible thought) can be quite useful while also providing adequate profile information for tracking the clinical progress of patients over time. To facilitate the recognition of subtle disorders such as MCI, the addition of a screen of functional ability may be necessary in order to establish the impact of a cognitive complaint on the patient's ability to carry out normal, routine activities of daily living. Although the current pharmacological treatments for Alzheimer's disease offer little hope in terms of disease reversal, early diagnosis allows the clinician to treat contributing conditions in an effort to optimize function and prevent excess disability. It also permits the anticipation of problems before they occur and allows inclusion of patients in care decisions, enhancing their sense of autonomy and self-determination in their illness.

Memory Training for Older Adults

Karen Miller, Linda Ercoli, Jeanne Kim and Gary W. Small

Semel Institute for Neuroscience and Human Behavior,
David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Normal ageing is typically associated with a decline in select domains of cognitive functioning, including processing speed, memory and executive functioning[1,2]. In addition, non-pharmacological interventions such as cognitive training and rehabilitation are being developed to enhance existing cognitive capacities, prolong independence in functional activities and promote healthy ageing. However, there is controversy as to whether cognitive stimulation enhances mental function[3] or decreases risk for Alzheimer's disease[4].

This chapter will present an overview of cognitive interventions that have been used with older adults, including healthy individuals with age-related memory changes, those with mild cognitive impairment (MCI), and persons with dementia, such as Alzheimer's disease (AD), and will include discussion of memory systems, metamemory, self-perceptions of memory, and interventions.

MEMORY SYSTEMS

Accumulated knowledge from studies in humans and animals has led to a widely accepted model of memory as being composed of multiple separate but parallel systems[5]. These multiple memory systems can be conceptualized as being either *declarative* or *non-declarative*[5]. Non-declarative memory is a general term for memory systems that do not involve conscious recollections but actions and performance-based tasks. Non-declarative memory is often targeted in rehabilitation interventions for skill maintenance, teaching skills, or functional abilities[6]. Declarative memory is the conscious recollection of information such as facts (*semantic memory*) and experienced single events linked to time and place (*episodic memory*)[7]. Individuals with progressive memory disorders, such as amnesic MCI and mild AD, present with deficits in declarative memory[8], which is the target of most memory enhancement strategies for non-demented persons and persons with milder forms of cognitive impairment.

Another conceptualization of memory relevant to cognitive enhancement interventions is the *levels of processing* approach, which comes from learning theory[9]. Levels of processing is the concept that memory is a function of the degree to which a stimulus is analysed. The deeper and more meaningful the analysis, the better the stimulus is remembered. In memory training, forming associations, images or stories can be considered deep processing strategies. It renders the information more distinctive, and helps integrate new information with a framework of pre-existing knowledge that provides cues for later retrieval[10].

METAMEMORY AND SELF-PERCEPTION OF MEMORY

A person's subjective understanding of their memory functioning is called *metamemory*. Most individuals have some understanding of their memory strengths, which might guide subsequent behaviours[11]. In non-depressed individuals, memory self-perceptions have been found to be accurate indicators of memory difficulties on objective tests[12], and may be indicators of underlying brain processes[13]. Several studies indicate that memory training interventions improve self-perceptions of memory ability and reduce memory complaints[14–16]. In healthy older adults, memory training may result in self-reported improvements in stability of memory functioning, and reduced anxiety and stress about memory functioning[15]. Effects of memory training on self-perceived memory are typically small, but nevertheless significant[14,17]. However, self-perceived memory ability is not always accurate. Persons with developing dementia may lose awareness of memory dysfunction as memory impairment advances[18,19].

TYPES OF COGNITIVE INTERVENTIONS

There are three primary approaches to cognitive training intervention: *cognitive stimulation, cognitive rehabilitation* and *cognitive training*[20]. The choice of approach depends on the degree and nature of deficits.

Cognitive stimulation typically involves participation in group activities and/or discussions aimed at general enhancement of cognitive and social functioning[21]. These types of interventions are non-specific to a cognitive domain, and include such activities as discussions of current events, supervised recreational activities, and group reminiscence therapies. Cognitive stimulation is typically used for demented patients and often as a control condition in studies investigating the effects of cognitive training.

Cognitive rehabilitation is an individualized intervention designed for patients with a specific brain injury or neurological disorder. Health-care providers work collaboratively with patients and their families or caregivers in order to identify personally relevant goals in day-to-day living and to develop strategies[20] that enhance functional tasks and activities of daily living, rather than increasing performance on a specific cognitive task[22].

The focus of this chapter is *cognitive training*, which involves learning and practising strategies to improve specific cognitive

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

functions, such as memory, attention, or problem-solving. Cognitive training is often administered to people with mild forms of difficulties associated with normal ageing, and to clinical populations, including persons with MCI, dementia or schizophrenia. The goals of cognitive training are to maintain or improve cognitive function, and to learn to compensate for deficits. Cognitive training is based on the assumption that, with intensive training, people will apply the strategies they learn to real-life situations beyond the training session. Cognitive training typically involves teaching skills and strategies in a standardized and structured fashion to individuals or to small groups[12]. Strategies vary in difficulty level and can be traditional paper–pencil tasks, classroom instruction or computerized activities[20].

MEMORY TRAINING APPROACHES

Many training techniques have been developed to specifically improve learning and recall. The techniques vary with respect to complexity, structure and application. One example is *errorless learning*, which is based on the premise that remembering new information will be more efficient if errors during learning are minimized and/or immediately corrected[23–25]. *Spaced retrieval*[26], which is also known as expanded rehearsal[27], is another common technique and involves learning and retaining new information by recalling the information over increasingly longer periods of time[28,29].

Mnemonic strategies have been one of the primary memory interventions used within clinical settings. Generally, mnemonic strategies facilitate encoding and aid retrieval by enhancing the meaningfulness or personal relevance of information. Mnemonic strategies involve organizing information in meaningful ways, forming associations, or forming visual images. Examples include: (i) verbal organization (i.e. forming acronyms), (ii) semantic clustering and elaboration (i.e. categorizing lists of words into subgroups or clusters of items that share something in common; or creating a story linking all target words on a list), and (iii) visual imagery strategies (i.e. method of loci, face-name association, creating a mental picture of a target)[11].

One of the most popular and oldest mnemonic strategies is the *method of loci* technique, which was used by ancient orators to remember long speeches. The method of loci involves imagining a familiar path and identifying unique landmarks along the path. Visual imagery is used to associate items on a list with each landmark along the imagined path. To remember the list, simply take a mental 'walk' along the path, recalling each image at each landmark.

Another popular mnemonic strategy is *face-name association*[30]. Individuals can use the face-name method for remembering someone they just met. The face-name strategy involves three steps: (i) looking at a person's face and identifying a prominent facial feature, (ii) transforming the person's name into something imaginative or that sounds concrete or meaningful, and (iii) developing a visual image integrating the prominent facial feature with the transformed name.

The efficacy of mnemonic or memory training strategies has been examined in a number of studies. Factors associated with memory improvement in one meta-analysis included younger age, higher cognitive functioning, group setting (versus individual training), shorter duration of sessions, education and 'pretraining'[17]. Pretraining allows the participant to get comfortable with visualization and move beyond their comfort zone of thinking about ordinary or logical images. In addition, the number of sessions did not appear to limit the efficacy of memory training[17]. In fact, interventions as short as 4 weeks can be just as effective as programmes that are 8 weeks, or even 6–12 months long[31,32]. Most research demonstrating effectiveness of mnemonic techniques has focused on healthy adults, both young and old, but persons over 75 years of age show less improvement[33]. The few studies of efficacy in MCI populations have yielded mixed results[34,35]. A subset of subjects from the ACTIVE study (Advanced Cognitive Training for Independent and Vital Elderly) who were identified as 'memory impaired'(comparable to MCI) showed no significant benefit from memory training when compared to a no-contact control group, but had gains in speed of processing and inductive reasoning[36].

COMPUTER-ASSISTED COGNITIVE INTERVENTIONS

With the advancement of technology, researchers and clinicians are interested in computer-assisted training interventions for both healthy older adults and people with memory impairments. Initial studies have demonstrated that computer-based cognitive training has improved learning efficiency in healthy older adults[37], and supported cognitive and functional improvements in patients with AD[38]. Computer-based software technology has also recently been introduced in rehabilitative and training settings for patients with AD and MCI. Results seemed to suggest that the individualized rehabilitative intervention could have different effects according to a patient's diagnosis[39]. Cognitively intact older adults who received computer-based training demonstrated improvements in information processing, working memory and verbal learning/memory, and these gains were maintained over a five-month follow-up[40]. In mildly demented patients, computer-based training improved immediate recall of visual information and delayed retention of topographical information[38]. Combining a cognitive seminar and computer-assisted training in demented patients resulted in short-term improvement on measures of global cognitive functioning and short-term memory, as well as behavioural and social improvements[41].

Posit Science has developed a cognitive training program that contains increasingly difficult tasks of stimulus recognition, discrimination, sequencing and memory. Participants with mild cognitive changes associated with age demonstrated a significant increase on all computer tasks, with maintenance of improvements in attention over three months, when compared to active and no-contact controls[42]. In a subsequent larger trial, the Improvement in Memory with Plasticity-based Adaptive Cognitive Training (IMPACT) study[43], subjects demonstrated improvement in auditory memory and attention as compared to a general cognitive stimulation program that functioned as the active control condition.

Additionally, pilot studies have evaluated a computerized program, Brain Fitness by Dakim, which provides cognitive training and stimulation in language, visual processing, and memory domains. Results indicated improvement in memory functioning for those who could participate in the higher levels of the program, in addition to improved encoding and delayed recall for verbal pairs after just 10 sessions[44,45]. Presently, a clinical trial is underway to investigate the short- and long-term impact of this computer program on memory functioning in a larger sample of older adults with mild memory complaints as compared to wait-list controls.

As people become more technologically aware, computer programs are likely to become an important conduit for simulating real-life environments and integrating goal-directed behaviours in order to increase ecological validity[38]. These newer computer-based cognitive training interventions, however, have both advantages and

limitations. Many of the tasks included in these interventions are laboratory based and likely lack ecological validity for functional activities. Moreover, many older adults have not had regular exposure to modern technology and thus may be hesitant or cautious in using them. Some of the advantages to using computer-assisted cognitive training programs are their flexibility and ability to tailor interventions to specific aspects of cognitive impairments, as well as the ability of the computer to provide immediate and specific feedback regarding performance[40].

The effects of computer-based training on brain function have not been widely studied. To date, one study has shown that computer use (via internet searching) may involve more than a two-fold increase in brain activation (as measured by functional magnetic resonance imaging) for the areas of the brain that are associated with vision, complex reasoning and decision making[46].

COMPREHENSIVE PROGRAMMES

Comprehensive or 'multifactorial' memory training programmes address non-cognitive factors in addition to teaching cognitive enhancement strategies. Non-cognitive factors include: (i) self-efficacy, expectations, and beliefs about one's ability to improve cognition; (ii) anxiety; and (iii) general education about memory[10,14,17,47,48]. Comprehensive training programmes may include interventions for stress or anxiety reduction, and cognitive restructuring to counter negative and self-deprecating thoughts about memory ability. Most programmes include pre-training because this facilitates learning more complex cognitive techniques. Overall, these integrative approaches take into account the multiple factors that impact an individual's receptiveness, or response to cognitive enhancement interventions.

There is recent evidence that the role of lifestyle and environmental factors can be neuroprotective and possibly lower the risk for developing AD[49]; therefore, some researchers have developed comprehensive healthy lifestyle programmes that incorporate aspects of diet, physical exercise, relaxation strategies and mental exercise[50]. Small and colleagues[51] developed a 14-day lifestyle programme consisting of memory mnemonics, mental puzzles, cardiovascular exercises, diet and recipe suggestions and relaxation strategies. Subjects in the healthy lifestyle intervention group demonstrated significant improvement on objective measures of verbal fluency, and FDG-PET imaging revealed a 5% decrease in activity in the left dorsolateral pre-frontal cortex, an area associated with working memory, semantic organization skills, anxiety and verbal fluency. This decrease in activity was interpreted as greater cognitive efficiency. This 14-day programme was then expanded into a classroom-based Memory Fitness curriculum, which has recently been implemented and studied in retirement homes[52,53]. Participants in the memory fitness programme had fewer memory concerns and better performance on immediate and delayed recall measures as compared to controls.

Researchers have developed similar programmes for individuals with amnesic MCI[34,35]. These programmes are typically comprised of multifaceted group-training sessions that include relaxation techniques, education regarding memory and ageing, memory skills training, cognitive restructuring of memory-related beliefs, information regarding appropriate diet and recreational activities, and availability of community resources[35]. Intervention programmes for those with MCI typically focus on improving memory for daily tasks and maintaining a level of functional independence[54]. A four-week multi-component rehabilitation programme resulted in improvement in activities of daily living, memory functioning and mood compared to a wait-list control group[55]. An additional programme utilized occupational therapy and behavioural training with computerized cognitive training; results showed improvement in cognitive and affective status of patients with MCI and mild dementia[56].

Another area of research to consider is the combination of medication with a computer-based cognitive training programme, suggesting that a combination of pharmacological and non-pharmacological treatment in MCI might maximize the effects of acetylcholinesterase inhibitors and delay memory deterioration and conversion to AD[32,57,58]. Gains may be maintained for approximately six months to one year, but individuals tend to experience a gradual deterioration by year two[57]. Although the effects are time limited, these findings suggest a complementary relationship between cognitive interventions and drug therapy for both cognitive and psychosocial disturbances.

LONG-TERM OUTCOMES

Few studies have evaluated the long-term effects of cognitive interventions in healthy older adults. Overall, the effects of memory training interventions have been found to last from six months to five years[59–62], although the benefits tend to attenuate over time. The largest clinical trial to date is the ACTIVE study ($n = 2832$), which evaluated the effectiveness and durability of cognitive interventions on objective cognitive tests and on subjective and objective instrumental activities of daily living (e.g. financial management, driving)[62,63]. This longitudinal study incorporated 3 cognitive training groups receiving a 10-session training programme for memory, reasoning, or speed of processing, and a wait-list control group. Subjects also received periodic refresher courses, called 'booster sessions', on the skills initially trained. Follow-up results from two[63] and five years[62] revealed that the cognitive interventions in each group helped increase performance on objective measures of cognitive ability for which they were trained. According to self-report measures, this effect was significant only for the reasoning group, although the effect sizes for memory and processing speed were similar in magnitude to the reasoning effect sizes. Performance-based results demonstrated significant speed of processing benefits after additional booster sessions[62]. It is important to note that the lasting impact of cognitive interventions is still dependent on the individual's effort and motivation to maintain the use of the strategies. Future research in this area may consider factors such as motivation and maintenance in order to preserve treatment gains.

FUTURE DIRECTIONS

Overall, cognitive interventions are effective in improving cognition in subjects with mild age-related cognitive declines. However, there are important aspects of cognitive training that deserve more scrutiny. For instance, there is a need for more studies of persons with mild cognitive impairment and additional longitudinal studies in healthy older adults, in order to address whether cognitive training can delay dementia onset. Future studies should include functional outcome measures, to better address whether training can generalize beyond laboratory tests and improve practical, day-to-day functions[34,35]. In addition, there are still unaddressed questions, such as how engaging in stimulating everyday activities (also called an engaged lifestyle) is as effective as specific cognitive training[64,65].

Another important area for study is non-compliance, which may partially account for the lack of generalization and maintenance of cognitive strategy use. The key to long-term benefit appears to be continued use of cognitive strategies after initial training ends[60]. One solution to improve compliance is the implementation of periodic 'booster sessions', which may further help individuals use techniques with greater consistency and in more generalized situations (e.g. daily 'to-do' lists)[62,63].

Another limitation is the knowledge-base for the impact of 'brain games' and programmes targeted at stimulating cognition (e.g. crossword puzzles, sudoku problems, hand-held computerized games) on facilitating memory improvement. Although epidemiological studies suggest an association between engaging in cognitively stimulating activities and lower dementia risk[4,66], these studies do not prove a cause and effect relationship.

Finally, the effect of cognitive training on brain function has received minimal attention. In the few studies available, cognitive training does affect brain activation or resting state brain activity, including areas associated with encoding and retrieval[50,67,68], and training may also result in changes in neurochemistry[69]. Including brain function outcome measures will be important in addressing the more direct effects of cognitive training on neural circuitry and the mechanisms of action in cognitive enhancement interventions.

CONCLUSIONS

In sum, the research to date suggests that cognitive training is beneficial to individuals with memory complaints associated with normal ageing. The effectiveness in demented individuals is less consistent compared to persons with normal ageing. Even less is known about the effects of training on persons with MCI. There are a number of factors to consider before implementing a treatment trial, including the design of the training, the duration of the training, long-term compliance and the possible necessity of concurrent medication for those with cognitive impairment. Many options and designs are available to tailor programmes to the needs of individuals, or to develop programmes for small groups. Additional studies on the effectiveness of cognitive training in persons with MCI will help clarify the outcomes for this growing patient group.

Complementary and Alternative Medicine Approaches to Memory Improvement in the Elderly

Helen Lavretsky

Department of Psychiatry and Biobehavioral Sciences, and Semel Institute for Neuroscience and Human Behavior, David Geffen School of Medicine at UCLA, Los Angeles, USA

THE TRENDS IN USE OF COMPLEMENTARY AND ALTERNATIVE MEDICINE IN THE US

The use of complementary and alternative medicine (CAM) in the US is increasing rapidly, exceeding a prevalence of 60% in a nationally representative survey conducted by the National Center for Health Statistics in 2002. CAM therapies are defined by the National Center for Complementary and Alternative Medicine as a group of diverse medical and health systems, practices and products that are not currently considered to be part of conventional medicine. An alternative approach to mental health care is one that emphasizes the interrelationship between mind, body and spirit. A national US survey noted a 47% increase in total visits to CAM practitioners, from 427 million in 1990 to 629 million in 1997. These figures surpass total visits to primary care physicians[1]. Estimated expenditures for CAM professional services were conservatively estimated at $21.2 billion in 1997, with at least $12.2 billion of out-of-pocket expenditures, exceeding out-of-pocket expenditures for all US hospitalizations. In a more recent nationwide survey, 36% of US adults aged 18 years and over were found to use some form of CAM[1], and ageing baby boomers are expected to accelerate the use of CAM in the coming years[2]. Barnes and colleagues noted that nearly 33% of older adults used CAM in the preceding year (2004)[2]. In a survey, 42% of the patients in a managed care organization reported using at least one CAM therapy, most commonly relaxation techniques (18%), massage (12%), herbal medicine (10%) or megavitamin therapy (9%). Perceived efficacy of CAM was very high, ranging from 98% (energy healing) to 76% (hypnosis)[1].

With the increasing public use of complementary and alternative medicine for preventive and therapeutic purposes, including a very active 'anti-ageing' movement, a significant effort is now devoted to the integration of alternative methods of treatment into mainstream health care practice and research[3]. The principal uses in older adults include anti-ageing effects of CAM for memory enhancement, and treatment of various neuropsychiatric symptoms, such as depression, anxiety, insomnia and pain. This chapter is devoted to the description of the existing CAM interventions applied to the care of older adults with late-life cognitive disorders.

DIET AND THE USE OF NUTRITIONAL AND HERBAL SUPPLEMENTS

Adjusting both diet and nutrition may help some people with mental illnesses manage their symptoms and promote recovery. For example, research suggests that eliminating milk and wheat products can reduce the severity of symptoms for some people who have schizophrenia and some children with autism. Similarly, some holistic/natural physicians use herbal treatments, B-complex vitamins, riboflavin, magnesium and thiamine to treat anxiety, depression, drug-induced psychoses and memory loss. A number of herbs and dietary supplements have demonstrable effects on memory, mood, and insomnia[4]. There is a significant amount of evidence supporting the use of *Gingko biloba* and omega-3 fatty acids for dementia, as reviewed below. Many users of CAM may take a variety of herbal products[5].

Gingko Biloba

Ginkgo biloba leaf extract is among the most widely sold herbal dietary supplements in the United States. Its purported biological effects include scavenging free radicals, lowering oxidative stress, reducing neural damage, reducing platelet aggregation, and anti-inflammatory, anti-tumour and anti-ageing activities. Clinically, it has been prescribed to treat CNS disorders such as Alzheimer's disease and cognitive deficits. It elicits allergy and changes in bleeding time. Its components, quercetin, kaempferol and rutin, have been shown to be genotoxic[6] but the mutagenicity or carcinogenicity of *Gingko biloba* itself has not been reported. There are no standards or guidelines regulating the constituent components of *Ginkgo biloba* leaf extract, nor are exposure limits imposed. Safety evaluation of *Ginkgo biloba* leaf extract is being conducted by the US National Toxicology Program.

Ginkgo biloba has been widely used for many years by people with symptoms attributed to 'cerebrovascular insufficiency,' despite the lack of evidence of a causal role. Many placebo-controlled trials of *Ginkgo biloba* in patients with various types of dementia have yielded contradictory results. Of the studies that revealed any

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

cognitive improvement, the effect was minor and did not last more than six months. Some studies reported haemorrhaging, indicating that it is necessary to use caution when prescribing *Ginkgo biloba* for cognitive deficits, especially in patients with increased risk of haemorrhage[7]. The recommended doses range widely, but in a trial of Alzheimer's disease prevention, 120 mg of *Gingko biloba* twice a day was not effective in reducing the overall incidence rate of dementia or Alzheimer's disease in elderly individuals with normal cognition or those with mild cognitive impairment[8]. Its short-term use is acceptable under some conditions, but the potential risk of bleeding must be seriously considered. *Gingko biloba* has been reported to reduce depression in dementia patients and counteract sexual side effects of antidepressants[9].

The Use of Nutritional Supplements

In addition to herbal remedies, consumers use a variety of nutritional supplements (including vitamins, amino acids and fish oil) that may affect mood and functioning.

Elevated plasma homocysteine concentrations have been implicated with risk of cognitive impairment and dementia, but it is unclear whether low vitamin B12 or folate status is responsible for cognitive decline or can protect against it[10,11]. Most studies reporting associations between cognitive function and homocysteine or B vitamins have used a cross-sectional or case-control design and have been unable to determine whether such associations are causal or merely a result of the disease. The homocysteine hypothesis of dementia has attracted considerable interest, as homocysteine can be easily lowered by folic acid and vitamin B12, raising the prospect that B-vitamin supplementation could lower the risk of dementia[10]. Incident dementia is more strongly associated with changes in folate, vitamin B12 and homocysteine, than with previous concentrations. These changes may be linked to other somatic manifestations of early dementia, such as weight loss[12]. However, in a trial of high dose vitamin B in patients with Alzheimer's disease, the supplement did not slow cognitive decline in individuals with mild to moderate Alzheimer's disease[13]. Two other placebo-controlled trials of treatment with B12, folic acid and B6 showed no advantage of vitamins over placebo at reducing the severity of depressive symptoms or the incidence of clinically significant depression over a period of two years in older men[14]. Similarly, a recent Cochrane review found no evidence for short-term benefit from vitamin B6 in improving mood (depression, fatigue and tension symptoms) or cognitive functions. For the older people included in one of the two trials mentioned in the review, oral vitamin B6 supplements improved biochemical indices of vitamin B6 status, but potential effects on blood homocysteine levels were not assessed in either study. This review found evidence that there is scope for increasing some biochemical indices of vitamin B6 status among older people[15]. The limited available evidence suggests folate may have a potential role as a supplement to other treatments for depression. It is currently unclear if this is the case both for people with normal folate levels and for those with folate deficiency. More randomized controlled trials are needed to explore possible benefits from vitamin B6 supplementation for healthy older people and those with cognitive impairment or dementia.

Omega-3 Fatty Acids

Fish oil and omega-3 fatty acids are also commonly used supplements. Reductions in cardiovascular risk, depression and rheumatoid arthritis symptoms have been correlated with omega-3 fatty acid intake, and there is increased interest in the use of omega-3 fatty acid supplementation for other psychiatric illnesses and prevention of Alzheimer's disease. Reported health benefits include improvements in cognition and mood in unipolar and bipolar mood disorders. Omega-3 fatty acids are found principally in fish and seafood although some can be derived from green vegetables. By contrast, omega-6 fatty acids are found in soft margarine, most vegetable oils and animal fat. Omega-6 is plentiful in most modern Western diets while omega-3 is often relatively lacking. A high dietary ratio of omega-6 to omega-3 has been linked to vulnerability to many physical and mental disorders[1]. Most studies recommend omega-3 essential fatty acids with a ratio of eicosapentaenoic acid (EPA) to docosahexaenoic acid (DHA) of 7:1. PUFA DHA 22:6(n - 3), a dietary essential, is important for maintaining normal nervous system function and cellular structure. A lack of DHA is associated with cognitive decline during ageing and neurodegenerative disease[16]. DHA-derived neuroprotectin D1 (NPD1) has recently been shown to provide homeostatic regulation of brain cell survival and repair involving neurotrophic, antiapoptotic and anti-inflammatory signalling[16]. Research suggests that growth factors and neurotrophins activate the synthesis of NPD1, which interacts with the molecular-genetic mechanisms affecting beta-amyloid precursor protein (betaAPP) and amyloid beta (Abeta) peptide neurobiology. Deficits in DHA or its peroxidation may play a role in inflammatory signalling, apoptosis and neuronal dysfunction in Alzheimer's disease[17,18].

In a well-designed trial of the effect of EPA and DHA on mental well-being using a double-blind, placebo-controlled design in the general older population, the study failed to find drug–placebo difference in improving cognition or well-being[18]. In a meta-analysis, the authors concluded that available data are insufficient to draw strong conclusions about the effects of omega-3 fatty acids on cognitive function in normal ageing or on the incidence or treatment of dementia[19]. However, limited evidence suggests a possible association between omega-3 fatty acids and reduced risk of dementia.

In summary, omega-3 fatty acids may have a role in the treatment of late-life dementia, cognitive impairment and neuropsychiatric disorders. Future studies should clarify the function and the optimal dose of omega-3 fatty acids or EPA in the treatment of cognitive decline and address lingering questions regarding the purity of marketed supplements.

S-ADENOSYL-L-METHIONINE (SAME)

S-adenosyl-L-methionine (SAMe) is one of the CAM products that has been studied under rigorous controlled conditions. SAMe is a methyl donor involved in the synthesis of monoaminergic neurotransmitters derived from the amino acid L-methionine through the one-carbon cycle. SAMe has been investigated for its antidepressant properties in both open[1] and randomized controlled[20] trials. SAMe dosages of 200–1600 mg/day (orally or parenterally) have been shown to be superior to placebo and as effective as tricyclic antidepressants in alleviating depression, although some individuals may require higher doses[20]. At this time, the recommended doses range from SAMe 200 mg bid up to 800 mg bid. Oral dosages of SAMe up to 1600 mg/day appear to be significantly bioavailable and safe. SAMe has been associated with minor adverse effects, e.g. gastrointestinal symptoms and headaches[1], and an occasional induced mania[21].

SAMe plays an essential role in maintaining neuronal health, and may prove to be an effective neuroprotective dietary supplement

in Alzheimer's disease. This disease is accompanied by reduced glutathione S-transferase (GST) activity, diminished SAMe, and increased S-adenosyl homocysteine (SAH), the downstream metabolic product resulting from SAMe-mediated transmethylation reactions. Panza *et al*. confirmed that SAMe can exert a direct effect on GST activity, thereby making SAMe an ideal neuroprotective candidate to slow the progression of Alzheimer's disease[22]. It remains unclear if such supplements can reduce the risk for cognitive decline in very mild Alzheimer's disease and mild cognitive impairment.

CULTURALLY BASED HEALING ARTS

Culturally based healing includes traditional Oriental medicine (such as acupuncture, shiatsu and reiki), Indian systems of health care (such as Ayurveda and yoga) and Native American healing practices (such as the sweat lodge and talking circles). All incorporate the beliefs that (i) wellness is a state of balance between the spiritual, physical and mental/emotional 'selves'; (ii) an imbalance of forces within the body is the cause of illness; and (iii) herbal/natural remedies, combined with sound nutrition, exercise and meditation/prayer will correct this imbalance.

Acupuncture

Acupuncture is the Chinese practice of inserting needles into the body at specific points to manipulate the body's flow of energy in order to balance the endocrine system. This manipulation regulates functions such as heart rate, body temperature and respiration, as well as sleep patterns and emotional changes. Acupuncture has been used in clinics to assist people with substance abuse disorders through detoxification; to relieve stress and anxiety; to treat attention deficit and hyperactivity disorder in children; to reduce symptoms of depression; and to help people with physical ailments. There have been only a few studies of acupuncture for dementia compared to studies of depression or stress. There is accumulating evidence from animal models of dementia that acupuncture can be useful for memory improvement. In a Chinese study, Zhou and Jin performed acupuncture on the scalp in areas corresponding to brain regions involved in Alzheimer's disease[23]. Twenty-six patients with clinically diagnosed Alzheimer's disease underwent functional magnetic resonance imaging (fMRI) while undergoing acupuncture at four acupoints. Activation occurred in both the right main hemisphere and the left hemisphere in locations consistent with brain regions frequently impaired in Alzheimer's disease. These areas are closely correlated with cognitive function (memory, reason, language, executive etc.), providing evidence that acupuncture has a potential effect on Alzheimer's disease[23].

Despite promising results, there is insufficient evidence to determine the efficacy of acupuncture compared to medication, wait list control or sham acupuncture in the management of depression. Scientific study design is generally poor and the number of people studied is relatively small. One of the barriers to conducting appropriate studies of acupuncture is the difference between diagnostic systems in Western and Chinese medicine, precluding fair comparison.

In a vascular dementia model using rats, the effect of electro-acupuncture was tested on the formation system of free radicals in brain tissues. The researchers used the Morris's water labyrinth for testing learning ability and memory in rats receiving electro-acupuncture and rats assigned to the control group. The mean escape latency in the electro-acupuncture group was much shorter in several cognitive tests compared with the control group. This research suggests that electro-acupuncture can improve learning and memory ability in vascular dementia rat models[24].

Ayurveda

Ayurveda is a natural health care approach that originated in India more than 5000 years ago. It is still widely used in India as a system of primary health care, and is growing in popularity worldwide. Ayur means 'life' or 'longevity' and Veda means 'knowledge or science.' Combined, Ayurveda means 'the science of life' and the practice of Ayurvedic medicine is described as 'knowledge of how to live'[25]. As a form of complementary and alternative medicine, Ayurveda is commonly used as a method to enhance memory, combat ageing and as nerve tonic. It is also used as an anxiolytic, anti-inflammatory and immunopotentive remedy. Ayurveda incorporates an individualized treatment regimen, such as diet, yoga, meditation, herbal preparations or other techniques to facilitate lifestyle changes and to teach people how to release stress and tension. It is often used as a treatment for depression. There are some preliminary encouraging results for its effectiveness in treating various ailments, including chronic disorders associated with the ageing process. Pilot studies of depression, anxiety, sleep disorders, hypertension, diabetes mellitus, Parkinson's disease and Alzheimer's disease yielded positive results[26]. However, no extensive controlled studies of Ayurveda in older adults are available to date.

There is an increasing number of publications on antioxidant, neuroprotective and memory enhancing properties of various herbal Ayurvedic preparations in rat and mice models of Alzheimer's disease[27]. The part of the Ayurvedic system that provides an approach to prevention and treatment of degenerative diseases is known as Rasayana, and plants used for this purpose are classed as rejuvenators. Traditional medicinal plants in various countries, particularly in India, have been used for centuries for various ailments; however, there has been little scientific effort to validate these anecdotal uses mentioned in the literature.

A number of these traditionally used plant extracts and various 'Ayurvedic medicines' have been screened using the National Institute of Mental Health Synthetic Screening Program for scientific validation and the development of new leads of psychotherapeutic compounds[28]. In young and ageing mice models, Anwala churna produced a dose-dependent improvement in memory scores. Furthermore, it reversed the amnesia induced by scopolamine and diazepam. Anwala churna may prove to be a useful remedy for the management of Alzheimer's disease because of its diverse beneficial effects, including its memory improving property, cholesterol lowering property and anticholinesterase activity[26]. *Ocimum sanctum*, a plant widely used in Ayurveda, has been shown to possess anti-inflammatory, antioxidant and cognition-enhancing properties[29]. In rats, the effect of methanolic extract from *Ocimum sanctum* leaves was studied in cerebral reperfusion injury as well as long-term hypoperfusion. Treatment significantly prevented long-term hypoperfusion-induced functional and structural disturbances. The results suggest that *Ocimum sanctum* may be useful in treatment of cerebral reperfusion injury and cerebrovascular insufficiency states[29].

Trasina is a herbal formulation of some Indian medicinal plants classified in Ayurveda as Medhyarasayanas, or drugs reputed to improve memory and intellect[21]. In a rodent model of Alzheimer's disease, subchronic administration of Trasina reversed deficits in

acetylcholine after 14 and 21 days of treatment. Thus the herbal formulation exerts a significant nontropic effect after subchronic treatment that may be due to reversal of perturbed cholinergic function[30].

Research that compares Ayurveda's comprehensive treatment approach, Western allopathic treatment and an integrated approach combining both the Ayurvedic and allopathic treatments would shed light on which treatment system is the most effective for the benefit of the patient.

YOGA AND MEDITATION

Practitioners of yoga, the ancient Indian system of health care, use breathing exercises, posture, stretch and meditation to balance the body's energy centres. Mindful physical exercise is a special kind of physical exercise with an additional element that focuses on one's state of mind. It has recently emerged as a therapeutic intervention for improving the psychosocial well-being of individuals. According to the IDEA Mind–body Fitness Committee (1997–2001), a mindful physical exercise is characterized by 'physical exercise executed with a profound inwardly directed contemplative focus.' A physical exercise is considered mindful if it: (i) has a meditative/contemplative component that is non-competitive and non-judgmental; (ii) has proprioceptive awareness that involves low to moderate level of muscular activity with mental focus on muscular movement; (iii) is breath centering; (iv) focuses on anatomic alignment, such as spine, trunk and pelvis, or proper physical form; and (v) concerns energy centric awareness of individuals' flow of intrinsic energy, vital life force, qi etc. With the above framework, yoga and qigong are two major streams of mindful physical exercise based on the literature. Yoga is used in combination with other treatments for depression, anxiety and stress-related disorders.

The principle of yoga is to achieve integration of mind, body and spirit. There are twenty-two types of yoga and many more modifications. The most popular in the US is Hatha yoga, a branch of yoga that requires a vast repertoire of physical postures during sitting, standing or lying on the floor, along with specific breathing patterns. Other than physical movement, participants are required to maintain a 'homeostasis' of mind and body, which refers to the relaxation of body tension with quieting of thoughts. The qigong exercise is a system of self-practising physical exercise, which includes healing posture, movement, self-massage, breath work and meditation. All forms of qigong are featured on balance, relaxation, breathing and good posture. The movements of qigong are executed at very low energy expenditure levels. A specific breathing pattern also applies to qigong. Similar to yoga, the breathing style of qigong is slow and deep in order to achieve body relaxation, clearing of mind and maintenance of health. Combining all of the above components, mindful physical exercise has been shown to provide an immediate source of relaxation and mental quiescence. Scientific evidence shows that medical conditions such as hypertension, cardiovascular disease, insulin resistance, depression and anxiety disorders respond favorably to mindful physical exercises[31]. Despite a growing body of evidence to show the effects of mindful physical exercises such as qigong, tai chi and yoga on depression, there is a dearth of review that examined mindful physical exercise as to its effects on memory enhancement. A review on complementary and alternative treatments on older adults shows that mind–body interventions were effective in treating depression, anxiety and insomnia in 10 out of 12 studies reviewed[32]. Some studies demonstrated improvement in functioning on a spatial cognitive task while breathing through the left nostril. Performance improved in the cerebral hemisphere contralateral to the patent nostril[33]. An integrated approach of yoga therapy in menopausal women improved cognitive functions such as remote memory, mental balance, attention and concentration, delayed and immediate recall, verbal retention and recognition tests[34].

RELAXATION AND STRESS REDUCTION TECHNIQUES, BIOFEEDBACK

Learning to control muscle tension and 'involuntary' body functioning, such as heart rate and skin temperature, can be a path to mastering one's fears. It is used in combination with, or as an alternative to, medication to treat disorders such as anxiety, panic and phobias. For example, a person can learn to 'retrain' his or her breathing habits in stressful situations to induce relaxation and decrease hyperventilation. Some preliminary research indicates it may offer an additional tool for treating depression.

Although there are no data in geriatric depression, an increasing number of publications describe the use of biofeedback for memory training and cognitive enhancement using neurofeedback. This is an electroencephalographic (EEG) technique for training individuals to alter their brain activity using operant conditioning. Research has shown that neurofeedback helps reduce symptoms of several neurological and psychiatric disorders. Ongoing research is currently investigating its application in the treatment of other disorders and for enhancing non-disordered cognition[35].

Angelakis *et al*. used EEG peak alpha frequency for neurofeedback because it has been shown to correlate positively with cognitive performance and to correlate negatively with age[35]. In a pilot double-blind study of neurofeedback training in older individuals, they observed that peak alpha frequency neurofeedback improved cognitive processing speed and executive function, but had no clear effect on memory. Kotchoubey *et al*. reported the results of two groups of subjects, aged 20–28 and 50–64 years, matched for health status and verbal abilities[36]. They described how subjects learned to control their slow cortical potentials in a feedback paradigm by producing, on command, shifts in these potentials in either the positive or negative direction. Both groups were able to differentiate significantly between the positivity task and the negativity task. Older subjects had only explicit, but not implicit, learning deficits. Elderly subjects showed consistently more negative slow cortical potential shifts, which may indicate their impaired cortical inhibition. This pattern is likely due to brain ageing. The question remains if biofeedback could be helpful in reducing cognitive deficits associated with ageing or dementia[36].

EXERCISE

Human and other animal studies demonstrate that exercise targets many aspects of brain function, providing broad effects on overall brain health. The benefits of exercise have been best defined for learning and memory, protection from neurodegeneration and alleviation of depression, particularly in elderly populations. Exercise increases synaptic plasticity by directly affecting synaptic structure and potentiating synaptic strength, and by strengthening the underlying systems that support plasticity including neurogenesis, metabolism and vascular function. In addition, exercise reduces peripheral risk factors such as diabetes, hypertension and cardiovascular disease, which converge

to cause brain dysfunction and neurodegeneration. Such exercise-induced structural and functional change has been documented in various brain regions but has been best studied in the hippocampus[37].

Randomized and crossover clinical trials demonstrate the efficacy of aerobic or resistance training exercise (2–4 months) as a treatment for depression in both young and older individuals that may have an effect on cognitive function[38]. The benefits are similar to those achieved with anti-depressants[38]. They are also dose dependent, and greater improvements are seen with higher levels of exercise[38,39].

In a study of exercise in early Alzheimer's disease, cardiorespiratory fitness was modestly reduced in subjects with Alzheimer's disease compared to subjects without dementia[40]. The results were associated with whole brain volume and white matter volume reductions after controlling for age. In participants without dementia, there was no relationship between fitness and brain atrophy[40]. Therefore, cardiovascular fitness may moderate brain atrophy related to Alzheimer's disease; however, further studies are needed to resolve inconsistent findings.

A key mechanism involved in the benefits of exercise on the brain is induction of central and peripheral growth factors and growth factor cascades. These growth factors instruct downstream structural and functional change. Inflammation, which can impair growth factor signalling both systemically and in the brain, is a common mechanism relating to the central and peripheral effects of exercise. Thus, through regulation of growth factors and reduction of peripheral and central risk factors, exercise ensures successful brain function[37].

In summary, cognitive ageing is one of the most common reasons for using complementary and alternative therapies in older adults. The amount of rigorous scientific data to support the efficacy of complementary therapies in the treatment of cognitive impairment is extremely limited. The areas with the most evidence for beneficial effects are exercise, herbal therapy (*Gingko biloba*), the use of fish oil, and, to a lesser extent, acupuncture and relaxation therapies (see Table 64.1). There is a need for further research involving randomized controlled trials to investigate the efficacy of complementary and alternative therapies in the treatment of dementia and cognitive impairment in late life. This research may lead to the development

Table 64.1 Complementary and alternative medicine interventions for the treatment of cognitive impairment and dementia[41]

Mode of intervention	*Postulated mechanism of action*	*Dementia, cognition*	*Main adverse effects and drug interactions*
Omega-3 fatty acids (fish oil)	Mood stabilization, memory enhancement, neuroprotection, reduction in amyloid production	Several RCTs are mixed or negative in the effect on cognition	Fishy aftertaste; gastrointestinal distress; increased effect of warfarin and NSAIDs
SAMe	Cofactor in neurotransmitter synthesis, methylation homocysteine to methionine	Animal studies are suggestive of potential use; no human studies available	Mania; gastrointestinal distress; headache interaction with SSRIs
Folate and B12	Cofactor in neurotransmitter synthesis, methylation homocysteine to methionine, precursor to SAMe	RCTs are suggestive of usefulness in prevention of cognitive decline and improved memory performance	Mania induction, interaction with SSRIs
Gingko biloba	Scavenging free radical; lowering oxidative stress; reducing neural damages; increased blood flow to the brain	Mixed and negative results in RCTs of dementia and other cognitive disorders	Increased bleeding time, allergic reactions
Ayurveda	Indian treatment system with the use of herbs, diet and lifestyle to achieve balance in cognition and well-being	Few RCTs; suggestive of positive effect; positive antiamyloid animal studies	Consistent with above side effect of herbals
Acupuncture	Balancing energy flow through the meridians in the body	In a few trials improved memory and other cognitive tests in Alzheimer's disease and vascular dementia	Needle phobia, bleeding
Yoga	Postures, breath, meditation; rebalancing the mind–body connections	A few uncontrolled studies showed improved attention and memory in nondemented adults	None
Biofeedback	Retraining of the autonomic nervous system or alpha brain waves	Alpha peak in brain waves is associated with enhanced cognitive performance	None
Spirituality	Lowers stress and enhances cognition via church attendance and prayer	Enhances cognitive performance in those who attend church	None
Exercise	Improved cardiovascular function, release of endorphins, increased energy, mental stimulation	Modest improvement in cognition in dementia and in ageing	None

SAMe, S-adenosyl-L-methionine; RCT, randomized controlled trial.

of effective treatment and preventive approaches for these serious conditions.

Ethics of Dementia Care

Eran Klein[1] and Jason Karlawish[2]

[1]*The Johns Hopkins Berman Institute of Bioethics, Baltimore, USA*
[2]*University of Pennsylvania Institute on Aging, Philadelphia, USA*

The stages of dementia, from presymptomatic concerns to diagnosis to death, present clinicians, patients and families with numerous ethical challenges. These challenges may stand out as acute problems or crises, while others simply form the background of living with chronic and progressive loss of cognition. Clinicians who aspire to provide the best care possible for their patients and patients' families need to recognize and respond appropriately to the ethical dimension of dementia. This chapter will present the major ethical challenges typical of each stage of dementia care – presymptomatic, symptomatic and end of life – and suggest ways to approach them.

AN OVERALL FRAMEWORK

The approach to the patient with dementia starts with identifying the goals of care. These vary with the stage of the disease. Early in the disease, the goal is to maximize autonomous decision making. The patient's own vision of what constitutes a life well lived should guide decisions. The clinician should help sustain this vision to the extent possible through pharmacotherapy, provision of patient and family education and support, treatment of co-morbid conditions, and an honest assessment of disease progression and what to expect in the future. As the patient's ability for autonomous decision making diminishes, the goals of care shift to those focused on what will maximize the patient's dignity and quality of life. Accurate assessment of quality of life relies on a complex interplay of expressed patient preferences as well as clinician and family observations and interpretations of patient moods and behaviours. To facilitate a commonsense discussion of quality of life, a clinician can ask both the patient and the family *what is a typical day?* The answers to this question will not only indicate the patient's abilities and disabilities but also the nature and character of the patient's social and emotional engagement in the world. The shift in goals of care tracks a shift in the role of the patient within the patient–caregiver–clinician relationship from being a co-participant in the decision making to a non-participant[1].

The patient, family and medical team all bring different perspectives and commitments that need to be taken into account. Sometimes these fit seamlessly together, such as when patients and families express a mutual preference for care that prioritizes comfort over longevity. At other times, disagreements may be evidence of deep differences in values, such as when a patient directs that care at a future stage of dementia be minimal out of a concern for preserving dignity but the family is committed to sustaining life when at all possible. Various methodological tools are available for working through some of these deep disagreements[2–5]. For instance, the appeal to – and balancing or specification of – the principles of respect for autonomy and beneficence is a common starting point for working through such cases[6].

MANAGING UNCERTAINTY

As researchers uncover more about the genetic and biological markers of the common causes of dementia, such as Alzheimer's disease[7], clinicians will have to address the ethical challenges of the presymptomatic stage of dementia. Can genes, biomarkers or imaging[8] – or some combination of these – reliably predict a person's risk of developing dementia? Communicating such prediction models to patients presents clinicians with real challenges. For example, the use of the apolipoprotein E4 allele in predictive testing – which initially indicated a threefold increased chance of developing Alzheimer's disease if heterozygous for the allele but with quite poor specificity[9] – already suggests that significant challenges face both the clinician in interpreting the meaning of predictive tests for patients and patients in applying probabilistic knowledge to future decisions. Similar questions and challenges apply to so-called biomarkers of common causes of neurodegenerative dementia such as tau protein in spinal fluid.

An approach to presympotomatic testing that addresses these issues is as follows. Patients are entitled to good quality predictive testing, if available, given the value that this information may have for some. In accordance with the Genetic Nondiscrimination Act of 2008 (GINA), this information has at least the same legal protections as other medical information[10]. The clinician (and the medical system) are only obligated to provide tests, however, that significantly improve upon current predictive information (e.g. family history, neuropsychiatric testing) and which the patient can understand and reasonably make use of (e.g. not make dramatic changes to future plans based on small differences in probability). The decision to provide a predictive test is an important clinical decision and, like the provision of other tests or treatments, requires clinical judgement. An essential clinical skill in exercise of this judgement is how to assess a patient's understanding and appreciation of such information. Below, we discuss techniques to do this.

DISCLOSING THE DIAGNOSIS

The first ethical issue that many clinicians face with regard to the detection of dementia is when, how and if to deliver a diagnosis of dementia[11]. The question of 'if' is largely settled as a matter of policy. Patients are morally and legally entitled to their diagnosis. Although this approach has been widely endorsed by the Alzheimer's Association[12], the AMA[13] and a consensus statement[14], studies suggest that this policy has not fully filtered down to practice. Surveys of caregivers suggest that some physicians often do not disclose the diagnosis to the patient[15]. Instead, they disclose the diagnosis to the family[16]. And many generalists[17] and dementia specialists[18–20] choose not to disclose a diagnosis of dementia, particularly at a more advanced stage when comprehension is seriously compromised. This practice persists despite evidence that most cognitively intact adults say they would want to know if they were diagnosed with dementia[21] (though the strength of this desire seems to wane with the increasing age at which this diagnosis would be made[22]). This obviously paternalistic practice reflects the complexity of a disease with progressive cognitive decline that impairs a person's ability to adequately understand relevant information. The most compelling reason to disclose even at later stages of disease is that the patient with dementia is owed the chance, however small in some cases, of understanding (or gaining a glimpse of) why the things that are happening are happening and what this portends for the future. To deny the patient this, whether to make things easier for a caregiver or to prevent purported psychological harm to the patient ('therapeutic privilege'), is to deny an opportunity, perhaps the most important and last opportunity, for self-knowledge left to the patient with dementia.

A reasonable approach to guide whether to disclose a diagnosis to a patient is to converse with the patient about his or her awareness of cognitive problems, and, if the patient is aware of these problems, about the patient's desire to know what is their cause[23]. Useful questions to elicit these symptoms include *Are you having problems with your memory?* and *Do your memory problems bother you?* If a patient endorses these symptoms, a follow-up question is *Would you like to know what is the cause of these problems?* In the case of a patient who has awareness of problems with memory and a desire to know the cause of these problems, a clinician has a clear warrant to disclose the diagnosis. Two useful techniques include asking the patient what he or she knows about Alzheimer's disease and clarifying any misunderstandings about the disease (*One of the most common causes of memory problems is Alzheimer's disease. Have you ever heard of that? Tell me what you know about it?*). This needs to be done in a way that balances truth with kindness. For example, after disclosing a diagnosis to a patient, it is sensible to ask how the patient feels about this diagnosis and whether any questions or concerns remain.

ASSESSING DECISIONAL CAPACITY AND MANAGING INCAPACITY

The central issue that is at the heart of many of the ethical concerns during the symptomatic stage of dementia care is the loss of decision-making capacity. Dementia progressively undermines the abilities necessary for competent medical decision making (e.g. understanding, appreciation, reasoning and expression of choice[24]) and consequently undermines the capacity for giving informed consent or refusal for treatment or research. While the development of some clinical instruments has shown some promise for aiding the assessment of capacity[25–27], the determination of whether someone has sufficient capacity is still ultimately a clinical judgement.

When a clinician does judge that a patient has lost the capacity to make a decision, the appointment of a surrogate provides a way to protect and promote the patient's interests. In clinical practice, a surrogate tends to appear naturally as part of that person's other roles as knowledgeable informant and caregiver. Often this person is a spouse, partner, adult child or sibling. A surrogate can be designated preemptively by the patient (via an advance directive) or appointed through established (often state) standards for next of kin. The *raison d'être* of the surrogate is to make decisions on the patient's behalf.

Acceptable standards for how the surrogate makes decisions vary[28]. Traditionally, ethics has posited a hierarchy of standards. The surrogate can try to decide *as the patient would have decided* given what is known of her previous beliefs, values, character and so on (called the *substituted judgement standard*). Absent the ability to fulfil this standard, the surrogate should decide based on what the surrogate believes is in the best interest of the patient (*best interest standard*). Studies suggest that most older adults do not want a surrogate to practice this hierarchy of standards, but instead to exercise a leeway that balances the two standards. In a study of 150 dialysis patients, two thirds preferred that their surrogate exercise at least 'a little leeway' in interpreting their advance directives to withdraw dialysis were they to develop advanced Alzheimer's disease[29]. This has substantial implications for clinicians when they talk with surrogates. Specifically, it suggests a useful approach to guiding surrogates in decision making; consideration should be given both to what preferences, if any, their relative told them, and what they think will maximize their relative's dignity and quality of life. A surrogate decision should be challenged, in court if necessary, if clear evidence suggests that the surrogate is not acting with the patient's interests in mind. In the absence of such, the presumption lies in favour of the surrogate knowing how best to act on the patient's behalf.

Patients with dementia can formulate *instructional* advance directives. These advance directives spell out how a person wishes to be treated when, at some future time, a decision needs to be made but capacity for making that decision is no longer present. These have great intuitive appeal but variable practical usefulness. Where next of kin knows little of the patient or of the patient's end of life wishes, however, these can be helpful. And they can be useful when instruction is categorical (e.g. under no circumstances perform CPR). Where one would want instructional advance directives to be their most useful, however, they often cannot be. To anticipate and fully articulate the myriad variables that a particular decision will involve one year, five years or ten years into the future is unrealistic. If a decision is truly difficult and contested, it will be *because* there is disagreement about whether the particularities of a situation – some variable or variables – make it different than what is spelled out in the advance directive. This does not entail that instructional advance directives are useless, just that they need to be approached in a particular way. In designing them, one should help patients communicate how in general they want the end of life to go. Is more or less aggressive treatment preferable? Should pain relief or longevity be afforded priority? Where they can be categorical (e.g. do not attempt resuscitation; DNAR), they should be, but where they cannot be they should provide examples as guideposts for decision makers (e.g. 'no feeding tube unless likely to need for fewer than two weeks'). The ideal should not be to spell out decision rules in so detailed a manner that exercising judgement is unnecessary; this is impossible. The goal should be to provide decision makers a tool for knowing the spirit in which judgements should be made.

LIVING WITH DEMENTIA: THE CASE OF PARTICIPATING IN RESEARCH

Those with dementia constitute a vulnerable research population, like other vulnerable populations (e.g. children[30], pregnant women[31], the mentally ill[32], the incarcerated[33]). The status of people with dementia as a vulnerable population has afforded needed protection from exploitation, but at some cost. It has exposed persons with dementia to the risks of medications for non-dementia ailments – risks that are largely unknown given the group's exclusion from most drug approval trials. And it has deprived a segment of the population that might be uniquely motivated to participate in research of the opportunity to do so and, in turn, closed off a way of giving expression to deeply held values. Though vigilance continues to be needed in protecting this vulnerable population in research, there is also a growing appreciation of the costs of excluding persons with dementia from research as well[34].

Surrogates face the decision of whether to enrol demented individuals in research. In the case of research procedures that involve the potential for therapeutic benefit to patients, the decision is made analogously to a surrogate treatment decision with a weighing of harms and benefits. In contrast, research procedures that do not involve direct therapeutic benefit present a challenge as exposure to these risks cannot be justified on the basis of benefits to the patient but rather on the value of the knowledge the research may realistically produce. In such a circumstance, a common set of proposals permit surrogate consent only if (i) the research presents minimal risk or some minor increment over minimal risk, (ii) the subject gives assent or lack of dissent, (iii) institutional review board (IRB) approval is obtained, and (iv) the surrogate gives consent on the subject's behalf consistent with the patient's previous preferences[35]. Difficult issues remain as to how to define 'minimal risk', whether assent is necessary or even meaningful, and whether surrogates accurately reflect subjects' views on acceptable risk[36], but the current protections allow those with dementia to participate in limited forms of research while still acknowledging their status as a vulnerable population.

LIVING WITH DEMENTIA: THE CASE OF DRIVING

For many patients, the restriction of driving privileges marks a turning point in the disease process and often in the patient–clinician relationship as well. For many patients, driving is essential for their involvement in the larger social world. It allows freedom of movement and independence, and is central to a sense of self. When clinicians seek to restrict driving, confrontation can arise. Patients with dementia can lack the insight necessary to recognize their deficits and fail to appreciate that restrictions align their safety with the public's safety. And even when they do recognize some deficits, the value of driving may outweigh for them the added risks to self and others.

In the case of driving, clinicians are not only advocates for their patients, but stewards of the public health. They are obligated to step in and restrict driving even when this threatens individual patient–clinician relationships. Strategies can help minimize this threat. Frank, early discussion of driving and dementia can prepare patients for future restrictions, and timely neuropsychiatric and driving performance testing can help convince patients of unappreciated and evolving deficits. While the Mini-Mental State Examination (MMSE) only roughly predicts driving performance[37], substantial evidence correlates Clinical Disease Rating (CDR) scores with driving performance. A CDR of 0.5 correlates with mildly impaired driving (akin to a 16- to 21-year-old) and a CDR of 1 with significant traffic safety risk[38]. At a CDR of 0.5, patients should be encouraged not to drive or to restrict driving (e.g. shorter distance, time of day), and patients at a CDR of 1 should be advised not to drive. Where required by state law, a report should be made to the appropriate driving authority (with full disclosure to the patient), and where not required by law, one should clearly and without equivocation advise against driving, with mention, if appropriate, of possible financial or legal ramifications from driving against medical advice. Although not always acknowledged as such, driving is a privilege and responsibility, not a civil right.

A useful strategy to address driver safety issues is to ask the patient's family if they would be comfortable with the patient driving the grandchildren or someone else's grandchildren. If the answer is short of a resounding 'yes', then a driver's assessment is warranted.

LIVING WITH DEMENTIA: THE CASE OF VOTING

Voting *is* a civil right that is threatened both by dementia and by how those with dementia are treated. The elderly form a significant and growing proportion of the eligible (and active) voting population in many industrialized countries. Given the incidence of dementia in this population, the disease poses a significant challenge to those interested in protecting and promoting the right to vote. States determine voter qualifications and already restrict voting (e.g. based on criminal convictions)[39] and mandate certain kinds of assistance with voting (e.g. for the blind). Many states have been slow to provide voting assistance for those with dementia. This needs to change as methods of voting shift from traditional in-person polling stations to more private venues (e.g. absentee ballots mailed from private homes or nursing homes, home electronic voting). Studies suggest wide and worrisome variation in the access that people with dementia have to the vote and in systemic opportunities for voter fraud[40]. At minimum, we owe to those with dementia an aggressive effort to extend the ease of voting (e.g. using mobile polling in nursing homes) and to all citizens simple safeguards against voter fraud (e.g. monitoring of absentee voting at large nursing homes).

DECIDING ON THERAPY

The decision to either pursue or to forgo therapy in dementia raises ethical concerns. Where potential therapies for dementia carry mild side effects and promise moderate benefits, such concerns may seem uncomplicated weighing of costs and benefits. However, as therapies are developed that promise significant improvement but at a cost of substantial inconvenience (e.g., intravenous medication infusion) or potentially seriously side effects (e.g. meningoencephalitis in an early beta amyloid vaccine trial[41]), the ethical importance of such decisions becomes more substantial. It is all the more important to clarify issues of capacity and surrogacy, and at an early stage, when potentially large risks and pay-offs are in the balance.

The need to clarify these issues arises as well for decisions about life-prolonging therapy (e.g. surgery, chemotherapy) for co-morbid conditions (e.g. oesophageal cancer). When capacity to make these decisions is lacking, a surrogate has to weigh the costs of potential side effects, including the cost of enduring side effects that the patient does not understand. In the case of incapacity, potentially life-prolonging therapy should be pursued if (i) the patient has previously

clearly expressed a prioritization for longevity over comfort and (ii) the therapy involves only mild to moderate time-limited discomfort in return for a substantially improved quality and quantity of life. Where these conditions are met, a complicated, expensive treatment should be regarded the same as a cheap, routine one (e.g. antibiotics). The aim of treatment in dementia should not be to prolong life for the sake of prolonging life; it should be to prolong life when the quality of that life falls within the range of that which someone could value.

The choice of whether to pursue enteral nutritional support in patients who have lost (or are soon to lose) the ability to swallow oral nutrition and hydration is one of the most difficult therapy decisions that surrogates face. Eating has deep symbolic and cultural meaning. The presumption has been that enteral nutritional support extends life, reduces respiratory infections by reducing aspiration, wards off other infections (e.g. skin ulcers) by improving nutritional status and provides a comfortable satiety. However, such presumptions, held by both physicians[42] and surrogates[43], are not borne out by evidence[44]. The emerging consensus is that since enteral nutritional support for the severely demented entails harms and provides little or no medical benefit, it can (and often should) be refused if requested by family or surrogates. Instead, the conversation should focus on what is good palliative care and how best to provide it for the patient.

PROMOTING SAFETY AND PRESERVING QUALITY OF LIFE

Personal safety can be an issue both for patients and for caregivers. Patients with impaired memory, insight, judgement and inhibition can wander out of beds, rooms and homes and exhibit other behaviour (e.g. aggression) that endangers themselves or others[45]. Traditionally, the options for ensuring safety have been restraints such as bed rails, medications and locked wards. However, these interventions carry harms[46,47] and may also mask the need to identify the underlying and potentially reversible causes of these behaviours (e.g. boredom, pain or thirst in the case of wandering and agitation). Recently, techniques of surveillance (such as video, electronic) have become increasingly popular. As valuable as these may be to limit concerns of safety, they must be balanced against other important harms (e.g. violations of privacy, infringements of liberty, indignity) that may result from their use.

Securing the physical safety of persons with dementia and those around them is a balance of freedom and control. Just as medical interventions (e.g. chemotherapy) have a cost in terms of suffering, so too do many safety measures. They should be judged in basically the same way. If these measures so distress the patient that it significantly diminishes whatever quality of life they are able to maintain, then one should seriously question their value. The goal in dementia care is not to prolong life by providing safety at all costs. It is to provide whatever safety is possible – balanced in terms of its costs – so that patients can enjoy the maximal quality of life of which they are able.

An appreciation of the ethical challenges in dementia care is important. It allows the clinician the opportunity for a more thoughtful and systematic approach to questions that are often the most vexing and meaningful for patients and families. There may be few easy answers in these areas but there are ways to approach problems that yield better results than others. Clinicians have an obligation to provide dementia patients with the best care possible and this includes attention to the ethical dimension of the care being provided.

INTRODUCTION

In the United States, an estimated 5.3 million people have Alzheimer's disease today[1]; that number is projected to grow to 13.2 million by 2050[2]. In the UK, approximately 700 000 people have some form of dementia, and that number is expected to top 1 million by 2025[3]. Most dementia patients will eventually need some form of care, and informal caregivers (usually family members) provide most of that care. It is estimated that there are about 9 million informal caregivers in the United States[1] and 4 million in England[3]. Family caregiving, although it allows dementia patients to stay in their homes with their loved ones longer and is less financially costly than nursing home care, places an immense strain on the caregivers.

Caregiving is difficult work, and dementia caregiving is particularly stressful[4]. Dementia family caregivers have higher rates of nearly every form of psychiatric and psychological distress, especially depression – several studies that used psychiatric interviews to evaluate caregivers found that rates of major depressive disorder were around 30% – considerably higher than anticipated in the general adult population[5]. Caregivers also report more physical health problems than non-caregivers, and numerous studies have found that compromised immune system function, changes in blood pressure and disrupted HPA axis function are common[6]. Although these indicators of stress are well documented, the development and careful evaluation of theoretically grounded interventions to address these problems and symptoms have been slow. Recent studies have begun to use better methodology and to show significant decreases in caregiver stress and depression. This chapter will describe assessment of caregiver distress, then review evidence-based treatments (EBTs) and other promising approaches emerging in the field today.

CAREGIVER STRESS

Dementia caregiving is stressful for many reasons. Caregivers are watching the inevitable decline of a loved one, often their significant other. They are often elderly themselves and face their own declining health. Family caregivers shoulder the intense burden of daily care activities, ranging from taking over the care recipient's finances to feeding and toileting. The constantly increasing level of care required over the course of a progressive illness like Alzheimer's disease deprives caregivers of time for their own activities and opportunities for social support, and can even compromise their jobs and their ability to meet obligations to other family members. Yet many caregivers also feel there are positive aspects of caregiving that tremendously benefit their lives[7].

The 'stress process' model has guided our understanding of caregiving for almost 20 years[9]. This model describes how caregivers use resources (both internal and external) to respond to the demands of their caregiving situation and other life circumstances (e.g. job, spouse, children). This process takes place within a sociocultural context. Perceived stress is a function of the extent to which demands exceed resources and the requisite coping skills to manage these demands are no longer adequate to the tasks at hand.

One must also take into account such 'individual difference' variables as age, gender, ethnicity, relationship and socioeconomic status, which interact with objective stressors and resources and play important roles in determining which caregivers develop physical and/or emotional problems in response to their situations. For example, spousal caregivers are particularly susceptible to depression and stress[10]. Being female and being married to the care recipient tend to be related to lower levels of both physical health and psychological well-being[11]. A caregiver's age is also significant: younger caregivers and non-spouses are more likely to experience role strain, which is usually magnified by lack of resources and perceived intensity of caregiving-related stressors[11].

Cultural diversity is another important dimension that adds heuristic value to the stress process model. Many studies find that cultural differences affect multiple aspects of caregiving. Racial/ethnic groups vary greatly in how they perceive objective and subjective stressors, the knowledge they have and the use they make of resources, and the kinds of coping skills they prefer to employ to help them manage their situations[11–14].[i] For example, Caucasian/white caregivers are

[i]There is great divergence in empirical findings on cultural differences, and to date there have been only a small number of studies on Asian-American and Hispanic caregivers. In order to give equal balance to each ethnic group and resolve heterogeneous or conflicting results, we rely here on available meta-analyses and reviews rather than individual studies. Note also that the terms 'Asian-American' and 'Hispanic' refer to very heterogeneous groups in terms of language, cultural heritage and socioeconomic status. These terms are used in this chapter because they are current designations used in the US Census; however, for clinical purposes, information about specific sub-groups is needed to work effectively – rather than relying on broad generalizations that may or may not be accurate or apply to the individual caregiver in your office.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

more likely to be married to the care recipient and report higher levels of caregiver stress, burden and depression than African-American caregivers[14]. They tend to use more formal support, such as attending support groups and receiving help from professionals, than non-white caregivers. However, Caucasian/white caregivers also tend to report lower levels of confidence and mastery and less positive appraisal of caregiving compared to ethnic minority caregivers[11,13,14].

African-American caregivers often report more role strain, such as more cognitive and physical impairment of the care recipient and a higher number of caregiving tasks, than white caregivers[11]. Their use of religious coping and their sharing of caregiving responsibilities with extended family and non-family members seem to buffer the impact of objective stressors. They express lower subjective burden, higher levels of mastery and greater satisfaction, and fewer depressive symptoms than white or Asian caregivers[12,13].

Asian-American and Hispanic/Latino caregivers may have language limitations, strong beliefs in filial obligation and low levels of both acculturation and health literacy. Combined, these factors make caregiving more stressful. Such caregivers are often reluctant to admit their distress openly, relying instead on more indirect means of expression. For example, Chinese-American caregivers tend to present with a high level of somatic complaints; Mexican-American caregivers often present with depression and guilt[13]. Those who have limited knowledge of English for both reading and writing also have less accurate information about dementia and less access to the health-care system in general and use fewer formal support services than do their Caucasian/white counterparts[11].

While cultural beliefs and practices, such as strong family ties and religiosity, can buffer and protect caregivers from negative health outcomes of caregiving, other cultural premises such as filial obligation, the priority of family needs over individual needs, and face saving carry special hazards. Many ethnic minority caregivers regard it as shameful or a 'loss of face' to admit caregiving-related distress. They are likely to under-report care recipients' behavioural and other problems, and to be reluctant to use formal services for elderly family members. Asian-Americans and Hispanics, in particular, may have low levels of acculturation, language barriers, and inadequate health literacy, which may lead to cultural isolation and inability to access services that are currently available in the US health-care system.

ASSESSMENT OF FAMILY CAREGIVERS

Current psychiatric practice emphasizes assessment and treatment of the patient with dementia[15]. We recommend a dyadic focus in which caregivers are also assessed and treated. Dementia family caregivers (across all racial and ethnic groups studied to date) are at risk of poor physical health and increased mortality, depression, anxiety, anger, frustration and feelings of grief and loss. A clinician should first assess a caregiver for serious difficulty in one or more areas; any diagnosable psychiatric disorders should be treated promptly with either pharmacotherapy or psychotherapy.

Existing guidelines suggest a variety of approaches for assessing the psychosocial and psychiatric status of the dementia family caregiver[15]. We suggest reviewing the Family Caregiver Alliance's recommendations on domains to assess[16,17]. An easily downloaded 'kit' of these resources, including actual measures and the 'Caregivers Count Too!' toolkit for practitioners[18], is available free from its website. These provide materials needed to follow up problem areas with detailed assessment and begin directing caregivers towards treatment.

Key Domains to Assess

First: Assess the caregiver's *knowledge of dementia*. A crucial part of understanding the disease process is knowledge of what to expect as a caregiver. Practitioners should assess medical knowledge of the dementing illness and familiarity with problems caregivers commonly face. It is helpful to have brochures on hand to send home with caregivers, and to have a list of specific websites, such as the Family Caregiver Alliance (www.caregiver.org), Alzheimer's Disease Education and Referral Center (ADEAR, sponsored by the National Institute on Aging in the US) (www.nia.nih.gov/Alzheimers/), National Alliance for Caregiving (www.caregiving.org), and the national website of the Alzheimer's Association in the US (www.alz.org). Several of these groups provide free, downloadable materials about dementia, managing caregiver stress and handling common behaviour problems, in multiple languages besides English. Local chapters of many of these organizations also offer free support groups.

Second: Assess *basic safety needs* of both caregiver and care recipient. Driving, for instance, is a common safety concern, and caregivers are often grateful for physicians' insistence that care recipients give up their car keys permanently. Other environmental issues – can the care recipient be safely left alone and for how long? Does he/she smoke? – are also essential points to cover. Hints of abuse by either the caregiver or care recipient are also important targets that must be followed up with referrals to Adult Protective Services or similar agencies whose role is to investigate such claims and seek remedies for the situation.

Third: Assess caregivers' *emotional and physical well-being*. Several measures are available starting with the brief 'Caregiver Self-Assessment Questionnaire'[19] developed by the American Medical Association as a screening tool for caregiver stress. It is free and downloadable from the AMA website.

The new 16-item Risk Appraisal Measure (RAM) was developed specifically for culturally diverse dementia caregivers and designed to provide a clear view of what treatments are indicated for a particular caregiver[20]. Short enough to be administered to the caregiver in the waiting room, it addresses depression, burden, self-care and health, social support and patient problem behaviours. It also assesses safety, focusing on risks associated with both caregiver behaviours (those suggesting an abuse risk) and care recipient behaviours (e.g. continued driving). Caregivers' answers indicate areas for further assessment or treatment. The RAM is available free of charge and can be obtained in English or Spanish from the study authors.

Other common areas to assess are depressive symptoms and extent of perceived burden. Depressive symptoms can be evaluated quickly and reliably using the CES-D scale[21] or the Geriatric Depression Scale[22]. The CES-D measures the frequency of occurrence of common symptoms of depression in the past week. The CES-D is not copyrighted and is available free of charge from numerous online sources.

The Geriatric Depression Scale is widely used in the US and other countries as a screen for depression. It was designed to tap psychological aspects of depression. Its simple 'yes/no' response format makes it easy to use with low-literacy caregivers. It is available free of charge and can be downloaded in many languages from the website: www.stanford.edu/~yesavage/GDS.html.

Perceived burden can be assessed using the Zarit Burden Inventory[23]. Many other scales exist to assess this and other relevant domains, but due to space constraints we cannot describe them all; see citations 15 and 16 for details.

Fourth: Assess the care recipient's *cognitive status* and ability to perform activities of daily living. As dementia progresses and cognitive impairment increases, the care recipient's functional abilities will decline, resulting in increased hours of care and increasingly demanding tasks. Often caregivers of patients in the middle stage of dementia are the most stressed since behavioural problems are most common then. They need to learn flexibility and creative problem solving. They must be willing to accept the level of care the patient requires, and must have the personal, social and socioeconomic resources to provide that care. While advanced skills for dealing with problem behaviours are a common target of effective intervention programmes even for highly skilled caregivers, a caregiver who does not recognize that a patient can no longer be safely left alone, or who is not able to help with the patient's basic needs, is not able to provide adequate care.

Fifth: Assess the caregiver's perception of instrumental and emotional *social support*. Such support can substantially decrease stress and also improve the quality of care the care recipient receives. Often, caregivers are unaware of available community- or hospital-based support services or feel too overwhelmed to research them; however, day and respite care are invaluable adjuncts to treatment for distressed caregivers[24]. Resources to assess include help from family and friends, transportation, legal and other professional services and financial assistance. The Administration on Aging's Eldercare Locator (www.eldercare.gov/eldercare.net/public/home.aspx) directs caregivers to the resources available to them locally. The Alzheimer's Association CareFinder service (www.alz.org/carefinder) is also an excellent guide.

Assessing Diverse Caregivers

Clinicians' cultural competence leads to more or less effective interactions with ethnically diverse patients and caregivers. 'Cultural competence' encompasses both clinicians' attitudes and knowledge about ethnic groups and their specific skills for interacting with them. The Stanford Geriatric Education Center (http://sgec.stanford.edu) provides online training in improving communication with ethnically diverse elderly; the *Diversity Toolbox* (Alzheimer's Association, www.alz.org) is likewise a useful resource. The book *Ethnicity and the Dementias*[25] is also a good source of information about working with ethnically diverse dementia patients and caregivers. A few points apply broadly to many minority groups: (i) health-care providers need to include the family unit. Ethnic elders generally prefer to be cared for by family, who often see caring for elderly parents and relatives as a family responsibility[26]; (ii) assess ethnic minority caregivers' health literacy and cultural and linguistic competency. Low education levels, language barriers and low levels of acculturation are related to lower health literacy, which in turn affects ability to comply with treatment plans and access appropriate services. There are explicit assessment tools to measure health literacy[27] and implicit screening strategies such as asking caregivers to bring all medications and explain them, or handing caregivers a written document upside down to see if they turn it over to read; (iii) practitioners need to enhance the comprehensibility of health messages, use culturally appropriate examples and materials, and use a team approach involving practitioners, family, culturally and linguistically competent counsellors and translators.

BEST PRACTICES FOR HELPING CAREGIVERS WITH STRESS

What are the Evidence-Based Treatments?

The most recent reviews[28,29] of evidence-based psychological treatments (EBTs) note that three modalities show consistent effectiveness: psychoeducational small group programmes focused on teaching caregivers skills for coping with depression, frustration and common behavioural problems; cognitive behavioural psychotherapy (for those in need of more extensive treatment); and multi-component interventions combining several approaches. Other approaches, particularly respite care, show some promising results but have not yet met criteria for EBT. Support groups are important pieces to consider in multimodal approaches but are not empirically supported standalone treatments for caregiver distress. Gallagher-Thompson and Coon[28] found that evidence-based psychoeducational and psychotherapeutic treatments had the most empirical support, and in general produced large effect sizes. They further concluded that interventions combining support with skills building and targeting specific quality-of-life components were the most effective overall.

From our review of this literature, we propose that five key factors delineate the most effective treatments. They are:

1. **Treatment should be drawn from evidence-based practice.** Treating dementia caregivers is particularly difficult because of the intense stress they face in daily life. The most successful interventions for caregivers' distress are drawn from the same pool as those most successful with other patients. Well-supported modalities rooted in cognitive behavioural therapy and stress-management theory work well with caregivers. For example, individual cognitive behaviour therapy is an effective treatment for caregivers with a diagnosable disorder such as major depressive disorder. Psychoeducational programmes work well to teach behavioural management[30], depression management[31], effective communication and relaxation and stress management[32].
2. **Treatment should require active participation.** Some educational interventions consist of giving caregivers printed materials to complement a lecture delivered to the group. Others take a more 'Socratic' pedagogical approach, actively soliciting input from group members and encouraging them to discuss and question the materials. While both approaches might increase knowledge, neither does much to guide caregivers in the implementation of that knowledge – a feature that some researchers[33] suggest is far more important than what precise materials are covered or what pedagogical style a leader takes. 'Active participation' consists of participation in discussion of new skills and actively putting those skills into practice, with regular check-ins to ensure caregivers are using what they have learned. Using role-playing exercises and 'homework' assignments are ways to support this learning.
3. **Treatment should be tailored to meet individual needs.** Effective treatment begins with assessing a caregiver's areas of strength and weakness, setting specific goals and determining which avenues to pursue most vigorously. Imagine a caregiver who complains of depressed mood and low social support, and

has trouble getting her care recipient's physician to address her concerns, but who has no other pressing complaints. Skills training tailored to managing depression, increasing social support and communicating assertively (especially with medical professionals) is recommended. She would benefit less from a one-size-fits-all programme stressing relaxation exercises, for example, or from a programme that covers quality of life as a general domain without any specific targets. Some other specific guidelines suggested by the reviews and analyses include referring depressed caregivers for treatment. For those with sub-clinical distress, refer to a psychoeducational group; for those whose stress is very high, refer to a stress-management programme[28]. Likewise, caregivers with more severe distress tend to require longer periods of treatment[8]. Finally, as Alzheimer's and other dementias are progressive illnesses, caregivers' specific profiles are likely to change over time as their caregiving situations change. Support groups are useful for learning about this process.

4. **Treatment should be tailored to caregivers' individual differences.** These include gender, age, family relationship, education, socioeconomic resources, ethnicity and language issues.
   - Gender: Although female caregivers are generally more distressed and show greater levels of distress initially, male caregivers remain more distressed after treatment[34] and so may require more intensive treatment to achieve the same improvement. More research is needed with male caregivers since intervention studies are few.
   - Age and family relationship: Spousal caregivers are usually older than adult child caregivers. Even when controlling for age, spousal caregivers show higher levels of depression[35] and are less responsive to treatment[28,34]. There are, as yet, no studies showing a solid basis for preferring specific treatments for spousal caregivers as opposed to other caregivers, though preliminary research[8] suggests that couples and family therapies may be of more help for them.
   - Education and socioeconomic status: Numerous studies have found that caregivers who begin treatment with low education and resources improve more quickly and dramatically than their more-educated peers[34,35]. Caregivers who have more knowledge about dementia and more access to support resources, but are still distressed, may not be helped much by extra information. They are therefore more likely to require psychotherapy or extended psychoeducational/skills-building programmes. At the same time, caregivers of lower socioeconomic status are less likely to avail themselves of services in the first place, so for these populations outreach is especially important.
   - Ethnicity and cultural issues: Intervention with dementia caregivers is an active process that consists of conceptualizing individual caregiving contexts, identifying specific demands and vulnerabilities, and designing and implementing interventions for individuals of different cultural backgrounds. For example, REACH II, the largest randomized control trial on caregiver interventions to date and the only one meeting CONSORT standards, suggested different intervention targets for each race/ethnic group[11]. Overall, the interventions produced statistically significant improvement on all short-term outcomes. Among African-American caregivers, however, only spousal caregivers benefited from the treatment. Furthermore, while all intervention groups except African-American non-spousal caregivers had lower depression scores, only white caregivers showed lower rates of clinical depression at six months. Based on these outcomes, REACH researchers have suggested refining treatments further. White caregivers were more likely to experience intrapsychic strain, and to benefit most from interventions that target this (e.g., learning to regulate negative emotions). In contrast, Hispanic caregivers might benefit from psychoeducational interventions that increase knowledge of dementia processes, resources and services, and that train them to respond effectively to memory and behaviour problems. African-Americans tend to experience financial strain, and might benefit from interventions that provide financial support, e.g. respite-type services.

     Finally, because minorities often place particular emphasis on familism and filial duty, family-based interventions may be particularly useful. They have been found to improve family communication and sharing of the caregiving role[8,11,36,37]. Further research is needed to support the usefulness of this approach with ethnically diverse caregivers.
5. **Consider multi-component treatments.** Although there is not a great deal of empirical data on multi-component treatments, it seems reasonable to expect a greater 'yield' from combining two or more approaches when possible. For examples, findings from Mittelman[38] and REACH I[37] suggest that multi-component treatments may be particularly effective at delaying nursing home placement and at reaching otherwise inaccessible groups.

   One of the difficulties with this is that, precisely because they do combine multiple approaches, these interventions are a heterogeneous group and it can be challenging to figure out which component is really having the main effect. For example, a novel delivery system (such as the telephone-computer technology used in Miami during REACH I) counts as a 'component', even though a telephone or computer is not a means of treatment in and of itself. Yet because some caregivers face difficulties in attending appointments, telephone-based treatments may make interventions more accessible to them. New programmes along these lines that need more study include the Savvy Caregiver Program[39], which includes take-home information for use at home, and Powerful Tools for Caregivers, a web-based psychoeducational programme[40]. New web-based programmes are currently in development and may be very useful at replacing at least some individual or small group meetings. Whether they should be viewed as 'supplements' or 'standalone' interventions requires additional research.

OTHER SUPPORT SERVICES FOR CAREGIVERS

Support groups are immensely popular, are usually free, have a long history and are readily available in most communities. However, support groups are not EBTs, as they simply do not have an empirical basis consistently demonstrating effectiveness.

Gallagher-Thompson and Coon[28] noted in their review that no methodologically sound study has shown support groups to be effective unless combined with another active therapy. Some studies have even shown worse outcomes for support-group participants[41]. Pinquart and Sorensön found in their meta-analyses[34,35,42] that support group interventions generally underperformed on all measures of caregiver distress, concluding that they had fewer positive effects for dementia caregivers than they did for other types of caregivers studied. At the same time, support groups are recognized as a valuable adjunct to EBTs. When possible, clinicians should direct caregivers to other treatment options as well as support groups, and should clarify caregivers' expectations about what they may get out of a support

group. Many caregivers subjectively report that support groups are extremely valuable to them for the social support and 'normalization' they provide. Used in combination with EBTs, support groups can be very helpful as dementia progresses.

Many other services are available to caregivers, including pharmacotherapy, case management, respite care, environmental management/modification and technology-based programmes. At least two studies support case management for improving caregivers' quality of life[43,44]. Respite care has been shown to be effective in reducing caregiver burden when used at least twice a week for at least three months. Its cost-effectiveness improves with increased use, suggesting that higher levels of funding for respite care to allow regular, long-term use might be a cost-effective public health policy[45–47]. Respite care can delay nursing home placement[45], especially among minorities. Even in low doses, many find respite care extremely welcome as an occasional relief.

Programmes focused on modifying the home environment and teaching caregivers skills for engaging the care recipient in everyday pleasurable activities have also shown promise[48]. This approach improves safety in the home and encourages positive interaction between caregiver and care recipient. It was especially helpful for elderly, poor, inner-city African-American families who would not otherwise have funds to make environmental modifications (e.g. installing grab bars in the bathroom, removing slippery rugs that could contribute to falls).

New technology-based programmes may be helpful for rural caregivers who are unable to travel to city centres for programmes. Although there are limitations to what these programmes can provide, they may meet the needs of some caregivers who otherwise would not have assistance[49,50]. These and other programmes show promise, and it is likely that additional research will support their efficacy, at least to some extent.

WHERE IS THIS FIELD GOING IN THE NEXT DECADE?

While we are gaining in our knowledge of 'what works' to reduce depression, improve adaptive coping skills and reduce caregiving-related burden, there is still considerable room for improvement. For example, the patchwork of services that can be found in one state or region of the US may not be available in other states, there is little coordination of care, and there are still very few culturally appropriate services and programmes for caregivers (and care recipients) who are mono-lingual or whose primary language is not English. Given the fact that ethnic minority older adults are a rapidly increasing segment of the US population, their needs will only continue to grow. Programmes that meet their needs *and* are evidence-based are sorely lacking at this time.

A particular challenge facing this field is the lack of research to develop 'practice guidelines' for working with caregivers similar to those that now exist in other areas of medicine. There is also a lack of substantial data on how to match effectively the client/patient in your office with existing programmes and providers. The study of what level of care and what kinds of services are needed to adequately treat a given caregiver is just beginning – but it is being pushed forward at a rapid pace because of the expected onslaught of the baby boomers. From a public policy perspective, progress in this area is essential.

A final area for study is how long-term caregiving affects caregivers' physical health. Although we have some information, it is not extensive, due in part to the difficulty securing funding to conduct long-term follow-up studies with caregivers at high risk for development of, say, type II diabetes or coronary artery disease. Since these conditions typically develop over a period of years, long-term follow-up is needed. New programmes that focus on modification of caregiver health habits are underway; it may be the combination of interventions focused on improving both physical *and* mental health that will have the greatest success with this population in the long run.

The Role of Alzheimer Societies in the United States

Ruth O'Hara[1,2] and Bevin Powers[1,2]

[1]*Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, USA*
[2]*VA Sierra-Pacific Mental Illness Research Education and Clinical Center, Palo Alto, USA*

Alzheimer's disease (AD) is listed by the Center for Disease Control and Prevention (CDC) as the sixth leading cause of death in the United States. Currently there are 5.3 million people diagnosed with AD[1], and it is estimated that one in eight people aged 65 or older will develop AD[2]. As the baby-boomer generation approaches older age, the need for medical care and caregivers will be immense. Incidence rates are projected to double every 20 years with the aging of the baby boomers, therefore, it is predicted that 7.7 million people will be diagnosed with AD by 2030, and by 2050, AD is estimated to reach between 11 million and 16 million people[1]. The psychological, social and financial costs of this illness are substantial, with approximately $148 billion per year in medical expenses[1].

Alzheimer's disease societies can be traced back to the 1950s with the forming of the National Counsel of Aging whose aim was to improve the lives of aging Americans[3]. From that point forward additional AD societies in the United States were created for multiple reasons, however largely humanitarian. Table 67.1 lists AD societies in the United States. As the prevalence of AD increases, the need for caregivers and services will be astronomical.

Approximately 54% of the US population has been touched in some way by AD, either having a family member diagnsed with AD, or knowing someone who has been diagnosed with AD[1]. In 2009 alone, AD contributed to the death of 660 000 Americans which continues to climb each year. AD produces more deaths compared to AIDS (16 316), prostate cancer (27 350), Parkinson's disease (17 898) and hepatitis C (12 000)[4]. Yet, the disparity of funds allotted to AD research compared to other diseases is striking. In 2007, the National Institute of Health (NIH) awarded AIDS research $2.9 billion, while AD research received $644 million[4]. As the frequency of AD diagnosis continues to climb with the growing aging population, the lack of caregivers, health-care professionals and burden on family and services will generate a national crisis.

Over the decades, AD societies have been developed in many ways to address these issues and gaps in service. These societies are dedicated to implementing and disseminating more effective treatments, assessment and supportive interdisciplinary services. The majority of AD societies particularly focus on the community need for resources, family needs and early detection and diagnosis. Some are more clinical and research oriented exploring prevention, the pathophysiological mechanisms and disease process, and ultimately, a cure. However, all provide levels of hope and support for victims of AD, their families and caregivers.

Alzheimer's disease societies have been shown to result in stress reduction in those diagnosed with AD or a caregiver for an individual with AD[5]. The burden of the disease and the quality of life are of great relevance to those who suffer from an illness or disease, and warrant careful consideration and comprehensive care. A number of AD societies aim to target care planning and other support needs required by the patient and their caregivers. However, it is estimated that those diagnosed with AD and caregivers do not seek support from AD societies for three years after diagnosis, and the support is often sought out only in a time of crisis[1]. Frequently, by the time support is obtained, patients with AD may be at a disadvantage; missing an opportunity to explore research options or other available treatments, advanced care planning, taking advantage of caregiver and family education and training, and establishing support before stress and burden have taxed the family and caregiver.

FEDERAL AGENCIES

As a federal agency of the United States Department of Health and Human Services agency, the Administration on Aging (AoA) has supported the Older Americans Act (OAA) of 1965 mandated programmes[6]. Also, the AoA awards research grants that support the needs of an aging population. Centers for Medicare and Medicaid Services also receive support from the AoA.

The AoA's primary interest is the aging population and caregiving, and it aims to invest in research, aging programmes and policy, including improvement of health care, aging in place, optimal aging and protecting the rights of older people. Some programmes are focused to provide home and community-based services such as home-delivered meals or nutrition services in congregate settings, or transportation, adult day care, legal assistance, health promotion programmes and local ombudsman[6]. In addition, AoA provides funding for a range of support services for family caregivers.

The US National Institutes of Health National Institute on Aging (NIA) is the aging and health scientific based agency of the NIH. By an act of Congress in 1974, the NIA was authorized to lead aged-focused research, training and health information distribution[7]. The NIA is the leading federal agency supporting research on Alzheimer's disease and other neurodegenerative disorders.

Through research, the NIA supports the well-being of older Americans with a primary focus on the aging processes, age-related diseases and distinct needs of the aged. The NIA train, develop and

Table 67.1 Alzheimer's disease societies in the US

Agency	*Funding source*	*Description*
Administration on Aging (AoA)	Federal	Awards research grants, provides home and community-based services including nutrition services, transportation, adult day care, legal assistance, health promotion programmes, ombudsman and support services for family caregivers
National Institute on Aging (NIA)	Federal	Health- and science-based agency focused on research, training and health information distribution
Alzheimer's Disease Cooperative Study (ADCS)	Federal	Primary aim is to conduct clinical trials on cognitive and behavioural treatments and interventions for AD
Alzheimer's Disease Neuroimaging Initiative (ADNI)	Federal	Primary aim is a worldwide clinical trial on MCI and AD, and to establish a database to improve future treatment trials
Alzheimer's Disease Centers (ADC)	Federal	Research focused on the mechanisms of AD, prevention, management and improvement of patient care. Also provides clinical and community programmes and services
National Alzheimer's Coordinating Center (NACC)	Federal	Provides collaborative research data collection, database, analysis, methodological and technical support.
The National Cell Repository for Alzheimer's disease (NCRAD)	Federal	National resource for clinical and genetic research, specifically housing a genetic databank
Alzheimer's Disease Education and Referral Center (ADEAR)	Federal	National archive centre for publications, audiovisual material. Responsible for dissemination for AD treatment and diagnostic information
The Geriatric Research, Education, Clinical Center (GRECC)	Federal	Primarily focused on research, education and clinical advancements for the care programmes and advancements in the quality of life of the aging veteran.
The Stanford Geriatric Education Center (SGEC)	Federal	Through academic and community educational dissemination the SGEC offers ethnogeriatric multidisciplinary education and didactics including health literacy, caregiving for dementia patients and other chronic disease, hospice and spirituality, ethics in geriatric care and emergency preparedness.
The National Association of Area Agencies on Aging (n4a)	Federal	Supports Agencies on Aging (AAA) to address support initiatives to assist older Americans through community-based and home services.
Stanford/VA/NIA Aging Clinical Research Center (ACRC)	Federal	Investigates normal cognitive aging and AD through medical and neuroscience disciplines to improve the lives of patients with memory loss
Memory and Aging Center	Federal/Private	Coordinating site for ADRC, conducts research, provides clinical services, education and outreach
Alzheimer's Disease Research Center (ADRC)	Federal	Focuses on laboratory and clinical studies in dementia and aging, improvements in diagnosis and treatments, and community education
Alzheimer's Caregiver Support Online (Alzonline)	Federal/Private	Provides online support for caregivers through education, information and support networks
Alzheimer's Association (AA)	Non-profit	Funds advance research, provides community support for AD or other dementias
Alzheimer's Foundation of America (AFA)	Non-profit	Several collaborating agencies dedicated to providing AD patients and families educational, social and emotional support
Association for Frontotemporal Dementias (AFTD)	Non-profit	Promotes and funds research and education for frontotemporal dementias
Alzheimer's Research & Prevention Foundation (ARPF)	Non-profit	Through the 4 Pillars of Alzheimer's Prevention programme, the agency provides training and educational opportunities for professionals and communities
Family Caregiver Alliance (FCA)	Non-profit	Supports caregivers with caring for those with AD or other chronic illnesses with local services tailored to each individual
The National Family Caregivers Association (NFCA)	Non-profit	Provides caregiver education, support and empowerment
The Lewy Body Dementia Association (LBDA)	Non-profit	Community support for family and caregivers, and research focused on scientific advances

Table 67.1 (*continued*)

Agency	*Funding source*	*Description*
National Council on Aging (NCOA)	Non-profit	Implements and disseminates programmes into communities to improve lives of older adults. Dedicates effort to raising awareness and lobbying for funding and programmes for the aging population
International Longevity Center	Non-profit	Research, education and policy driven to advance healthy aging, promotes productive engagement and to eliminate ageism
Institute on Aging (IOA)	Non-profit	Improves the quality of live for aging Americans in diverse community settings. Promotes independent living for older and disabled adults
National Alliance for Caregiving	Non-profit	Conducts research, analyses policy and produces programmes devoted to improving the quality of live for care recipients
Dementia Advocacy and Support Network (DASN)	Non-profit	Internet-based support group for individuals with dementia
American Federation for Aging Research (AFAR)	Non-profit	Research aimed at exploring the aging process and age-related diseases

support researchers in the field of aging, and place a funding priority on those research endeavours that will likely help illuminate the mechanisms underlying the pathological features of AD.

In 1991, the Alzheimer's Disease Cooperative Study (ADCS) was established by the National Institute on Aging's (NIA) Neuroscience and Neuropsychology of Aging Program, and the University of California San Diego[8]. Funded by the Federal Alzheimer's Disease Prevention Initiative, the ADCS clinical trials focus on cognitive and behavioural treatments for AD in response to an increased need to development of drugs that might be useful for treating patients with AD. The ADCS employs a multi-site approach to conduct pharmaceuticals clinical trials to test new treatments that may improve cognition, decrease decline and delay the onset or progression of AD. The ADCS offers over 30 research studies nationally which are disseminated though the media and journal publications. A strength of this approach is that the investigators across the different sites comply a core set of identical assessment tools in order to achieve the maximum leverage for ongoing research projects.

The Alzheimer's Disease Neuroimaging Initiative (ADNI) was built upon the resources of the ADCS. ADNI is funded through NIH, National Institute of Bioimaging and Bioengineering, the pharmaceutical industry and several foundations. The ADNI's aim was to produce, conduct and report the results of a worldwide study designed to 'define the rate of progress of mild cognitive impairment (MCI) and Alzheimer's disease, to develop improved methods for clinical trials in this area, and to provide a database which will improve design of treatment trials'[9]. Using a national network of centers engaged in AD research, ADNI employs a common protocol to assess cognition, function, biomarkers and brain structure in the elderly with mild cognitive impairment, and AD across the multiple sites. This allows investigators to have sufficient numbers of subjects enrolled to be able to get a better scientific picture of the pathology, course and symptoms of this disorder.

The NIA funds the Alzheimer's Disease Centers (ADCs) at major medical institutions across the United States[10,11]. Research at ADCs focus on the basic mechanisms of AD, prevention, management of symptoms and improvement in patient care[10,11]. Each ADC has a unique focus within a common goal shared by all centres, to enhance research on AD. ADC programmes offer collaborative clinical, research and community programmes, such as, diagnosis and medical management, information about the disease, services and resources, opportunities to participate in drug trials and clinical research projects. Additionally ADCs offer diagnostic and treatment services and research opportunities in underserved, rural and minority communities.

Created by NIA, the National Alzheimer's Coordinating Center (NACC) was founded in 1999 to promote collaborative research and offer technical support throughout the 29 nationwide NIA-funded ADCs[12]. The NACC encourages ADC collaborative research and data collection, and maintains a primary database of clinical and neuropathological research data collected from each ADC. From the NACC-maintained database, data analysis is conducted to generate descriptive and hypothesis within specific areas, and develop methodological areas of study.

The National Cell Repository for Alzheimer's Disease (NCRAD) was also founded and funded by the NIA in 1989[13]. The Repository serves as a national resource for clinical and genetic research. The Repository's mission is to help identify the genes that lead to the development AD which can lead to more effective treatment and eventually prevention[13]. Programmes offered by the Repository are primarily research based and focused on families with a history of AD. This databank is instrumental in storing genetic data from Alzheimer's patients and their families for future use and current scientific exploration.

The Alzheimer's Disease Education and Referral Center (ADEAR) is the information centre and library on AD and is also operated under the NIA umbrella. It provides access to publications and audiovisual materials that can be retrieved online or through mail. ADEAR was created in 1990 to 'compile, archive, and disseminate information concerning Alzheimer's disease' for health professionals and the community[10,11]. This federally funded agency has the most updated, comprehensive information about the cause, treatment and diagnostic advancements of AD. As a community resource for information, the ADEAR services include free publications, referrals for services and AD specialized centres, literature and educational materials.

Within the Veteran Health Administration (VHA) system are 20 Geriatric Research, Education, and Clinical Centers (GRECC)[14]. In the mid-1970s, the VHA focused awareness on the aging veterans and their care[14]. The GRECCs were designed to advance and integrate research, education and clinical achievement in geriatrics and gerontology into the VHA health-care system. GRECCs have

developed and expanded clinical models such as Geriatric Evaluation and Management (GEM) programmes, Palliative Care Programs for Late-Stage Dementia patients, education and training products[14].

The National Association of Area Agencies on Aging (n4a) supports the 629 Area Agencies on Aging (AAA) and 244 Title VI programmes. AAA was created in 1973 by the Older Americans Act (OAA) to address the needs of aging Americans[15]. The n4a oversees programmes to support initiatives that help older adults age in place through community-based and home services. The n4a advocates in large for services and resources for older adults and persons living with disabilities.

Beyond federal-supported enterprises, there are several state-supported centres dedicated to AD. For example, in 2000, Alzheimer's Caregiver Support Online (Alzonline) was established to support the caregiver community through daily challenges and provide expanded caregiver education, information and support[16]. Alzonline continues to receive funding through the State of Florida Department of Elder Affairs and the University of Florida (UF) Center for Telehealth[16]. Alzonline provides caregivers of Alzheimer's patients support, education and up-to-date information on caregiving.

NON-PROFIT AGENCIES

The Alzheimer's Association (AA) was started in 1980 by Jerome Stone in Chicago, IL, as it merged with the Alzheimer's Disease and Related Disorders Association[1]. Beginning with only seven chapters, the Alzheimer's Association has developed into one of the most prominent non-profit health associations focused on Alzheimer's care, support and research. Appropriately, Alzheimer's Association's vision is a 'world without Alzheimer's disease'[1]. Its purpose is to promote prevention and elimination of AD through advances in research, and to provide and improve care and support for all those affected by AD, or other dementias[1]. The programmes offer vast community outreach, support and education through local chapters, including telephone hotlines, support groups for caregivers and those in the early stages of the disease, personal consultations, referrals to local health-care services and facilities, online services and caregiver workshops.

The Alzheimer's Foundation of America (AFA) is a non-profit organization consisting of a number of agencies across the nation. These collaborating agencies are committed to providing AD patients and their families, educational, social and emotional support. The AFA promotes community awareness about the disease and contributes expertise and grants to health-care professionals and other organizations to enhance services[17]. The AFA was established in 1999 to oversee quality of care and services nationally that are provided to individuals with AD, their caregivers and families. They strive to improve the quality of life and public awareness of AD for those affected by the debilitating disease[17].

The AFA offers educational, social, emotional and practical needs of individuals with AD and related illnesses, and their caregivers and families with 950 member organizations untied under the AFA's umbrella[17]. Some of the AFA's member organizations include Dementia Care Professionals of America, Teens for Alzheimer's Awareness, AFA Quilt to Remember and National Memory Screening Day for early diagnosis[17]. The National Memory Screening Day for early diagnosis and detection of AD and other dementia began in 2003, and is dedicated to early recognition of AD to provide patients and families the opportunity to explore treatment and care-planning options. Frequently early symptoms of AD are mistaken for cognitive decline associated with normal aging. Failure to recognize early symptoms of dementia may lead to possible harmful and unsafe behaviours displayed by the patient as the disease progresses. Moreover, early detection can help lessen the burden on the family and/or caregiver(s) and can provide opportunities for research and other medical interventions to help slow the progression of the disease.

The community services accessible are social work case managers, resource and referral centres, educational conferences and workshops, Early-stage and middle-stage programmes, adult day services, family services, respite and telephone support, and memory assessments.

The Association for Frontotemporal Dementias (AFTD) was created in 2002 by a caregiver who lost her husband to Pick's disease and saw the need to address the requirements of all those with frontotemporal dementias with treatment and cure promotion and education[18]. The AFTD is a national non-profit organization that promotes and funds research and education for the cure of frontotemporal dementias[18]. AFTD provides information, education and support to those afflicted with frontotemporal dementias (FTD), their families and caregivers.

The academic research based Alzheimer's Research & Prevention Foundation (ARPF) was founded as a first of its kind in implementing a prevention programme for memory loss and AD through the 4 Pillars of Alzheimer's Prevention[19]. The 4 Pillars of Alzheimer's Prevention combines training conferences on preventing memory loss and AD for medical professionals, educational opportunities for communities and medical professionals, and conducts research for the possible prevention of AD[19].

PATIENT AND CAREGIVER SUPPORT ORGANIZATIONS

Although all of the organizations previously mentioned provide excellent support and education, several organizations were founded to specifically provide ongoing services and resources for AD patients and their caregivers. Founded in 2000, Dementia Advocacy and Support Network (DASN) has formed an internet-based support network for people with dementia. DASN establishes a forum for autonomy, respect and support for persons with dementia[20]. Through educational services, counselling, advocacy and local service connection, DASNI promotes quality of life for those diagnosed with dementia.

In 1977, the Family Caregiver Alliance (FCA), a non-profit organization, was founded to assist and support caregivers of those with AD and other chronic conditions[21]. The FCA is a national community-based programme funded through corporate and foundation grants, the State of California, Area Agencies on Aging, and program participants and donations, which promotes services for caregivers and families providing care for those with chronic illnesses[21].

The FCA established the National Center on Caregiving (NCC) to develop national programmes and policies for caregivers[21]. The FCA acts as a concierge for services and programmes, helping caregivers locate support services in their communities. It offers a broad array of services from caregiver service and programmes, publications, education and training programmes, direct services, online information and support programmes, research and policy development. The National Family Caregivers Association (NFCA) was founded in 2003 to educate, support and empower caregivers of those who are living with a chronic illness or disability[22]. The community-based NFCA raises awareness about the caregiver's role and helps empower caregivers with education and support to lead full, productive and healthy lives.

The National Alliance for Caregiving was established in 1996 as a non-profit association in collaboration with other national organizations dedicated to caregiving[23]. In union with grassroots organizations, professional associations, service organizations, disease-specific organizations, a government agency and corporations, the National Alliance for Caregiving conducts research, analyses policy, pioneers national programmes and continues public awareness of family caregiving challenges[23]. Moreover, the Alliance remains devoted to improving the quality of life for families and care recipients. The Alliance has implemented the National Caregiver Survey, the Family Care Resource Connection, a National Caregiving Agenda and international conferences on family caregiving.

OTHER ORGANIZATIONS PROVIDING SUPPORT FOR AD

There are several other programmes and centres, that do not specifically focus on AD, but who still consider it under the boarder umbrella of their mandates. In 1950, the National Council on Aging (NCOA), a non-profit organization, was formed to develop, implement and disseminate innovative programmes to improve the lives of older adults[3]. NCOA collaborates with organizations nationally to provide older adults affordable and independent living, employments and activities. Although the NCOA does not have a primary focus on AD, it does consider the impact of AD. This is important as this organization has been instrumental in shaping public policy. The NCOA has had a congressional hand in Medicare, the Age Discrimination in Employment Act (ADEA), and the Older Americans Act (OAA)[3]. Furthermore, the NCOA is dedicated to raising awareness of the challenges older Americans with limited income and resources face.

Other such organizations include the International Longevity Center, a research and educational organization, devoted to the development of science-based policies[24], the Institute on Aging (IOA) a community-based, non-profit organization, which embraces diverse aging communities' need for health, social service, creative arts, spiritual support and education programmes, as well as continuous research. Today the IOA is one of the largest providers for community-based services for the aging population[25].

The American Federation for Aging Research (AFAR), established in the 1980s, has been a leader in a 'revolutionary approach to the science of healthier aging'[26]. AFAR explores aging and the aging processes in understanding age-related diseases. By studying the components of disease that are related to aging and the underlying mechanisms of aging and how they regulate the processes in our bodies, AFAR has contributed to the understanding of aging and mechanisms of age-related disease. AFAR funds 2500 early-career scientists from prominent institutions each year, and together explores the fundamental mechanisms of aging and aging with age-related diseases[26].

Psychiatric Manifestations of Nervous System Infections

Jeffrey T. Guptill and E. Wayne Massey

Duke University School of Medicine, Duke University Medical Center, Durham, USA

This chapter highlights nervous system infections that may masquerade as psychiatric disease or may be coincident in the geriatric patient with psychiatric disorders. This is not meant to be an exhaustive discussion, but rather emphasizes a few conditions that may enter into the differential diagnosis of patients presenting with psychiatric symptoms.

A thorough history and clinical examination are paramount to recognizing the neurological origin for patients presenting with psychiatric symptoms. Rapidly progressive symptoms, alteration in the patient's level of consciousness, seizures, focal weakness or numbness, slurred speech, tremor, vision change or diplopia, difficulty walking or falls, and headache are symptoms that should raise the suspicion for neurological disease and should be investigated further. The reader is encouraged to refer to the provided references for in-depth reviews of each topic.

Subacute and chronic infections are more likely to have manifestations confused with primary psychiatric disease. We have limited our discussion to the neurological manifestations, diagnosis, and treatment of tuberculosis, Lyme disease, syphilis, cryptococcosis, and herpes virus.

MYCOBACTERIUM TUBERCULOSIS

Although relatively uncommon in the United States, the incidence of tuberculosis has been increasing since the mid-1980s related, in part, to the increased prevalence of HIV infection. Other than patients with HIV, tuberculosis infection in the USA is mostly seen in substance abusers, immigrants from underdeveloped countries (35% of new cases in the USA), and the elderly (25%)[1]. In Europe 80% of infected individuals are over the age of 50 and similar figures have been reported in Asia[2]. The incidence in the USA is estimated at 4.4 per 100 000[3], but it is more common in developing nations, particularly Africa and Asia. Approximately one third of the world population, about 2 billion people, is infected with *Mycobacterium tuberculosis*. One in ten will develop active disease[4].

Three important, and occasionally overlapping, presentations occur with central nervous system (CNS) tuberculosis infection. A myeloradiculitis may result in pathologic hyperreflexia, spasticity, paraplegia, sensory level, and/or radicular weakness and numbness with depressed reflexes. Next, tuberculomas of the brain parenchyma are composed of inflammatory cells and granulation tissue and often behave like tumours due to mass effect. Tuberculomas are often multiple but can be single and large. Symptoms and signs are usually related to location and size. If located in a periventricular location, hydrocephalus may develop. Tuberculomas are more likely to be confused with psychiatric disease, particularly with involvement of the frontal lobes or with the gradual development of hydrocephalus[5]. Finally, tuberculous meningitis may present with slowly progressive headache, confusion, lethargy and meningeal signs or as an acute meningoencephalitis. Multiple cranial neuropathies are not infrequent due to basilar leptomeningeal involvement[6]. Hydrocephalus with increased intracranial pressure, develops later in the course and results in progressive lethargy and confusion. Importantly, meningitis may occur in patients with inactive lung nodules, no other evidence of infection, and a negative purified protein derivative (PPD) test[7]. As expected, the patient with HIV co-infection tends to have a more fulminant presentation. Rapid clinical deterioration may also be associated to HIV/AIDS.

Although 75% of geriatric patients present with pulmonary tuberculosis, extrapulmonary presentations increase with age[1]. Atypical presentations of tuberculosis, including meningitis, are well described in the elderly. However, the prevalence is not well known. Geriatric patients may present with non-specific symptoms such as fatigue, cognitive impairment, encephalopathy, and impaired activities of daily living[2]. As a result of co-morbid conditions, tuberculosis is often not initially considered in the elderly, resulting in delayed diagnosis, more advanced disease and lower cure rates with higher mortality.

When the diagnosis of tuberculous meningitis is suspected a lumbar puncture should be performed following computed tomography (CT) scan of the brain evaluating for impending herniation. The cerebrospinal fluid (CSF) profile typically shows an elevated opening pressure, high protein content, lymphocytic pleocytosis and a mildly low glucose. Rarely, acid-fast bacilli are identified. Early in the disease process polymorphonuclear (PMN) cells may be the predominant immune cell type, but if the lumbar puncture is repeated several days later, the typical lymphocytic pleocytosis will usually be observed[5]. Paradoxically, the lymphocytic pleocytosis may shift towards a PMN predominance following initiation of treatment. This shift is felt by some experts as nearly pathognomonic of tuberculous meningitis and has been utilized in developing countries to direct therapy[6]. Methods of identifying the organism include

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

standard culture, rapid culture techniques and polymerase chain reaction (PCR) with DNA amplification. The diagnostic yield of culture is highly dependent on the amount of fluid sent for analysis (10 cc recommended). Growth with standard culture techniques would not be expected before about four weeks and rapid culture techniques may yield results in a week or slightly less. Treatment is often begun without isolating the organism when there is a high clinical suspicion and a compatible CSF profile. Brain CT or magnetic resonance imaging (MRI) may show evidence of hydrocephalus or infarct. Imaging obtained with contrast often shows strong enhancement of the basilar meninges and cranial nerves. Tuberculomas have imaging characteristics suggestive of primary brain tumours such as peripheral enhancement and vasogenic oedema.

Therapy of CNS tuberculosis typically consists of a three- or four-drug regimen, usually rifampin (10 mg/kg/d, maximum 600 mg daily), isoniazid (5 mg/kg/d), ethambutol (15 mg/kg/d), ± pyrazinamide (20–35 mg/kg/d) or ethionamide (15–25 mg/kg/d in divided doses). Streptomycin (10 mg/kg, maximum 750 mg daily) may be considered with isoniazid, rifampin and pyrazinamide in multidrug-resistant strains. Antimicrobial therapy typically lasts 12–18 months, but may extend up to two years and should be tailored to the presence/absence of drug-resistant mycobacterium[5]. Pyridoxine (50 mg daily) is typically added to prevent the neuropathy associated with isoniazid. Corticosteroids may be used to reduce inflammation and are recommended in cases of hydrocephalus, spinal block or impending herniation. Rifampin, streptomycin and ethambutol penetrate the CSF better in the presence of meningeal inflammation, whereas isoniazid and pyrazinamide are unaffected. Mortality may be reduced with dexamethasone treatment, but morbidity appears unaffected[6]. Large tuberculomas exerting significant mass effect or spinal osteomyelitis/granulomas resulting in cord compression may require surgical intervention. In the immunocompetent population mortality is about 10% and is greatest in children and the elderly. In the HIV-infected population mortality is higher, at 20%. Residual neurological deficits are seen in a quarter to one third of patients[5].

BORRELIA BURGDORFERI: LYME DISEASE

In the USA, Lyme disease is contracted from *Ixodes* ticks harbouring the spirochete *Borrelia burgdorferi. Borrelia garinii* and *Borrelia afzelii* account for the overwhelming majority of organisms isolated in Europe in cases of neuroborreliosis. Lyme neuroborreliosis is felt to occur in Asia and has been documented in Russia. Currently, there is no evidence of the disease in South America or Africa[8]. The majority of cases in the USA occur in northeastern, mid-Atlantic and north-central states. The number of cases reported to the Centers for Disease Control (CDC) in Atlanta, Georgia has climbed steadily since it became a reportable disease in 1991[9]. In 1992 approximately 10 000 cases were reported, while 2007 produced more than 27 000 cases with an incidence of 9.1/100 000. In the 10 states reporting the most cases, the incidence was significantly higher at 34.7/100 000[10]. Mandatory reporting does not exist in Europe, so obtaining accurate epidemiological data is more difficult. The eastern central region of Europe probably has the highest incidence of neuroborreliosis[8].

Early manifestations of *Borrelia burgdorferi* infection include an expanding 'bullseye' rash, also known as erythema migrans, as well as headache, fever, myalgia or arthralgia, and fatigue[11]. CDC review of cases from 2003 to 2005 demonstrated that erythema migrans was present historically in about 70% of cases[9], while other sources cite 90% of cases with rash, about 40% of which have central clearing[12]. The rash typically appears within 30 days of *Ixodes* tick exposure. In the European form, rash is much less common. Other early presentations include facial palsy, radiculopathy, meningitis/encephalitis and heart block. European Lyme neuroborreliosis most commonly presents with a painful radiculitis (86%), which is called Bannwarth's syndrome[8]. Onset of symptoms in the USA is typically during the months of June, July or August, and less than 8% of cases occurred from December to March[9]. Rickettsial infections, including Rocky Mountain spotted fever, can also present with acute encephalitis and patients may have cranial neuropathies, focal neurological signs and seizures.

Patients with untreated *Borrelia burgdorferi* infections often develop a subacute to chronic disease with musculoskeletal, cardiovascular or neurological symptoms. Arthritis is typically oligoarticular and most commonly involves the knee joint (60%). Cardiovascular involvement occurs in about 8% of patients and is typically a pericarditis or myocarditis producing conduction abnormalities[5]. Chronic skin manifestations are more common in European Lyme neuroborreliosis and take the form of acrodermatitis chronica atrophicans and lymphocytoma. Neurologic symptoms and signs develop in about 15% of patients and include cranial neuropathy, painful radiculopathy, peripheral neuropathy and meningoencephalitis. The most common cranial nerve affected in Lyme neuroborreliosis is the facial nerve, causing a 'Bell's palsy'. Between 25% and 50% of patients developing meningitis will have multiple radiculopathies or peripheral nerve lesions. The peripheral neuropathy is typically axonal and not severe[8]. Myelitis, cerebellar ataxia, seizures and chorea are rare[5].

Manifestations of chronic infection may overlap with its subacute features and include fatigue, dermatitis, arthritis and neuropsychiatric symptoms such as depression and cognitive dysfunction. Patients with chronic Lyme disease may report poor concentration and attention, irritability and memory complaints. Other considerations in the differential diagnosis typically include fibromyalgia and chronic fatigue syndrome. Importantly, symptoms and signs suggestive of early disseminated disease should have been present at an earlier point[13]. Other reported psychiatric symptoms include mania, delirium, dementia, psychosis, panic attacks, personality change, obsessions/compulsions and catatonia[14,15]. There is no clear evidence that Lyme disease causes the majority of these reported symptoms.

Cerebrospinal fluid examination in patients with Lyme disease typically shows a mild lymphocytic pleocytosis with a mildly elevated protein and normal glucose. In patients with a history of tick exposure, erythema migrans and suggestive symptoms and signs, the enzyme linked immunosorbent assay (ELISA) is a helpful screening test. A positive test with a rise in IgM occurs in about 90% of patients who have acute and chronic serum samples tested[5]. The presence of elevated IgG without IgM suggests a chronic exposure. A positive ELISA test must be confirmed with Western blot due to the possibility of false positive screening tests. In Europe where multiple strains cause neuroborreliosis, an antibody index comparing CSF and serum antibody levels is typically used for diagnosis[8]. CSF culture has a yield of about 5% and is not useful, while CSF PCR is positive in about 30–40% of cases, usually early in the disease. CT and MRI are usually most helpful in ruling out other neurological diseases, but may rarely demonstrate multifocal periventricular white matter lesions in advanced cases[5]. These lesions are not specific for Lyme disease and are seen in several other neurological diseases, including demyelinating disease, migraine and cerebrovascular disease.

Treatment of acute disease is typically with oral doxycycline (100–200 mg bid) or amoxicillin (500 mg tid) for 2–4 weeks. Options for neuroborreliosis include intravenous ceftriaxone (2 g daily) for 2–4 weeks, high-dose penicillin (20 million units daily) for 2–4 weeks or tetracycline (500 mg qid) for 30 days[16]. A recent European trial demonstrated similar efficacy when comparing two weeks of therapy with intravenous ceftriaxone 2 g daily versus oral doxycycline 200 mg daily[17]. Following treatment, patients may report continued fatigue, difficulty concentrating and memory difficulty. This is the so-called 'post-Lyme syndrome.' These patients have often been given extended courses of treatment with oral or intravenous antibiotics in an attempt to clear their 'chronic infection'. Typically, there are alternative explanations for their symptoms, and there is a little data to support prolonged antimicrobial treatment in individuals who have received adequate treatment[8,16,18].

TREPONEMA PALLIDUM: NEUROSYPHILIS

Close to 37 000 cases of syphilis were reported in the continental United States in 2006 and the majority occurred in the southeastern region. Late and latent syphilis accounted for over 17 000 of the total cases[19]. During that same year, it was noted that 64% of cases occurred in men who have sex with men. Cases occur predominantly in young adults, and there has been a steady increase in syphilis cases in patients with HIV. Syphilitic chancres increase the risk of acquiring HIV when exposed to the virus between two and five times[20].

Neurosyphilis may occur at any point after exposure to *Treponema pallidum* and is most commonly an asymptomatic meningitis. The meningitis occurs in about 25% of syphilis cases and may remain asymptomatic for years before becoming symptomatic or regressing. Early nervous system involvement with *Treponema pallidum* typically affects the meninges, blood vessels and cranial nerves. Late CNS infection typically involves the parenchyma of the brain and spinal cord[5]. The classical late presentations of 'tabes dorsalis' and 'general paresis of the insane' (dementia paralytica) have become exceptionally rare following the widespread availability and general use of antibiotics[21,22]. General paresis is a progressive dementia with prominent neuropsychiatric features, including psychosis. Tabes dorsalis affects the dorsal columns of the spinal cord and sensory nerve roots and manifests with sensory ataxia, urinary incontinence, lancinating pain and lower extremity hyporeflexia[23]. Recent reviews and case series emphasize the atypical presentations of neurosyphilis and its preponderance in the HIV-positive population. The remainder of this discussion focuses on 'modern neurosyphilis' in the antibiotic era. The reader is encouraged to refer to Ropper and Brown[5] for further information on paretic and tabetic neurosyphilis.

Meningovascular neurosyphilis may present with stroke symptoms such as hemiparesis, aphasia, sensory disturbance or visual loss. The symptoms are commonly referable to medium and small branch arteries of the anterior and middle cerebral arteries. Confusion, psychosis, delirium and dementia have been increasingly reported. About 50% (82 of 161) of neurosyphilis cases in a recent South African retrospective review had neuropsychiatric presentations defined as psychosis, delirium or dementia. 15% presented with stroke, 12% with ocular symptoms, with myelopathy, 9% with seizure, about 9% with seizure and 5% with cranial neuropathy or other brainstem symptoms. Overlapping presentations occurred predominantly with seizure, neuropsychiatric features and stroke[21]. Other series from Europe and the USA have emphasized neuropsychiatric presentations of neurosyphilis, including psychosis, atypical depression and memory loss[24,25].

Ocular and otologic infections are often included in discussions of neurosyphilis. Ocular syphilis may involve any eye structure and can occur at any time during the course of infection. Overall, however, ocular involvement tends to occur early and uveitis is the most common clinical diagnosis. Though otologic syphilis with sensorineural hearing loss has traditionally been associated with chronic *Treponema* infection, more recent studies have reported early otologic involvement with sensorineural hearing loss and occasionally tinnitus and vertigo. Treatment of ocular and otologic syphilis is the same as neurosyphilis, though the addition of steroids is recommended by many experts for ocular syphilis[22].

CSF examination typically shows a lymphocytic pleocytosis and elevated protein with a normal glucose. An elevated IgG index and oligoclonal bands are often present[23]. According to the CDC, the diagnosis of neurosyphilis is confirmed with a reactive CSF Venereal Disease Research Laboratory (VDRL) test and syphilis of any stage. Probable neurosyphilis is defined as syphilis of any stage, a nonreactive VDRL, symptoms and signs consistent with neurosyphilis and no other known cause, and an elevated CSF protein or WBC count without another explanation[26]. The CSF-VDRL test is very specific but not sensitive and, therefore, may be negative in cases of neurosyphilis. The fluorescent treponemal antibody (FTA-ABS) is a direct treponemal test with very high sensitivity and less specificity. Many experts advocate using the FTA-ABS to essentially exclude the diagnosis of neurosyphilis with a negative test due to its high sensitivity. All patients with syphilis should be tested for HIV[22]. Neuroimaging may be normal or show meningeal, nerve root or cranial nerve enhancement, cerebral atrophy or stroke.

Traditionally, treatment is with aqueous penicillin G (3–4 million units every 4 hours or 24 million units daily) for 10–14 days. Procaine penicillin (2.4 million units IM daily) with probenecid (500 mg orally qid) is an alternative[27]. Patients with penicillin allergy may be desensitized, but ceftriaxone (2 g daily) is more convenient and appears effective. Lumbar puncture should be repeated every six months after treatment until a normal CSF profile is demonstrated. The CDC recommends re-treatment if the WBC count has not normalized six months after adequate treatment or other CSF abnormalities persist after two years. Other experts recommend re-treatment with an increase in CSF WBC count or a four-fold rise in the CSF-VDRL titre[22].

CRYPTOCOCCOSIS

Cryptococcal infection was once rare, but it is now one of the most common fungal infections of the nervous system due to the HIV epidemic and more widespread availability of organ transplantation. Although it is most prevalent in immunocompromised patients with solid organ transplant or HIV/AIDs, it may also occur in immunocompetent individuals[28]. In the HIV-positive population, cryptococcal infection typically occurs with a CD4+ count less than 50, and approximately 10% of AIDS patients will develop cryptococcal CNS infection. Worldwide, 80% of patients infected with *Cryptococcus* are HIV positive, and cryptococcal meningitis may be the presenting illness in patients with undiagnosed HIV infection. The highest incidence of cryptococcal meningitis occurs in Africa and Asia where HIV is most common, and 20–30% of

HIV patients in Africa die from cryptococcal meningitis[29]. In the USA, the incidence is about 4.9/100 000.

Cryptococcosis is usually acquired through the respiratory tract or occasionally through mucus membranes or wounds. Two species cause disease in humans, *Cryptococcus neoformans* and *C. gattii*. The nearly ubiquitous *C. neoformans* is present in soil and is associated with bird nesting sites. *C. gattii* is unique in that it is more geographically limited, typically affects immunocompetent patients, presents more insidiously, and is associated with a delayed response to treatment. *Cryptococcus* can infect any organ, though the central nervous and respiratory systems and skin are common sites of clinical involvement[28].

Cryptococcal CNS infection commonly presents as a chronic granulomatous meningitis or meningoencephalitis developing over days to weeks or months. Headache, encephalopathy, dementia, nausea and vomiting, and cranial neuropathy are common[5]. Importantly, headache may be the only symptom and cryptococcal meningitis should be considered in the adult patient without a prior headache history developing a chronic, unremitting headache[28]. Patients may also have gait difficulty, and case reports have described new-onset psychosis and mania[30,31]. Fever is documented on presentation in less than 50% of immunocompetent patients. In a recent French prospective study French of 230 patients with cryptococcosis, neurological abnormalities were present in 46% of patients diagnosed with meningoencephalitis at the time of initial evaluation, independent of HIV status; 77% of the patients were HIV positive. Mental status changes (33%), seizures (10%) and cranial neuropathy (15%) were the most common abnormalities[32]. Another series of 43 adult patients with neoplastic disease (predominantly leukaemia and lymphoma) reported 90% had altered consciousness on presentation, which varied from mild behavioural change to psychosis or coma[33]. More rarely, cryptococcomas, consisting of small cortical gelatinous cystic nodules or large predominantly subcortical granulomas, may occur and cause focal neurological symptoms. Due to meningovascular infiltration, strokes may rarely occur[5].

Lumbar puncture in cryptococcal CNS infection may show an elevated opening pressure, lymphocytic pleocytosis and elevated protein. The CSF glucose level is low in about 75% of cases. However, the glucose and cell count may be normal in AIDS patients. India ink preparation often shows the thickly encapsulated organism and cultures often become positive, but take days to yield results. Microscopy and culture are labour and time intensive and have a sensitivity of 50–80%. Furthermore, large volumes of CSF may need to be analysed and cultured if the burden of the organism is relatively low. A capsular polysaccharide antigen forms the basis of the widely available latex agglutination test. It is a rapid test and has a sensitivity of 93–100% and a specificity of 93–98%, though false positives are well described in the literature[28]. A titre of $>1:8$ should be considered a positive test. Finally, enzyme immunosorbent assays have been compared to the polysaccharide antigen agglutination test with promising results[34]. This test is not widely available, however. Neuroimaging is usually normal but may show parenchymal lesions, hydrocephalus, meningeal enhancement, dilated Virchow–Robin spaces and cystic lesions (see Figure 68.1). Abnormal brain imaging generally confers a poorer prognosis.

Treatment is with amphotericin B (0.5–0.7 mg/kg/d), typically with flucytosine (150 mg/kg/d) for 2 weeks, followed by fluconazole for at least 10 weeks. In the AIDS patient, maintenance fluconazole therapy is generally continued for life unless the CD4+ count rises above 100–200 cells/μl for 3–6 months at which time the asymptomatic patient with sterile spinal fluid may be discontinued. Historically, a lumbar puncture has been performed after the first two weeks of therapy to confirm therapeutic response, although some authorities now forgo the second lumbar puncture if the patient is clinically responding and has a normal neurological examination. If the initial lumbar puncture showed an elevated opening pressure and the patient has symptoms of increased intracranial pressure, a lumbar puncture should be repeated daily until the patient becomes asymptomatic or the pressure normalizes for a minimum of two days. HIV patients with low CD4+ counts who are started on highly active antiretroviral therapy at the time of diagnosis of a cryptococcal CNS infection are at risk for immune reconstitution inflammatory syndrome (IRIS)[35]. Independent risk factors for treatment failure regardless of HIV status include high serum antigen titres, widespread dissemination at the time of diagnosis, and the absence of flucytosine during the induction phase of treatment. Three-month survival is reduced in patients with an abnormal neurological exam or brain imaging at baseline and haematological malignancy[32,33]. The three-month mortality rate of CNS cryptococcal infection is at least 20%, and 40% of survivors have lasting neurological impairment.

HERPES SIMPLEX ENCEPHALITIS

Herpes simplex virus type 1 (HSV-1) is the most common sporadic viral encephalitis in the USA and accounts for about 10% of all encephalitis cases. Over 2 000 cases occur annually in the USA and the worldwide incidence is estimated at 2–4 cases per million per year[36]. HSV-2, associated with genital infection, also causes neurological disease, which is most commonly aseptic meningitis and occasionally acute encephalitis. The remainder of the discussion will focus on HSV-1 CNS infection due to its prevalence (HSV-1 accounts for 90% of herpes encephalitis cases)[37] and significant morbidity and mortality. Herpes simplex encephalitis (HSE) occurs more commonly in individuals with recurrent HSV infection. It has been hypothesized that propagation of the virus from the trigeminal ganglion, where it lies dormant, along the ophthalmic division of the trigeminal nerve results in its tropism for the orbital frontal lobes, insular cortex and medial temporal lobes[38].

HSE usually presents acutely with fever and seizures, behavioural changes, altered mentation, aphasia or other focal neurological deficits. Olfactory hallucinations may occur. Without treatment the patient usually progresses to obtundation and coma[39]. Although HSE typically has a fulminant course, cases progressing over several weeks to months occur, and merit mention due to the potential diagnosis of psychiatric disease. In a series of 24 adult patients with HSE, 4 (17%) reportedly had atypical presentations, consisting of slowly progressive encephalitis often with a non-focal clinical exam[40]. Patients with several months of memory impairment, confusion, lethargy and progressive headache have been reported in the literature[41]; these patients may or may not have focal signs.

Examination of the CSF shows a lymphocytic pleocytosis with normal glucose and elevated protein. The opening pressure may be elevated. Although HSE causes haemorrhagic pathology in the brain, xanthochromia and red blood cells are only occasionally present on CSF examination. HSV PCR, which is sensitive and specific, should be sent. Imaging classically shows temporal lobe hypointensities on CT (see Figure 68.2) and areas of T2 prolongation on MRI. Abnormalities may extend contiguously to the insular cortex and orbitofrontal lobes, as well as into the rostral midbrain. Enhancement usually occurs following administration of contrast (indicating disruption of the blood–brain barrier)[5]. Electroencephalography may

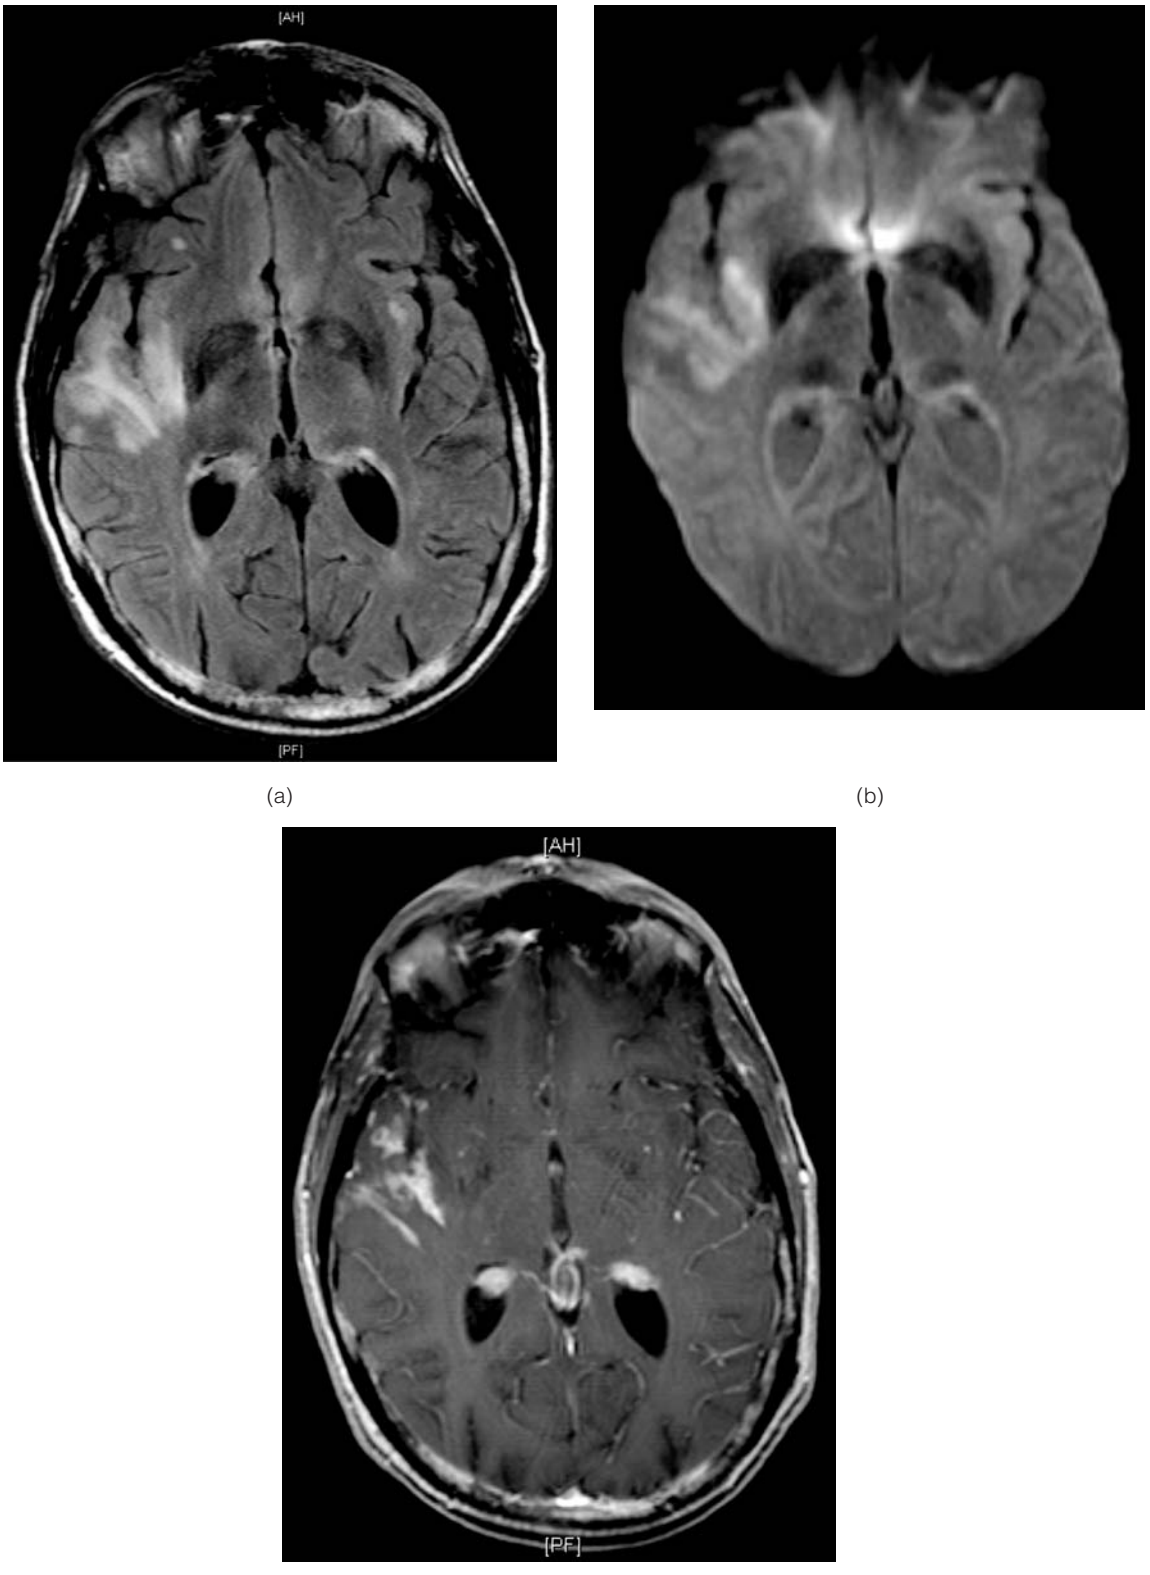

Figure 68.1 A 60-year-old male with hepatic cirrhosis from alcoholism presented with eight months of progressive headache, several months of intermittent left arm numbness and new onset gait difficulty. Neurological exam revealed encephalopathy and gait ataxia. MRI of the brain showed A) prominent T2/FLAIR signal prolongation in the right temporal lobe with B) restricted diffusion. C) Contrast enhancement was present in the right temporal lobe and diffuse leptomeningeal enhancement was also seen. Lumbar puncture showed 83 nucleated cells, glucose <20, 3 red blood cells, protein 584. Opening pressure was normal. Cryptococcal antigen was positive (1:16) in the CSF and serum. HIV testing was negative.

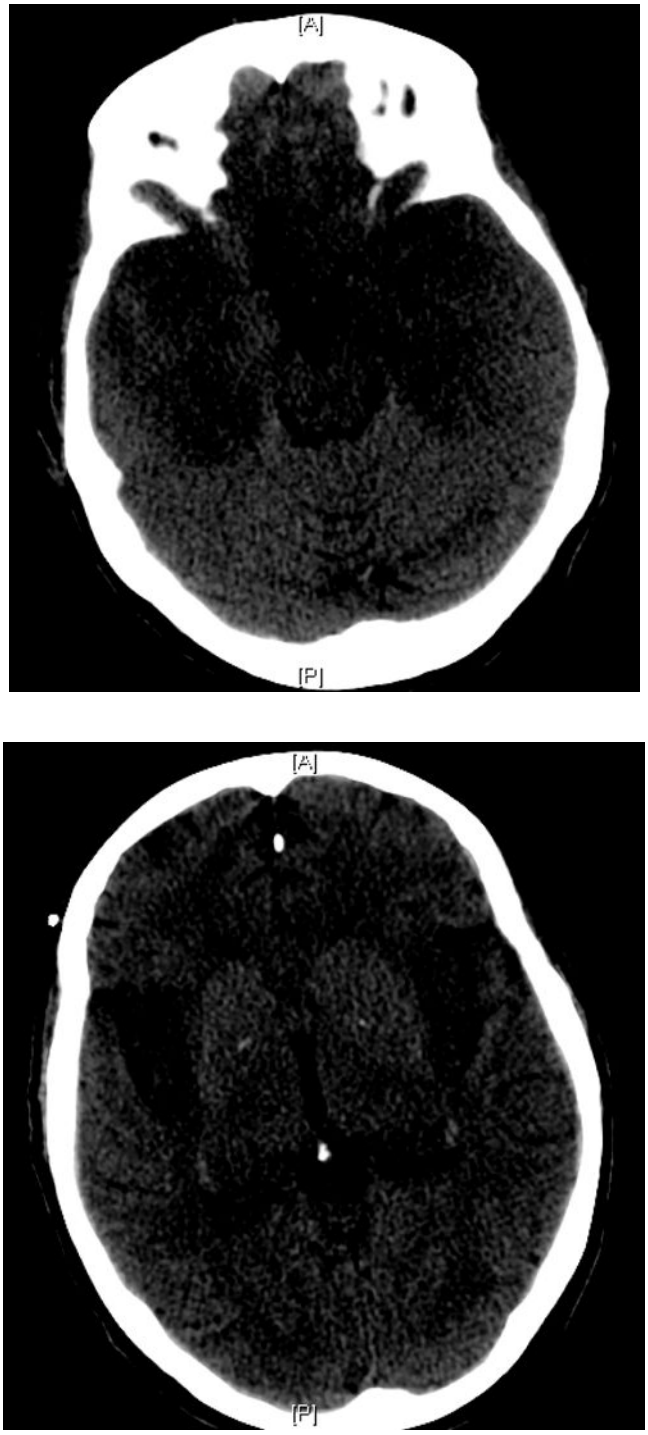

Figure 68.2 A 70-year-old female presented with four days of progressive confusion, lethargy and fatigue. Sodium on presentation was 110, and neurologic exam was non-focal. Non-contrasted head CT on presentation was read as normal. Repeat head CT 10 days after onset of symptoms (shown above) shows bilateral temporal, insular and inferior frontal lobe hypodensities. Lumbar puncture showed 69 nucleated cells (94% lymphocytes), protein 78, and glucose 53. HSV PCR was positive. EEG showed slowing in the theta and delta range with interspersed GPED activity.

show focal temporal slowing or more generalized slowing. These findings often evolve into periodic lateralized epileptiform discharges (PLEDS) at two to three per second intervals or generalized periodic epileptiform discharges (GPEDS)[38].

Treatment with acyclovir (30 mg/kg per day divided three times daily) should be started as soon as possible in suspected cases and should not be delayed for PCR results. Treatment is continued for 10–14 days[5], and some experts emphasize 14 days of treatment to reduce the risk of relapse[39]. Other management includes medical treatment of seizures, supportive ventilation and possibly corticosteroids to control cerebral oedema. There is scant evidence to support worsening of infection with administration of steroids. The mortality from untreated HSE is 60–70%. Treatment reduces mortality to about 20–30% in some series[38]. Practically, the patient's age and level of consciousness at the time of treatment initiation strongly predict outcome[5].

Neuropsychiatric and cognitive sequelae of HSV-1 encephalitis occur in up to 80% of patients[38]. In one series of 34 patients, the most common long-term effects included memory impairment (69%), behavioural and personality change (45%) and epilepsy (24%). Clinical examination following HSE infection revealed short-term memory loss (70%), anosmia (65%) and aphasia (41%)[42]. The memory impairment following HSE is typically anterograde, resulting from damage to medial temporal structures. Other reported sequelae include visuo-spatial, executive function and retrograde memory deficits, as well as aggression, disinhibition, catatonia and Klüver–Bucy syndrome (behavioural and cognitive deficit, placidity, apathy, hypersexuality, hyperorality and visual/auditory agnosia)[38]. Although imaging typically reveals evidence of infection in both hemispheres, residual deficits may be relatively lateralized, and right hemispheric infection tends to produce less severe functional impairments. Hokkanen and Launes[36] recently published a comprehensive review of the neuropsychological sequelae of acute viral encephalitis. Typical and atypical antipsychotics, antidepressants, benzodiazepines, stimulants and anticonvulsants have been used to manage the behavioural and cognitive sequelae. Treatment, however, remains empirical due to a paucity of data[38].

Magnetic Resonance Imaging and Computed Tomography

Howard Aizenstein and Vijay Venkatraman

University of Pittsburgh School of Medicine, Pittsburgh, USA

COMPUTED TOMOGRAPHY

Computed tomography (CT) is a general term for several radiographic techniques that result in a series of images showing slices of an organ or body region, such as the brain. The CT systems measure the attenuation of X-ray beams passing through target tissue; this is done using a small X-ray device that rotates around the body region of interest in a fixed plane. Various absorption and scattering processes are utilized in CT: coherent scattering, photoelectric absorption and Compton scattering. The X-ray tubes provide incident X-rays yielding a spectrum of X-rays with a transmission of the signals. The signals are sent to a computer that produces the corresponding cross-sectional slice for that plane. The image is composed of a set of individual pixels, which represent the attenuation of the X-ray at the corresponding point. These attenuation values are referred to as the CT number or Hounsfield units. The computer can create sections in axial, coronal and sagittal alignments using an image reconstruction process. The three major paradigms of image reconstruction are (i) simple back-projection, (ii) filtered back-projection, and (iii) iterative reconstruction.

In a single CT scan across one section in a patient, thousands of X-ray transmission measurements are obtained along many different angular projections. From these measurements, utilizing a variety of mathematical paradigms, a matrix of CT numbers can be computed for the cross-sectional plane through the patient and then displayed as a grey-scale image. There are a number of artefacts that affect the performance of CT scanning and the quality of the acquired data. These artefacts lead to streak patterns on the image display or appear in the form of CT number inaccuracies. Some of the artefacts are caused during the X-ray transmission phase (e.g. patient motion, polychromatic effects), X-ray detection and measurement (e.g. detector imbalance, scatter collimation), data acquisition (e.g. slice geometry, profile sampling) and data processing (e.g. algorithm effects). CT scans require the use of a limited amount of radiation, which presents a potential health risk for those undergoing CT scans. The estimated radiation exposure varies by the particular type of CT scan performed. It is estimated that a head CT is associated with 1.5 millisieverts, which is equivalent to the radiation exposure from 75 chest X-rays. This amount of radiation exposure is considered an acceptable risk when the CT is medically indicated. CT studies should follow the radiation recommendation, including the special cases for multiple exposures and overlapping scanning techniques.

With advances in scanning, software and display systems, the quality of CT images improved (i.e. better resolution) and has led to many useful clinical applications, including virtual CT colonoscopy or angiography. Neuroimaging with CT is used for studying various psychiatric populations including schizophrenia and depression, as well as aging and dementia.

CT imaging is used to examine brain structure; it allows for the ready identification of many structures, although it does have limitations. By measuring differences in density, it can distinguish among CSF, blood, bone, grey matter and white matter. CT is particularly useful for demonstrating injuries such as skull fractures (bone abnormalities), subdural haematoma (haemorrhage regions) and different lesions (mass effect). CT is also used to study variation in atrophy or ventricular enlargement. However, CT studies are restricted by location of the structures like the brain stem because of surrounding bone. CT has been used to measure cerebral atrophy and grey matter (secondary loss of neurons) since 1974[1]. CT has been widely used in the identification of dementia[2]. Many studies were performed to study age variation in geriatric populations[3–6], normal ageing[7] and the effect of presence of dementia[8,9].

With improvement in resolution of CT, it was used to distinguish some pathological processes, which primarily affect white matter (i.e. demyelination)[10,11]. A large number of CT studies of white-matter diseases in the geriatric population were published[12–16]. CT measurements of the cerebrospinal fluid (CSF) spaces from patients with geriatric depression, normal control subjects and patients with primary degenerative dementia have been compared and studied also[17].

CT is widely available and well understood, but is nowadays supplemented with magnetic resonance imaging (MRI) to use the advantages of both techniques.

MAGNETIC RESONANCE IMAGING

In 2003, Paul C. Lauterbur and Peter Mansfield were awarded the Nobel Prize in Medicine for their discovery of MRI. MRI revolutionized *in vivo* human brain imaging, allowing for remarkably clear high-resolution images of the brain. MRI is based on the concept of nuclear magnetic resonance (NMR), where the measurement of the signals comes from the nuclei in response to radio waves that have the same frequency as the nuclei themselves[18,19]. For a comprehensive review, please refer to[18,19].

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

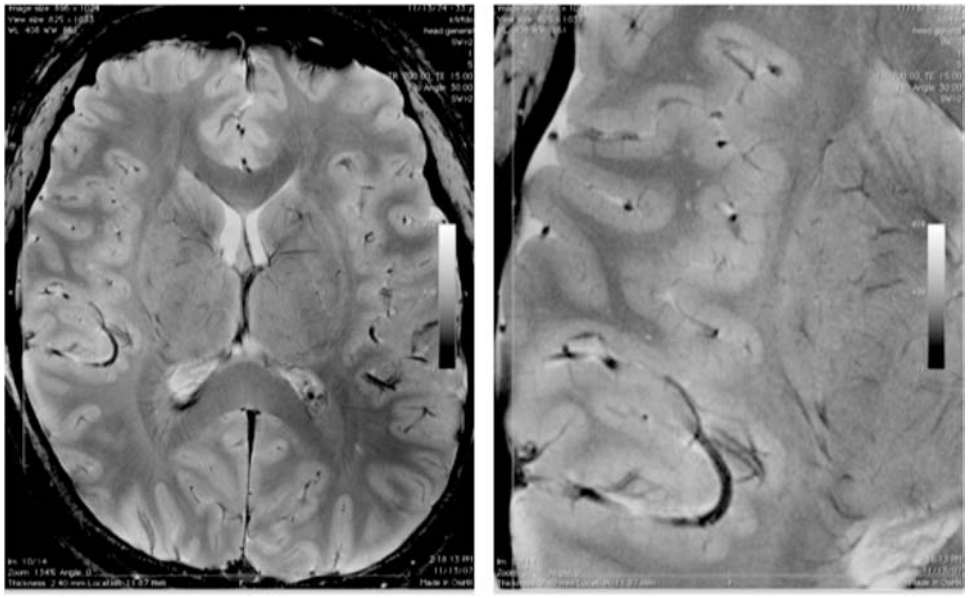

Figure 69.1 SWI image using 7 T Siemens scanner

The relaxation time (T1) is a property of a tissue at a given magnetic field strength. With each excitation pulse, the longitudinal magnetization begins to recover and reduces to steady state after several pulses. The time between repetitions of the excitation pulse is called the repetition time (TR). The repetition time and flip angle are the two major parameters varied to control the T1 weighting of an image. The transverse magnetization decays at the rate of T2 relaxation time. The delay between the creation of the transverse magnetization and the measurement of the resulting echo is called the echo time (TE). The images where signal intensity is largely dependent on T2 differences (or TE values) are called T2-weighted images. The various pulse sequences are designed based on TR, TE and other parameters to obtain the necessary contrast variation in the magnetic resonance image. The magnetic resonance image can have different artefacts, such as motion-induced artefacts, susceptibility, wrap around, edge artefacts (partial volume, chemical shift edge, truncation, relaxation), ghost artefacts, altered signal intensity, stripes and image distortion. The different pulse sequences used in imaging sequences, such as T2*, echo planar imaging used in BOLD fMRI, fluid-attenuated inversion-recovery imaging (FLAIR), diffusion weighted imaging, magnetization transfer imaging and others, are novel variations obtained from optimization of the various parameters.

Difference between 1.5 T, 3 T vs. 7 T Images

Typically the MRI scanner is built around a permanent magnet, which is the most expensive and important component of the scanner[18,19]. The strength of the main magnet and its precision (homogeneity of the field strength) is important. Magnetic field strength is an important factor in determining image quality. Higher magnetic fields increase signal-to-noise ratio, permitting higher resolution or faster scanning. The higher field strengths have drawbacks such as more costly magnets, higher maintenance costs, increased safety concerns and increases in certain artefacts compared to lower field strengths. The 1.0–1.5 T field strengths are a good option for general medical use. Field strengths up to 3.0 T may be desirable for research (such as brain imaging) and the latest research studies use 7 T field strengths. Figure 69.1 provides the susceptibility-weighted imaging (SWI) using a 7 T Siemens imaging scanner.

Structural MRI

Structural MRI methods can be used to identify and quantify patterns of changes in volumetric neuroimaging studies. The various structural MRI sequences enable the identification of structural alterations such as (i) volume in grey matter, white matter and cerebrospinal fluid from high resolution T1-weighted images[20–22], (ii) white matter hyperintensities (WMH) from FLAIR images[23,24], (iii) white matter integrity from diffusion weighted imaging[25,26], and (iv) myelination from magnetization transfer imaging[27] (Figure 69.2). Advanced neuroimaging sequences such as diffusion spectrum imaging (DSI) and Q-ball imaging are currently been used for studying the white matter tracts[28].

Structural MRI is useful for studying the patterns of neuroanatomical changes in geriatric research. Structural MRI is important for studies in normal ageing, late-life depression, dementia, Alzheimer's disease and other cognitive disorders to examine how age-associated changes in neuroanatomy are associated with specific age-related changes, such as the changes in cognition.

Functional MRI

In the 1960s and 1970s a number of investigators showed that not only could MRI be used to visualize neuroanatomy and structural

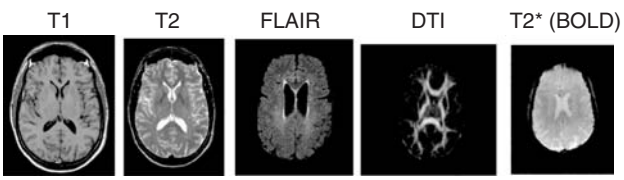

Figure 69.2 T1, T2, FLAIR, DTI and T2* images from 3 T scanner

pathology, but by tuning the MRI contrast appropriately, MRI could be used to visualize the dynamic changes in blood oxygenation across the brain; this was the beginning of functional MRI (fMRI). Over the subsequent years, a number of studies have shown that this blood oxygenation level dependent (BOLD) signal could be used to map brain activity on a variety of cognitive and affective tasks.

Functional MRI has been a major advance for the fields of cognitive and affective neuroscience by allowing investigators to test theories of the underlying neural pathways controlling cognitive and emotional processes. This approach is often referred to as 'human brain mapping'. In addition to studying 'normal' human brain function, fMRI can also be used to characterize the functional activation patterns in patient groups. This area of clinical fMRI research has recently led to a number of new insights into the nature of psychopathology and treatment – including recognition of a dorsal versus ventral processing imbalance in depression[29], overlap in response patterns with placebo as with medication[30], and paradoxical nonlinear activation patterns in mild cognitive impairment[31], suggesting a compensatory stage prior to the onset of dementia.

The functional circuit involved in a particular task can be identified by contrasting the MRI images acquired while someone is doing the task versus when they are doing a control task. There are two main ways this can be done: (i) blocked design, where the subject performs several minutes of task and then several minutes of control, and the images during these blocks are compared; and (ii) event-related design, where the subject performs discrete events during the scanning session, and the images during discrete events are compared. The task could also be a mixed design of block and event designs. Several studies have examined the statistical advantages between block design and event-related fMRI, and the general view is that for the same amount of time spent scanning (on the same task), the observed effect size is larger for a block design study as compared to an event-related study[32].

Perfusion MRI: An Alternative to BOLD

A significant limitation in BOLD fMRI is concern that the BOLD haemodynamic response is inherently relative. That is, the raw BOLD signal does not provide a reliable estimate of regional blood flow in a region. Rather, it is contrast of the BOLD signal on alternating experimental versus control tasks that provides the meaningful signal. In contrast to this limitation, PET imaging with an O15 radioligand is capable of providing quantitative blood flow measures. In MRI, a technique analogous to O15 PET is also available, and is referred to as arterial spin label (ASL) imaging, or perfusion imaging[33,34]. In perfusion MRI the MRI excitation signal is inverted to provide a 'tagged' signal, which is alternated with an 'untagged' image. Comparing the tagged and untagged images provides a quantitative measure of the perfusion of the region. Full-brain voxel-wise perfusion images acquired can provide a quantitative image of the perfusion across the brain. Investigators have recently used perfusion imaging to demonstrate similar findings as with PET blood flow studies, e.g. decreased parietal-temporal resting perfusion with Alzheimer's disease[35]. In addition to providing quantitative resting perfusion, ASL has also recently been used for investigating the blood flow changes associated with tasks. For instance, Fernandez-Seara *et al*.[36] have used ASL to show medial temporal lobe activity on an encoding task. The two primary methods for perfusion imaging are referred to as continuous arterial spin labelling (CASL) and pulsed arterial spin labelling (PASL). CASL is believed to provide better signal quality, but generally requires special hardware for providing the continuous tagging pulse.

Methodological Challenges of fMRI in Geriatric Psychiatry

In order to appropriately interpret fMRI results in geriatric psychiatry, it is important to consider whether differences in brain structure may impact the resulting fMRI signal, and similarly it is important to consider whether changes in brain physiology may influence assumptions about the BOLD fMRI signal. These concerns about brain morphometric changes in the elderly and age-related changes in the BOLD signal are the two primary methodological challenges of fMRI in geriatric psychiatry.

The change in brain volume with age and with the diseases of ageing presents a particular challenge for fMRI studies in these populations: how should these structural changes be accounted for when comparing the functional signal? In a standard fMRI analysis plan, the functional signals from all the subjects in a study are lined up with each other (referred to as normalization). If the brains have significantly different shapes and sizes then this brain alignment may bias the results by contributing more CSF (due to the larger sulci and ventricles) of the more atrophic brains as compared to more grey matter from the less atrophic brains. The standard alignment algorithms vary in their ability to account for the variability in brain structure[37]. Some investigators have addressed this problem by using a larger smoothing kernel in studies of ageing subjects (e.g. 10 mm instead of standard smoothness of 6 mm or 8 mm full-width half-maximum Gaussian). An alternative approach that other investigators have used involves avoiding the registration problems altogether, by focusing on a region-of-interest (ROI)-based analysis[38].

SUMMARY

There has been tremendous increase in the use of CT and MRI (functional and structural) in studying the brain. The neuroimaging studies have provided insight into normal ageing and the neuropsychiatric diseases of ageing. In this chapter we reviewed the basis of CT and MRI (structural and functional).

INTRODUCTION

The last few years have seen a rapid upsurge in the number of functional magnetic resonance imaging (fMRI) studies of Alzheimer's disease (AD). The increasing popularity of fMRI is likely due to the tremendous need to find early markers for this devastating illness, prior to the point of irreversible neuronal loss. The clinical course of AD is typically insidious, characterized by episodic memory impairment beginning years prior to the time a clinical diagnosis is established. Evidence from postmortem and antemortem molecular imaging studies of subjects at risk for AD suggests that underlying pathology of AD may begin more than a decade prior to onset of dementia[1]. The link between the pathophysiological process of AD and the earliest clinical manifestations remains to be fully elucidated. Animal studies indicate that amyloid-related synaptic dysfunction precedes the onset of neuron loss and may account for early memory deficits[2,3]; however, autopsy studies suggest that tangle pathology and neuronal loss may correlate better with clinical dementia severity at later stages of the disease[4,5].

The lack of reliable diagnostic biomarkers, which can detect AD early in its course, continues to limit our ability to effectively develop and initiate disease-modifying therapies. In this respect, fMRI has the potential to elucidate the pathophysiological process that ultimately leads to AD and could prove to be an invaluable tool for early detection of the disease and to assist in monitoring the effectiveness of new therapies.

This chapter will focus on recent findings from fMRI research on ageing and early AD, focusing on potential applications of fMRI for the diagnosis of AD and development of therapeutic agents.

POTENTIAL APPLICATIONS OF FUNCTIONAL IMAGING

Functional imaging techniques, in particular those that study brain activity during cognitive processes, have the potential to detect the earliest impact of pathophysiological changes on the functional integrity of neural networks. Although volumetric magnetic resonance imaging is presumably quite sensitive to loss of neurons and surrounding neuropil, it may not be able to detect changes until there is significant neuronal loss in specific medial temporal lobe (MTL) structures[6], at a point too late to intervene with disease-modifying therapies. Functional imaging techniques that observe the brain at rest, such as fludeoxyglucose (^{18}F) (18-fluorodeoxyglucose; FDG) positron emission tomography (PET), perfusion MRI[7,8] and resting-state fMRI[9,10], have shown evidence of regional abnormalities in early AD and may prove valuable in predicting subsequent decline in at-risk subjects. In order to detect brain dysfunction in individuals with very subtle cognitive impairment, and even asymptomatic individuals with early pathology of AD, we may need to employ more sensitive measures that probe the brain during exactly the types of cognitive processes that will become clinically impaired as the disease progresses. Task-related functional MRI may be able to detect alterations in the brain's functional capacity prior to neuronal loss, or even evidence of dysfunction at rest.

PHYSIOLOGICAL BASIS OF fMRI

The fMRI technique most widely used to investigate neural activity is based on imaging of the blood-oxygen-level-dependent (BOLD) contrast[11]. This depends on the magnetic properties of haemoglobin, which differ depending on whether or not it is bound to oxygen. The ratio between oxygenated haemoglobin, which is a diamagnetic substance with zero magnetic moment, and deoxyhaemoglobin, which instead is a natural paramagnetic substance, in capillary beds and larger blood vessels subserving neural tissue creates an image contrast detected by the MRI machine. Neuronal activity affects the ratio by increasing oxygen consumption and blood supply. Since the blood supply exceeds the oxygen demand, this results in an increase of the amount of deoxyhaemoglobin and therefore of the MR signal[12]. Thus, BOLD fMRI is an indirect measure of neuronal activity but

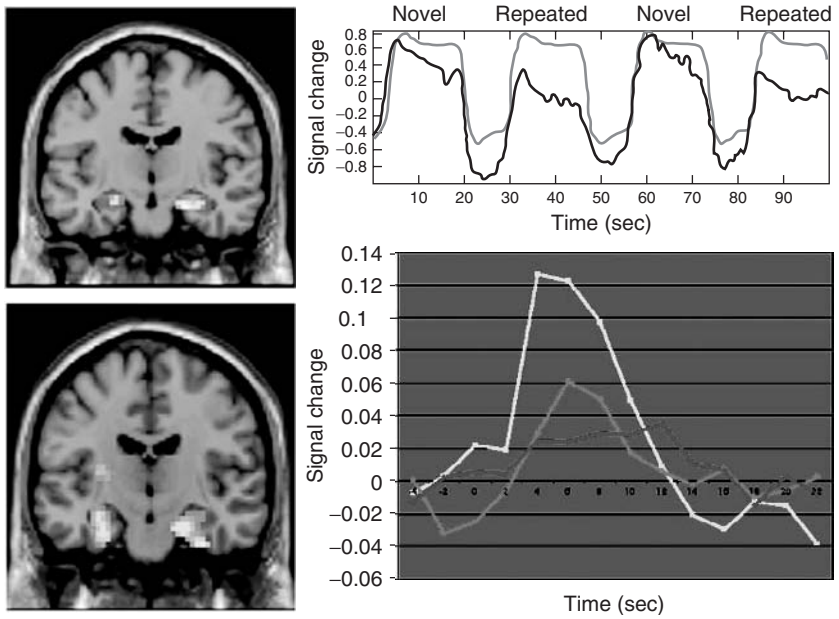

Figure 70.1 Functional MRI data during a face-name encoding paradigm. The top left figure demonstrates a statistical parametric map (SPM) of the hippocampus showing greater MR signal response to novel (N) face-name pairs compared to repeated (R) face-name pairs in a block-design fMRI paradigm. The top right shows a representative time course of the MR signal in the block-design paradigm, with marked increase in signal during novel blocks compared to blocks of visual fixation (+) or repeated blocks. The bottom left demonstrates significant hippocampal activation for an event-related face-name paradigm comparing successful vs. failed encoding. The bottom right graph shows the MR signal change in the right hippocampus for those face-name pairs correctly remembered with high confidence (yellow line), low confidence (pink line) or forgotten (blue line). *A full colour version of this figure appears in the colour plate section*

can provide an important 'window' into the neural underpinnings of complex cognitive processes.

Typically BOLD fMRI is almost always reported as a 'relative measure', comparing the MR signal during one task (e.g. memory encoding) to a control task (e.g. viewing familiar stimulus) or a 'baseline condition' (e.g. visual fixation). Stimuli of each cognitive condition can be either grouped together in blocks lasting 20–40 s, as in a 'block-design' paradigm (see Figure 70.1), or can be interspersed with single stimuli of different conditions as in 'event-related' paradigms. The peak haemodynamic response is typically observed 4–6 s after the stimulus onset. Comparisons between conditions are performed using statistical packages that analyse the raw data of each voxel according to a general linear model (Statistical Parametric Mapping (SPM) and Brain Voyager are some commonly used analysis toolboxes). This type of analysis considers all the variables that can affect signal within each voxel and ultimately translates in either increased BOLD signal, referred to as 'fMRI activation', or decreased BOLD signal, referred to as 'fMRI deactivation' in one condition compared to another. Deactivations or negative BOLD responses have been shown to reflect task-related decreases in neuronal activity below levels detected during spontaneous activity[13], but it remains unclear whether this phenomenon is due to specific inhibitory influences.

At the present there is no way to determine an absolute measure of fMRI signal at 'baseline', and even resting fMRI scans investigate the correlations between regional MR signal over time to measure resting activity. Arterial spin labelling (ASL) perfusion fMRI techniques may provide a more robust baseline measurement of perfusion, but most task-related fMRI studies utilizing ASL techniques still rely on the 'subtraction' of MR signal in one condition versus another. Intrinsic or resting connectivity studies examine the inter-regional correlations in the MR signal time course[14].

In the future, information from multiple imaging modalities, particularly perfusion MR, FDG-PET, and task-related BOLD fMRI, may be useful in determining whether the observed functional changes in patient populations relate primarily to alterations in 'baseline' function vs. the neural requirements of the cognitive task, or perhaps to a combination of both factors.

A few studies have demonstrated fMRI alterations in sensorimotor areas in both cognitively normal older and AD patients[15–17]. These findings have invited caution in the interpretation of fMRI study results in ageing and AD, and raised concerns that changes in BOLD response could be due to a global decoupling of the haemodynamic response related to ageing and pathological processes of the vascular system.

Multiple studies have now demonstrated that the fMRI alterations in subjects with mild and moderate AD reflect regional changes specific to the memory task and that the BOLD response in unaffected brain regions is quite similar in magnitude and extent to that seen in age-matched normal older control subjects[18,19].

NEUROIMAGING IN NORMAL AGEING

In recent years, fMRI studies have provided important insights into the neural underpinnings of the cognitive changes associated with ageing. Neuroimaging studies of non-demented older subjects compared to normal young adults have demonstrated group differences in the activation of brain regions responsible for the cognitive task in study. These findings have led to the formulation of the functional compensation theory and the dedifferentiation

theory to explain the observed changes. The first theory postulates that decreased activation of brain regions in older compared to younger adults may represent less efficient processing. Instead, increased activity reflects compensatory mechanisms recruited to maintain efficient performance. Both PET and fMRI studies of memory performance have found loss of hemispheric asymmetry activation in older adults who have performances similar to those of young adults. Cabeza renamed this phenomenon 'hemispheric asymmetry reduction in older adults' (HAROLD). In one fMRI study of a word recognition task controlled for performance[20], older participants showed increased activation of bilateral regions. In addition to increased bilateral activation to maintain performance, additional evidence points to age-related increased activation of the prefrontal cortex (PFC) associated with successful performance. This mechanism has been called 'posterior–anterior shift in ageing' (PASA)[21] and is thought to compensate for deficient perceptual processing in the sensory areas seen in ageing. According to the dedifferentiation theory, the more widespread engagement of brain areas, not found to be involved in the execution of the same task in younger individuals, represents loss of efficiency of networks activated in younger subjects. To further support this view, some authors propose that various cognitive processes possess a higher degree of interdependence in older individuals[22]. These changes can be thought of as lying on a continuum that moves from lack of differentiation in childhood, to differentiation in adulthood, then to dedifferentiation in older adults.

The adaptive nature of the changes described above is at the core of what Park and Reuter-Lorenz have termed the 'scaffolding theory of ageing and cognition' (STAC). They define scaffolding as 'a process that results in changes of brain function through strengthening of existing connections, formation of new connections, and disuse of connections that have become weak or faulty'. In their view, both HAROLD and PASA can be conceptualized as part of the same compensatory process that reallocates tasks to preserved circuitries unaffected by ageing and possibly pathology to meet the task demands[23].

NEURAL NETWORKS SUPPORTING MEMORY FUNCTION

The use of fMRI can be extended to investigate the brain networks involved in memory formation and how they are affected in AD. In particular, those studies using a 'subsequent memory' paradigm have demonstrated that greater fMRI activity in the MTL, as well as the left inferior prefrontal cortex, during encoding is associated with the likelihood of subsequent successful retrieval of the information[24–28]. This is further supported by the observation that compounds with known amnesic effects, such as benzodiazepines and anticholinergics, induce decreased activation in the hippocampus and prefrontal regions[29,30].

Our own fMRI work has focused primarily on associative memory processes and, in particular, face-name associations. One primary role of the hippocampal formation in episodic encoding is to form new associations between previously unrelated items of information[31,32]. Learning the relationship between a name and a face is a particularly difficult cross-modal, non-contextual, paired associate memory task, and difficulty remembering proper names is the most common memory complaint of older individuals visiting memory clinics[33,34]. Tasks that tap into this cognitive process may be particularly useful in detecting the earliest memory impairment in AD[1,35,36]. Several fMRI studies, including our own in young subjects using a face-name associative encoding task[27,29,37] show that associative memory paradigms produce robust activation of the anterior hippocampal formation[38–40].

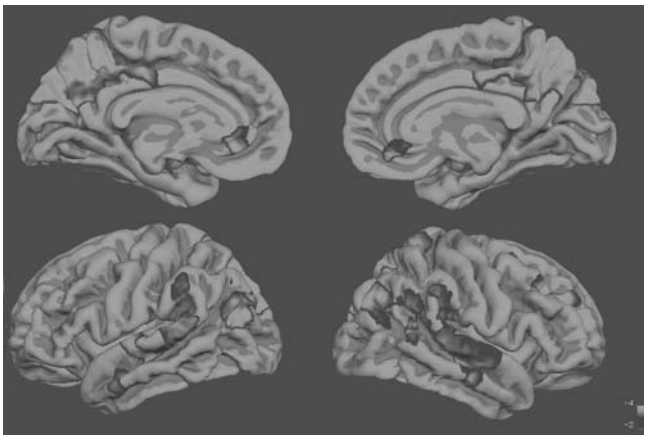

Figure 70.2 The default network, a set of regions that demonstrate higher fMRI activity during rest compared to challenging cognitive tasks. In this group fMRI data map, regions in blue demonstrate greater MR signal during rest (visual fixation) compared to novel face-name encoding. *A full colour version of this figure appears in the colour plate section*

While activation in the anterior hippocampal formation is required for successful memory formation, a similar task-induced decrease in MR signal (i.e. deactivation), particularly in medial and lateral parietal regions, is also associated with successful encoding[41,42]. These lateral and medial parietal regions, including the precuneus and posterior cingulate, are central components of the 'default-mode network' (see Figure 70.2), characterized by Raichle and colleagues in a series of both PET and fMRI studies[43,44]. These regions typically exhibit increased activity at rest and decreased activity during externally focused task performance[44]. These parietal regions also appear to have significant connectivity with the hippocampus in resting-state network analyses[14,45], and overlap with a 'retrospenial memory system' that typically activates during memory retrieval tasks[46,47]. Our own work in cognitively normal young and older adults suggests that the MTL system and the default-network system can be conceptualized as the 'yin–yang' of a distributed memory network. Successful encoding appears to require coordinated activity between these components, such that the lateral and medial parietal regions need to deactivate, while the MTL regions are activated[42,48] (Figure 70.3).

fMRI STUDIES IN PATIENTS WITH CLINICALLY DIAGNOSED ALZHEIMER'S DISEASE

Since episodic memory impairment is an early finding of AD, the majority of fMRI studies to date have focused on episodic memory tasks[18,19,49–57]. These studies have employed a variety of unfamiliar visual stimuli, including faces[17,49], face-name pairs[19,55], scenes[54], line-drawings[50,57], geometric shapes[51] and verbal stimuli[56], and have consistently reported decreased hippocampal and parahippocampal activity in AD patients compared to healthy older controls during the encoding of novel stimuli. In our own studies using the block-design face-name paradigm, we found evidence that AD patients demonstrate significantly less hippocampal activation in the novel vs. repeated comparison than normal older controls[19,53]. Instead,

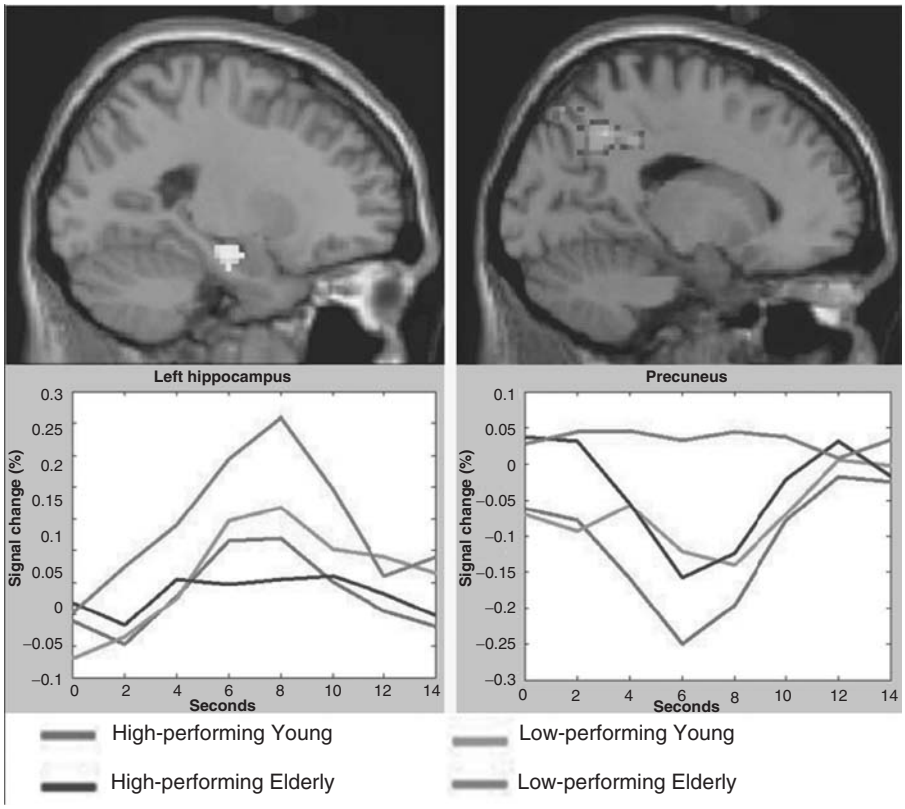

Figure 70.3 Group fMRI data maps (top) with MR signal time courses (bottom) for Young and Elderly controls show hippocampal activation (left) and precuneus deactivation (right) during the successful encoding of face-name pairs. Low-performing Elderly failed to deactivate the precuneus and demonstrated increased hippocampal and prefrontal activation for successful but not failed encoding trials, perhaps as a compensatory response to failure of default network activity. *A full colour version of this figure appears in the colour plate section*

during repeated stimuli exposure, AD patients continue to demonstrate increased MTL activation to stimuli that are highly familiarized to normal older controls[58], and the degree of hyperactivation relates to poor post-scan memory performance. These findings indicate that intact MTL response suppression is an integral part of successful memory encoding and consolidation process and that failure of repetition suppression may be a sensitive marker of hippocampal dysfunction early in the course of AD[59]. Interestingly, in addition to MTL hyperactivation, several fMRI studies have also found evidence of increased activation in frontal and parietal regions in AD patients compared to controls, which, as described before, may represent a compensatory process in the setting of hippocampal failure[19,55,56,60].

Abnormal patterns of fMRI activity have also been found in the default-mode network regions of AD patients[17,47,61,62]. Buckner *et al*.[47] were the first to note that these regions are strikingly similar to those regions that typically demonstrate evidence of fibrillar amyloid deposition binding with Pittsburgh compound B (PiB) in PET studies in AD[63], as well as to the pattern of hypometabolism found on FDG-PET studies of AD patients[64–66] and subjects at-risk for AD[67–69]; and of hypoperfusion on resting MR perfusion studies in AD[7,8]. More recently, we have also noted that the pattern of intrinsic connectivity, or 'hubs' also overlaps the pattern of amyloid deposition[70], supporting the hypothesis that amyloid-beta deposition is dependent on neuronal activity[71].

The alterations in hippocampal activation and parietal deactivation over the course of mild cognitive impairment (MCI) and AD appear to be strongly correlated[72]. Similarly, resting-state fMRI data has demonstrated alterations in parietal and hippocampal connectivity in MCI and AD[9]. Thus, converging evidence suggests that a distributed memory network is disrupted by the pathophysiological process of AD, which includes both medial temporal lobe systems and medial and lateral parietal regions involved in default-mode activity. Future studies to probe alterations in connectivity between these systems, which combine fMRI with other techniques such as diffusion tensor imaging, may prove particularly valuable in elucidating the early functional alterations in AD[73]. Of particular interest is a recent study by Seeley *et al*.[74], combining functional and structural network mapping in patients with AD and other neurodegenerative disorders. This study evidences how each neurodegenerative disorder affects a specific intrinsic connectivity network. The regions showing the greatest atrophy and functional connectivity disruption in AD corresponded to the 'default-mode network' involved in episodic memory, thus further confirming the previous findings of the fMRI studies described above.

fMRI ALTERATIONS IN MEDIAL TEMPORAL LOBE ACTIVITY IN MILD COGNITIVE IMPAIRMENT

We began this chapter by describing the realm of possibilities available through the use of fMRI as a diagnostic tool for early diagnosis of AD and for establishing the effectiveness of disease-modifying treatments. Unfortunately, the use of fMRI to characterize the cognitive changes of mild cognitive impairment is still in its infancy. This is due to several limitations including: (i) the heterogeneity of MCI

as a diagnostic category, and (ii) the lack of standardized criteria until very recently developed and implemented in large-scale clinical trials and imaging studies[75]. Although we conceptualize MCI as a transitional state between normal ageing and mild AD[76], in reality MCI includes a diverse group of subjects, some of whom will never develop clinical AD. Most studies suggest that 15–18% of individuals with MCI convert to clinical AD within one year of follow-up. Interestingly, both autopsy and amyloid imaging studies have not demonstrated evidence of AD pathology in a large proportion of MCI patients, suggesting that the mechanisms for cognitive impairment in those who do not convert to AD may be different[77,78].

It is not surprising, then, that the few fMRI studies in MCI which have been published to date have shown heterogeneous findings, with some studies reporting hyperactivation and others hypoactivation of MTL. In part this apparent discrepancy could be ascribed to the broad definition of MCI, the wide range of cognitive impairment allowed in these studies and the type of cognitive tasks employed. In addition, we hypothesize that the MCI subjects' ability to perform the specific cognitive tasks has contributed to the variability in the published literature.

Studies Showing MTL Hypoactivation

Several studies[18,49,62,79] have reported hypoactivation in the MTL of MCI subjects similar to that seen in AD subjects during novel pictures encoding[18], face-encoding paradigm[49] and forced-choice recognition (retrieval) condition[62]. In addition, the study by Small *et al*. also found a group of impaired subjects with entorhinal and hippocampal activation similar to controls, and decreased activation in the subiculum. In the study by Petrella *et al*.[62], hypoactivation disappeared when memory performance was included as a covariate in the analysis. One of our own studies also found evidence of decreased MTL activation during face-name encoding in subjects who were thought to be at late stages of MCI with significant functional impairment as assessed by a high Clinical Dementia Rating Sum of Box score (CDR-SB)[72,80]. Other examples of hypoactivation findings include two studies by Johnson *et al*.[59,79]. In the first one, using a paradigm involving face repetition, MCI patients failed to show the same slope of decreasing hippocampal activation with stimulus repetition seen in control subjects, suggesting disruption of the habituating response to familiar stimuli in MCI[59]. The second study instead found right hippocampal hypoactivation in MCI patients compared to controls during a recognition paradigm for novel compared to previously learned items[79].

Studies Showing MTL Hyperactivation

In contrast, several studies have reported increased MTL activation in MCI subjects[53,57,81–83]. Using a visual object encoding paradigm, Hämäläinen *et al*. found greater activation in the caudal hippocampal formation, parahippocampal gyrus and fusiform cortex. Based on MMSE (mini-mental state examination) and neuropsychological data, this group had intermediate impairment between AD and mild MCI. Our own group has showed evidence of increased MTL activation in MCI subjects, using an associative face-name encoding paradigm. One study compared subjects across a range of clinical impairment assessed with CDR-SB and controls, using a scene encoding fMRI paradigm[83]. The results indicated a positive correlation between the degree of clinical impairment and the extent of activation in the posterior hippocampus and parahippocampal regions, such that subjects with more impairment had a greater extent of MTL activation. A multivariate analysis showed that increasing impairment (CDR-SB) was related to older age, *decreased* volume of the left hippocampus, and *increased* extent of activation in the right parahippocampal gyrus. Greater MTL activation and larger MTL volume correlated with better performance on the post-scan recognition memory test. Importantly, two years later, those subjects with greater MTL activation were more likely to demonstrate clinical decline. We recently published a longer follow-up study, which further suggested that greater hippocampal activation at baseline predicted faster rate of clinical decline up to four years later[84]. The phenomenon of hippocampal hyperactivation in MCI subjects compared to controls was further confirmed by one of our studies which used the face-name encoding paradigm to compare MTL activation in subjects with very mild MCI (vMCI), AD and controls[53]. Compared with controls, the vMCI subjects showed a greater extent of hippocampal activation, and only minimal atrophy of the hippocampus. These very mild MCI subjects also performed in the same range as controls on post-scan memory test. The AD patients had smaller MTL volumes, decreased activation in these regions, and performed below controls on the post-scan memory test. Post-scan memory task performance of each group correlated with extent of activation in the hippocampus. Another one of our studies confirmed evidence of greater activation in the vMCI subjects compared to controls, particularly in the MTL (Figure 70.4) using the same face-name paradigm. A subset of subjects from the first study was analysed, applying independent component analyses to explore the alterations in larger memory networks in older controls, two groups of MCI subjects, one on the milder end and one on the more impaired end, and a group of mild AD patients[72]. In line with the previous findings, the significantly impaired MCI (sMCI) group showed significantly decreased activation down to levels similar to those found in AD. The MTL hypoactivation paralleled changes in medial and lateral parietal regions of the default network so that performance on the post-scan memory task was directly related to activation in the MTL and deactivation in the default network.

Further confirmation of the validity of the finding of MTL hyperactivation in MCI comes from fMRI studies that have applied an event-related design. This type of design allows the division of stimuli on the basis of successful vs. failed memory processes and can better control for the effects of memory performance. In one study, Kircher *et al*.[82] found that while performing similarly to controls, MCI subjects activated the left hippocampus and surrounding cortical regions to a greater degree than controls. This result was echoed by the evidence from an event-related verbal memory retrieval task, in which Heun *et al*. also found evidence of increased activation in MCI subjects compared to normal older controls when specifically examining successful retrieval trials[85].

How to Reconcile Hyperactivation and Hypoactivation?

Despite variability related to demographic, clinical and neuropsychological data, there is evidence that less-impaired MCI subjects, who perform better on the fMRI memory tasks, show greater MTL activation, whereas subjects who have more cognitive impairment perform worse and display less MTL activation. Thus, these differences may lie on a continuum, with MTL hyperactivation at one end happening early in the course of MCI, representing a compensatory mechanism to counteract the network dysfunction early in its course and to maintain an efficient memory performance. On the other hand, subjects with more severe MCI, whose pathology

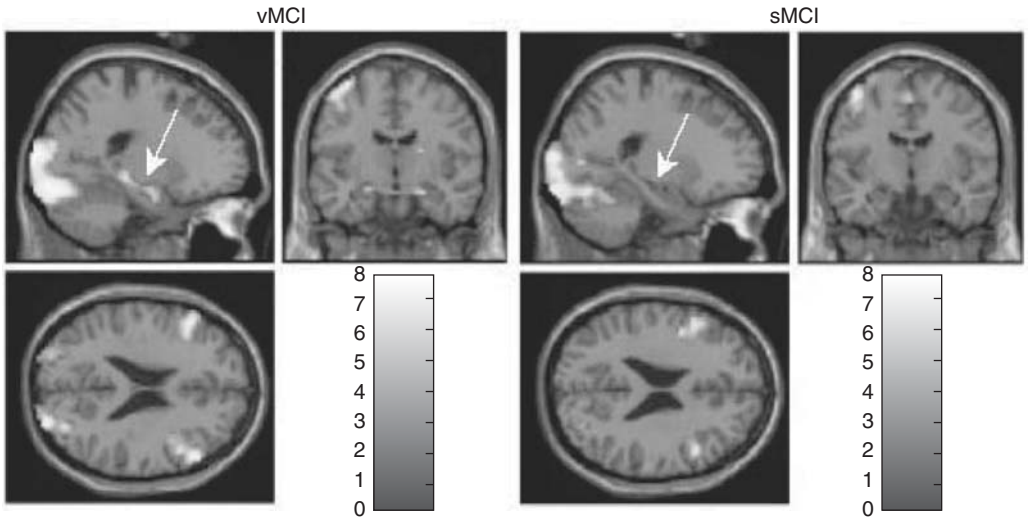

Figure 70.4 Group fMRI data from 15 very mildly impaired MCI (vMCI) and 12 significantly impaired MCI (sMCI) subjects on a face-name encoding task. The vMCI subjects showed evidence of hippocampal 'hyperactivation' compared to controls. The sMCI subjects showed significantly decreased hippocampal activation at levels similar to those seen in mild AD patients. *A full colour version of this figure appears in the colour plate section*

is closer to that found in AD, fail to perform well on the memory task and have MTL hypoactivation. This may represent an inability to compensate for the overwhelming pathological changes that have irreparably damaged the memory network with extensive synaptic and neuronal loss. We can assimilate the course of these changes to an 'inverse U-shaped curve' which goes progressively from normal to hyper to hypoactivation, paralleling changes in behavioural and neuropsychological performance.

PHARMACOLOGICAL fMRI IN MCI AND AD

A relatively new but promising area of application for fMRI is that of clinical trials of pharmacological agents. fMRI may provide a faster and more sensitive approach to assess efficacy of new therapies without the need to await for the completion of large and long trials. As of today, there have been few published studies that use fMRI to assess pharmacological effects of the available cholinesterase inhibitors for the treatment of AD, but their number is expected to grow as soon as other ongoing trials are completed.

One of these studies[86] looked at the effects of donepezil in patients with amnesic MCI compared to matched controls using working memory tasks. The results showed improvement of activation in the frontoparietal regions, which were found to be hypoactive before initiation of treatment. The changes occurred in the presence of preserved hippocampal integrity and were visible after only an average of six weeks of treatment. Another study[87] investigated the effects of acute rivastigmine treatment in patients with mild AD using fMRI with both a face encoding and a working memory task. The results indicated that rivastigmine increased bilateral activation in the fusiform gyrus during the face encoding task and in the prefrontal cortex in the working memory task. When working memory load was further increased, not only was increased activation seen, but in certain areas there was also decreased activation.

In a following study, Goekoop *et al.*[88] compared patients with AD to subjects with MCI using a face recognition task before and after a single dose of, or five-day treatment with, the cholinesterase inhibitor galantamine. Acute exposure to the drug produced strong activation in both groups. In particular, MCI subjects showed increased activation in the posterior cingulate, left inferior parietal and anterior temporal lobe. Prolonged exposure decreased activation in similar posterior cingulate areas and in bilateral prefrontal areas. In AD, acute exposure increased bilateral hippocampal activation, while prolonged treatment led to decreased activation in the same areas. The authors argued that differential response to cholinergic stimulation in MCI and AD could suggest differences in the functional status and integrity of the cholinergic system and provide a useful biomarker to monitor disease progression and treatment response.

More recently, Petrella *et al.*[89] published the first double-blind placebo-controlled fMRI study of the effect of a cholinesterase inhibitor, donepezil, on brain function in subjects with MCI. The subjects were assessed at baseline and following 12 or 24 weeks of therapy with an event-related delayed-response visual memory task for novel faces. The imaging findings were correlated with ADAS-Cog score, a commonly used clinical outcome measure in trials of therapies for dementia and MCI. The results indicated that donepezil increases activation in the ventrolateral prefrontal cortex, compared with baseline, and in both the bilateral dorsal and ventrolateral prefrontal cortices, compared with the placebo group post-treatment. The authors conclude that donepezil, when administered during a three to six month period to subjects with MCI, may potentially induce brain activation in the left inferior frontal gyrus during memory processing, thus improving performance.

CONCLUSIONS

Functional MRI has begun to establish itself as an important tool to probe the neural underpinnings of cognitive functions in the living brain. Although the use of fMRI in the study of MCI and AD is relatively new, it holds great potential for illuminating the black box between the pathophysiological process of AD and the early clinical symptomatology. A lot of questions remain to be answered, particularly regarding the early phases of MCI and how to identify

subjects who will ultimately develop dementia. This can be done only with a rigorous methodological approach that reduces intergroup variability[90]. Integrating different imaging modalities including volumetric MRI, FDG-PET and PiB-PET with neuropathological analysis, will expand our knowledge of the temporal and spatial course of the pathophysiological changes involving the affected brain networks. Ultimately, fMRI may prove particularly valuable in early 'proof of concept' studies for novel pharmacological approaches to treating AD, predicting long-term response to potential disease-modifying therapies for this devastating illness.

BASIC PRINCIPLES OF MAGNETIC RESONANCE SPECTROSCOPY

In vivo magnetic resonance spectroscopy (MRS) is a non-invasive technique that allows for the measurement of brain biochemicals in particular regions of the brain. In magnetic resonance imaging, the image is generated from the signal derived from water hydrogen nuclei. MRS suppresses the water signal to measure metabolites in the tissue fluid. It takes advantage of the chemical shift effect, a property that describes the notion that the same nuclei in different molecules respond differently to a magnetic field. Magnetic field strengths usually range from 1.5 Tesla (T) to 4 T in human studies. The chemical shift is typically measured in parts per million relative to the nuclear frequency and plotted on the horizontal axis of a spectrum with the vertical axis displaying the amplitude or intensity of a peak (Figure 71.1). Each peak represents a metabolite of interest for a given nucleus, with the area under the peak reflecting the concentration of that metabolite in the measured region.

There are several signal detection parameters that determine the shape of a spectrum. One is the voxel size which determines the region of tissue being studied and the concentration of metabolites measured. Another important parameter is relaxation time represented by T1 and T2. T1 is the time necessary for hydrogen nuclei to emit 63% of the energy from the stimulating pulse, while T2 is the time for 63% of the transverse energy pulse to be lost due to dephasing. These parameters affect signal strength since long T1s and short T2s are typically found in intracellular molecules with high molecular weights and thus can lead to weak signals. As a result, MRS is particularly useful for measuring low molecular weight molecules that are highly concentrated. Typical concentrations of metabolites detected by MRS are in the range of 4–10 mM. It is difficult to detect metabolites under 1 mM. These concentrations can be reported in absolute measures or as ratios to creatine concentrations, using creatine as an internal control.

NUCLEAR ISOTOPES USED IN MRS

Phosphorous

^{31}P-MRS (Figure 71.2) can be used to measure the following metabolites: adenosine triphosphate (ATP), phosphomonoesters (phosphoryl choline, phosphoryl ethanolamine and glycerophosphate), phosphodiesters (glyceryl phosphoryl ethanolamine, glyceryl phosphoryl serine and glyceryl phosphoryl inositol), phosphocreatine and inorganic phosphate. This is a useful isotope to measure the bioenergetics of neuronal processes.

Table 71.1 Summary of metabolites detected using proton MRS

Metabolite	*Measure*
N-acetylaspartate	Neuronal density and viability, mitochondrial function
Choline and choline-containing metabolites	Neuronal membrane integrity
Myo-inositol	Glial function
Glutamate/glutamine	Excitatory neurotransmitter
GABA	Inhibitory neurotransmitter

Proton

Hydrogen or proton MRS is used to probe for the following neurochemicals: choline (Cho), creatine (Cr), *N*-acetylaspartate (NAA), myo-inositol (mI), glutamate/glutamine and gamma amino butyrate (GABA) (Table 71.1). NAA is generally viewed as a marker of neuronal viability and may represent a measure of neuronal volume, number and/or function. However, some evidence suggests that it may more specifically reflect mitochondrial function[1,2]. The choline signal represents a composite of choline-containing metabolites such as phosphocholine, glycerophosphocholine and phosphotidylcholine. These metabolites are involved in cell membrane integrity. Myo-inositol is seen as a marker of gliosis and is the storage form of the inositol phosphate second messenger system. Glutamate/glutamine and GABA are the most ubiquitous excitatory and inhibitory neurotransmitters, respectively.

Other less commonly used nuclei include carbon, lithium, fluorine and sodium. Often, studies utilizing these nuclei involve measuring the impact of pharmaceutical agents containing these metabolites.

NORMAL AGEING

Several studies have used MRS to study neurochemical changes associated with normal, healthy ageing. Perhaps due to methodological

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

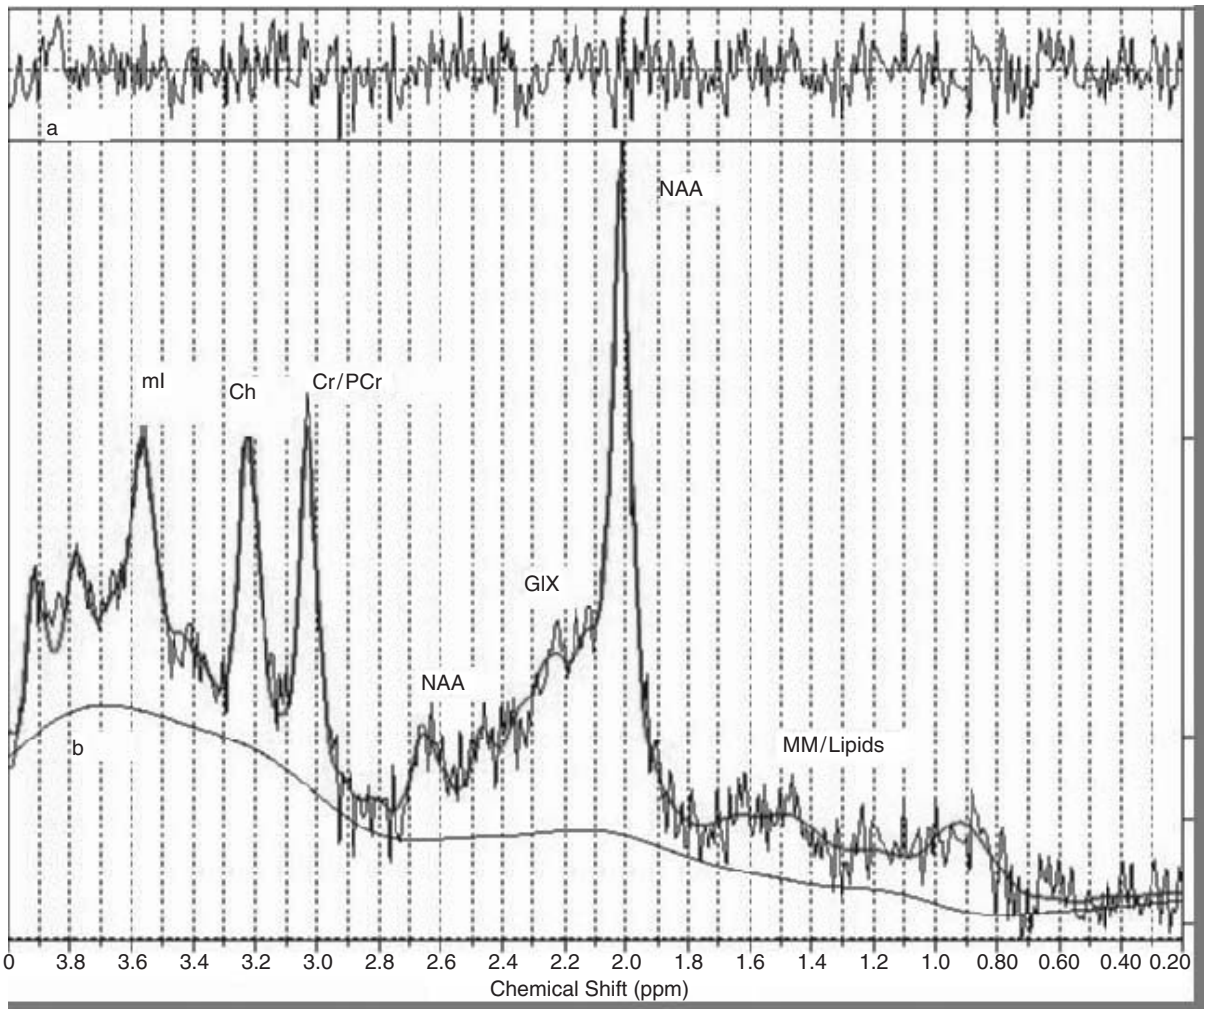

Figure 71.1 Sample proton MRS spectrum. Each peak represents a different metabolite with the area under the peak equivalent to the concentration of the metabolite

limitations, early studies using MRS to examine brain alterations associated with normal ageing failed to find significant changes over time[3,4]. However in a study by Cohen and colleagues comparing brain uptake of choline using proton MRS in younger subjects (mean age 32) and older subjects (mean age 73), it was shown that older subjects had decreased choline uptake[5]. In a 2001 study, Brooks *et al*. showed a significant decline in frontal lobe NAA comparing subjects from age 20 to 70 with an overall decrease of 12%[6]. This decline was interpreted as a decrease in neuronal volume, number or function as NAA is thought to be a marker of neuronal viability. In addition to decreases in NAA, increases in myo-inositol have also been seen in white matter associated with normal ageing. Kaiser *et al*. found a significant increase in both absolute levels and myo-inositol ratios in older subjects (mean age 56 years) compared with younger subjects (mean age 26 years)[7].

The impact of these neurochemical changes associated with ageing in frontal white matter have been explored in correlational studies examining the relationship between metabolite levels and cognitive function. For example, in a study by Valenzuela *et al*., frontal white matter NAA/Cr ratios were significantly correlated with cognitive tasks of executive function[8]. In a study by Elderkin-Thompson *et al*., choline, myo-inositol and phosphocholine ratios were correlated with performance on learning and recognition tasks[9].

The neurochemical changes described above are not limited to frontal white matter as demonstrated in a study that showed age-related decreases in NAA, NAA/Cho and NAA/Cr ratios across 30 different voxels[10]. In a longitudinal study examining similar measures over a three-year period, Ross *et al*. demonstrated that there were no significant changes in brain metabolites (with the exception of myo-inositol) or cognitive function over the time period studied[11]. In a comprehensive review and meta-analysis of MRS studies in normal ageing, while the majority of studies showed no significant change in metabolites with age, the authors did note a trend towards an increase in frontal and parietal choline with increasing age and a trend towards increases in parietal and occipital creatine with increasing age[12].

The studies above describe whole brain or cortical measurements of metabolites associated with normal ageing. However, age-related neurochemical changes in subcortical regions have also been demonstrated. For example, significant decreases in NAA/Cr and increases in choline/Cr in the genu of the corpus callosum have been shown when older subjects have been compared with younger subjects[13]. In the pons, decreases in NAA and increases in choline and creatine were noted in subjects over 50 years of age compared with subjects under 50[14]. In a study of the hippocampus, age-related decreases in NAA were measured by Szentkuti *et al*.[15]. These changes appear

to have a functional impact as well, noted by a correlational study showing that hippocampal NAA/Cr was a significant predictor of performance on a verbal memory task[16].

GERIATRIC DEPRESSION AND BIPOLAR DISORDER

MRS has been used increasingly to study mood disorders in geriatric populations (Table 71.2). Comparing older adults with depression or bipolar disorder with healthy control subjects may offer insight into the pathophysiology of geriatric depression and predictors of treatment response and aid the development of more specific therapeutic interventions.

Most of the studies of geriatric depression utilize proton MRS. Changes in myo-inositol, choline and NAA have been observed in association with major depression. In the prefrontal region, increased myo-inositol and decreased NAA have been observed[17–19]. These findings are hypothesized to be associated with changes in myelination and/or neuronal loss. However, there have been differing findings for choline in which Venkatraman *et al*.[17] found a significant decrease and Kumar *et al*.[18] a significant increase. Two proposed reasons for these differences include differing severity of depression and region of interest. The subjects in the Venkatraman study were depressed older adults who were responsive to treatment and had only residual symptoms, whereas Kumar and colleagues studied acutely depressed older adults. Additionally, Venkatraman *et al*. focused on the anterior cingulate while Kumar's findings were located in the dorsolateral prefrontal cortex. An additional novel finding for Venktraman and colleagues was increased NAA in the left medial temporal lobe, which may result in increased amygdala activity via diminished frontal lobe inhibition. Furthermore, changes in metabolite concentrations were found in the basal ganglia, where NAA was decreased in the caudate and choline was increased in the putamen[20].

A negative correlation was found between magnetization transfer ratio (MTR) and NAA+NAAG/Cr (*N*-acetylaspartylglutamate) and between myo-inositol/Cr and MTR[21] in white matter. MTR is associated with structural tissue integrity and it is hypothesized that changes in myo-inositol and NAA pools may result in the observed changes in macromolecular protein pools. Decreases in NAA were also found to be positively correlated with increased severity of white matter hyperintensities[22].

Changes in glutamate and glutamine have also been observed in geriatric depressed subjects. In comparing older adults with major depression, diabetes mellitus and healthy controls, subcortical nuclei glutamate and glutamine levels were significantly decreased in subjects with diabetes mellitus and depression compared with diabetic subjects and healthy controls. It is hypothesized that reduced glutamate and glutamine may be a result of glial dysfunction as well as impaired glucose metabolism. Also of note, myo-inositol was significantly increased in both depressed patients and depressed patients with diabetes mellitus versus controls[23]. In another study examining myo-inositol levels and visuo-spatial functioning, it was found that increased frontal white matter myo-inositol levels, present in both depressed and non-depressed diabetes mellitus subjects, were correlated with visuo-spatial dysfunction[24]. Patients with diabetes are

Table 71.2 Brain MRS findings in geriatric depression and bipolar disorder

Author	*MRS type*	*Findings*
Venkatraman[17]	^{1}H	NAA decreased in prefrontal cortex
		NAA increased in left medial temporal lobe
		Cho decreased in prefrontal cortex
		Cre decreased in prefrontal cortex
		mI increased in left medial temporal lobe
Binesh[19]	^{1}H	mI increased in dorsolateral prefrontal region
		PE increased in dorsolateral prefrontal region
		Glx increased in dorsolateral prefrontal region
Kumar[18]	^{1}H	mI/Cr increased in frontal white matter
		Cho/Cr increased in frontal white matter
Vythilingam[20]	^{1}H	NAA decreased in caudate
		Cho increased in putamen
Wyckoff[21]	^{1}H, MT and MRS	Inverse relationship between MTR and mI/Cr in left dorsolateral white matter
		Inverse relationship between MTR and (NAA+NAAG)/Cr in left dorsolateral white matter
Murata[22]	^{1}H	Correlation b/t increased WMH severity and decreased NAA/Cr in frontal white matter
Ajilore[23]	^{1}H	Significantly decreased Glu and Gln for DM+MDD and DM vs. HC in subcortical nuclei
Haroon[24]	^{1}H	Increased mI in DM and DM+MDD correlated with visuo-spatial dysfunction in frontal white matter
Moore[29]	^{31}P	Beta NTP decreased in basal ganglia
		Total NTP decreased in basal ganglia
Volz[30]	^{31}P	Beta NTP decreased in frontal lobes
		Total NTP decreased in frontal lobes
Renshaw[31]	^{1}H and ^{31}P	Average purine levels were not different between depressed and comparison groups in basal ganglia; however, female responders to fluoxetine treatment had 30% lower purine levels than non-responders
		Beta NTP 21% lower in beta NTP of responders to fluoxetine than non-responders, correlated with purine levels
Iosifescu[32]	^{31}P	Mg^{2+} decreased at baseline in frontal and parietal slice superior to corpus callosum of depressed subjects
		Total NTP increased in frontal and parietal slice superior to corpus callosum of T3 responders
		PCr decreased in frontal and parietal slice superior to corpus callosum of T3 responders
Pettegrew[33]	^{31}P	Prefrontal phosphomonoester levels increased at baseline; decreased with ALCAR treatment, trend between HDRS and phosphomonoester
		ALCAR increased PCr in prefrontal region, PCr levels correlated with HDRS
Forester[34]	^{31}P	Whole brain total NTP decreased in geriatric depressed, difference in WM, not GM, total NTP decreased with treatment
		Whole brain beta NTP decreased in MDD
		Whole brain pH increased in GM for pretreatment depressed; pH decreased following treatment
Forester[35]	^{7}Li	Increased brain Li in the superior edge of the corpus callosum associated with increased HDRS scores and frontal lobe dysfunction
Forester[36]	^{7}Li	Brain Li levels in the anterior cingulate gyrus associated with increased NAA in BP
		Brain Li levels in the anterior cingulate gyrus associated with increased mI in BP

ALCAR, acetyl-L-carnitine; BP, bipolar disorder; Cho, choline; Cre, creatine; DM, diabetes mellitus; Gln, glutamine; Glu, glutamate; Glx, glutamate + glutamine; GM, grey matter; H, hydrogen; HDRS, Hamilton Depression Rating Scale; Li, lithium; MDD, major depressive disorder; Mg^{2+}, magnesium ion; mI, myo-inositol; MT, magnetization transfer; MTR, magnetization transfer ratio; NAA, *N*-acetylaspartate; NAAG, *N*-acetylaspartylglutamic acid; NTP, nucleoside triphosphate; P, phosphorous; PCr, phosphocreatine; T3, triiodothyronine.

at increased risk of suffering from depression and increased medical burden may be a risk factor for poor response to antidepressant treatment[25].

These metabolic changes associated with major depression seem to be clinically relevant as demonstrated by treatment effect studies. For example, an increase in amygdala region NAA was seen in depressed patients who exhibited a positive response to electroconvulsive therapy[26]. In addition, Glx concentrations (a composite of glutamate and glutamine) in left dorsal lateral prefrontal cortex were negatively correlated with severity of depression and increased significantly after electroconvulsive treatment[27]. In a report examining the effect of antidepressant treatment, it was shown that decreased NAA levels in the anterior cingulate cortex in depressed patients were reversed with venlafaxine treatment[28].

In addition to using proton MRS in depression, ^{31}P-MRS allows for examination of membrane phospholipids and high-energy

phosphorous-containing molecules, such as ATP and phosphocreatine (PCr). Previous ^{31}P-MRS studies have demonstrated lower levels of beta and total NTP in the basal ganglia[29] and the frontal lobes[30] of depressed adults. Bioenergetic changes have also been demonstrated to correlate with response to pharmacological treatment[31,32]. Earlier studies have been inconclusive regarding whether differences in bioenergetic metabolism reflect a trait condition for those individuals at risk for depression or a state condition related to depression severity[32].

Studies examining changes in high-energy phosphate metabolites with treatment in geriatric depression are limited. In prefrontal tissue, phosphomonoester concentration was increased in two male older depressed subjects compared with six male controls of similar age. In the depressed group, prefrontal phosphomonoester levels decreased with acetyl-L-carnitine (ALCAR) treatment[33]. In addition, following ALCAR treatment there was a significant increase in PCr levels. In this study a trend level correlation was also found between phosphomonoester levels and Hamilton Depression Rating Scale (HDRS) scores[33]. A recent ^{31}P-MRS study of 13 older depressed adults and 10 healthy older controls at 4 T demonstrated that both total NTP (nucleoside triphosphate) and β-NTP (which primarily reflects levels of ATP) were decreased in the geriatric depressed subjects. More specifically, total NTP among depressed subjects was significantly decreased in white matter, but there was no significant difference in grey matter vs. controls. Following sertraline treatment, there was a significant decrease (2%) in total NTP. In addition, intracellular pH in grey matter, which was significantly greater in depressed subjects vs. controls pretreatment, was decreased to levels similar to that of healthy controls following treatment[34]. The authors propose that further study of high-energy phosphate alterations in geriatric depression is warranted and this may lead to bioenergetically based treatment approaches in late life major depression.

MRS studies in late-life bipolar disorder are more limited, though recent findings using ^{7}Li-MRS hold promise for a clinical application of this method to help regulate lithium dosing more accurately in older bipolar adults. Examining the superior edge of the corpus callosum in a 4 T MRS study of older adults with bipolar disorder treated with lithium, increased brain but not serum Li levels were associated with increased depression symptoms (measured by the HDRS) as well as frontal executive dysfunction (measured by the Stroop Interference Tests, Trails B and Wisconsin Card Sort)[35]. In addition, brain Li levels were associated with increased myo-inositol and NAA levels[36]. Increased NAA suggests potential neuroprotective and neurotropic effects of lithium treatment while increased myo-inositol levels were thought to reflect increased inositol monophosphatase activity in the setting of chronic lithium treatment.

Studies utilizing proton (^{1}H) MRS have identified changes in cerebral concentrations of NAA, Glx, choline-containing compounds, myo-inositol and lactate in adult bipolar subjects compared with normal controls[37]. Other studies using ^{31}P-MRS have examined additional alterations in levels of PCr, phosphomonoesters and intracellular pH (pH_i)[37]. Based on these findings, some have hypothesized that the majority of MRS findings in bipolar disorder can be fit into a cohesive bioenergetic and neurochemical model that is focused on central nervous system (CNS) energy metabolism[19]. Treatment studies examining bioenergetic changes in geriatric bipolar depressed individuals utilizing both ^{1}H- and ^{31}P-MRS at 4 T are currently underway and may provide further insight into the pathophysiology of late-life bipolar disorder.

DEMENTIA AND COGNITIVE DISORDERS

Mild Cognitive Impairment/Cognitively Impaired Non-Demented

MRS studies in mild cognitive impairment (MCI) have been used to distinguish MCI from normal ageing, as well as more advanced forms of cognitive dysfunction. An early study by Kantarci *et al*. examined regional metabolic changes associated with MCI. They found that increases in myo-inositol/Cr ratios in the posterior cingulate were the metabolic change unique to patients with MCI and Alzheimer's disease, while decreases in NAA/Cr and Cho/Cr only seemed present in the patients with more progressive disease[38]. Subsequent studies have shown a similar pattern of changes associated with MCI compared with control subjects[39]. Other regions have been shown to demonstrate metabolic perturbations restricted to MCI. For example in a study by Ackl *et al*., hippocampal decreases in NAA occurred in MCI and Alzheimer's patients, but NAA changes in the parietal region seemed to only occur in more advanced patients[40]. MRS has been studied as a predictor of developing dementia in a number of studies. For example, cognitively impaired non-demented (CIND) patients have been shown to have reduced NAA in the medial temporal lobe, hippocampus and neocortical grey matter compared with controls. There was also a difference between stable CIND patients and CIND patients who developed dementia over 3.6 years of follow-up[41]. In another study, changes in occipital NAA/Cr ratios predicted conversion to dementia with 100% sensitivity and 75% specificity[42]. Thus, MRS has been a useful tool in determining the early metabolic profiles that distinguish MCI from more advanced dementia and the changes that predict the development of more advanced dementia.

Alzheimer's Disease

The majority of studies using MRS to measure brain metabolites associated with dementia have been in Alzheimer's disease. The most consistent finding is reduced NAA, a marker of neuronal viability, and increased myo-inositol. This has been demonstrated in a number of cross-sectional studies[43–46]. These patterns also occur longitudinally as demonstrated in a brief report from Adalsteinsson *et al*. They showed that grey matter NAA levels (on average) declined 12.26% over the course of year in Alzheimer's disease patients, whereas controls had no significant change over the same time period[47]. Metabolic alterations associated with AD have associated with cognitive function as well. For example, NAA reductions in the left medial temporal lobe were associated with impairment in verbal memory, while myo-inositol increases in the right parietotemporal cortex were associated with impairment in visuoconstructional performance[48].

There have been several studies looking at the effects of treatment of Alzheimer's disease on brain metabolic profiles. In a study on donepezil, the authors found that patients receiving treatment demonstrated higher NAA concentrations compared to patients receiving placebo over a 24-week period[49]. In a subsequent study, these types of changes were shown to be significantly correlated with cognitive improvement associated with donepezil treatment[50]. Rivastigmine has also been shown to positively affect the metabolic profile associated with Alzheimer's disease. Patients treated with rivastigmine over a four-month period exhibited significant increases in frontal cortex NAA/Cr ratio[51].

The newest pharmaceutical agent in the treatment of Alzheimer's disease, memantine, is thought to exert an anti-excitotoxic effect by the inhibition of the glutamate-receptor agonist, *n*-methyl D-aspartate

(NMDA). In keeping with this mechanism, a recent proton MRS study has shown that memantine decreases hippocampal glutamate in Alzheimer's disease[52]. Thus, with the evidence from these treatment effect studies, it appears the metabolic alterations seen in Alzheimer's disease appear to be related to the underlying pathophysiology of the disease and in the case of memantine may reflect pharmaceutical mechanisms.

Vascular Dementia

While a number of studies have attempted to use MRS to distinguish Alzheimer's disease from vascular dementia[53,54], there are more similarities in the patterns of change than differences. The main distinguishing feature of vascular dementia is the subcortical predominance of metabolic alterations versus more cortical changes in Alzheimer's disease. However, as with Alzheimer's disease, patients with vascular dementia have been shown to have decreased NAA as well as increased myo-inositol[54].

Frontotemporal Dementia

As to be expected with frontotemporal dementia, metabolic changes in this disorder are associated with more frontal structures, as evidenced by a study showing decreased NAA in frontal areas compared with more posterior regional changes in Alzheimer's disease patients[55]. In a study comparing patients with frontotemporal dementia patients with those with Alzheimer's disease and controls, frontal lobe NAA and Glx concentrations were decreased in conjunction with increases in myo-inositol[56]. The NAA results have been replicated in a later study examining metabolites in the posterior cingulate cortex of frontotemporal dementia patients[57].

Lewy Body Dementia

A few studies have used MRS to examine brain changes associated with Lewy body dementia. One report including 20 patients with Lewy body dementia showed Cho/Cr ratios were significantly elevated compared with healthy controls[58]. In another study, white matter changes were detected with significantly lower mean NAA/Cr, Glx/Cr and Cho/Cr ratios in patients with Lewy body dementia compared with controls[59].

SUMMARY

Overall, the studies outlined above demonstrate a general pattern that applies to most of the neurodegenerative diseases. Dementia subtypes appear to differ only in terms of the neuroanatomical regions affected. In a number of areas, including grey and white matter and cortical and subcortical regions, NAA tends to be decreased compared to controls, while increases in myo-inositol and choline have been detected. This is thought to reflect the loss of neurons (with NAA), membrane breakdown (choline) and reactive gliosis (detected by myo-inositol) associated with these diseases.

STRENGTHS AND LIMITATIONS OF MRS

The major strength of MRS is that it allows for the measurement of specific metabolites in a particular region of the brain. Thus, the selection of crucial brain regions plays a vital role in the understanding of the pathophysiology underlying late-life mental illness. This is also a potential limitation as many studies choose different brain regions to study the same illness, thus generalizability and broad interpretation across studies are difficult to achieve.

Another limitation is poor resolution of specific peaks. Often, GABA, glutamate and glutamine peaks overlap, making it difficult to determine exact concentrations of these metabolites. One technique designed to surmount this limitation is two-dimensional magnetic resonance spectroscopy (2D-MRS).

TWO-DIMENSIONAL MAGNETIC RESONANCE SPECTROSCOPY

Two-dimensional (2D) spectroscopy is a technique that allows for greater resolution. The advantage of 2D spectroscopy is that is allows for the detection of GABA which is typically masked by the spectral peaks of other metabolites such as *N*-acetylaspartate and glutamate/glutamine. One of the first papers to apply 2D-MRS techniques to brain chemistry was done by Thomas and colleagues showing the feasibility of the 2D J-coupled point-resolved spectroscopy (JPRESS) technique in human subjects[60]. They were able to detect peaks representing NAA, glutamate/glutamine and lactate in occipital cortex.

Two-dimensional J-resolved spectroscopy has been successfully applied to measure previously hard-to-detect levels of GABA[61]. This technique has also been used to measure grey matter/white matter differences. In a study by Jensen *et al*., it was shown that GABA levels are significantly higher in grey matter than in white matter[62].

Localized two-dimensional chemical shift correlated magnetic resonance spectroscopy (2D-COSY) is a method that presents certain advantages over the JPRESS and J-resolved techniques. This method was successfully used in human brain in a study by Thomas *et al*. where peaks for *N*-acetylaspartate (NAA), glutamate/glutamine (Glx), myo-inositol (mI), creatine (Cr), choline, aspartate, GABA, taurine, glutathione, threonine and macromolecules were identified[63]. The authors demonstrated that 2D-COSY generates spectra with better resolution and less overlap of peaks. 2D-COSY has also shown to be highly reliable and reproducible[64].

The advantage of this technique is that it allows for the detection of important metabolites that are difficult to measure by traditional MRS methods. In particular, it allows for better resolution of aspartate and GABA, important neurotransmitters that have been implicated in mood disorders.

CONCLUSION

MRS is an important tool for the localized measurement of brain metabolites that has been successfully applied to the understanding of geriatric mental illness. Despite its limitations, the method continues to evolve more sophisticated techniques for the improved measurement of clinically important neurochemicals to better understand pathophysiology, functional impact and treatment effects.

Nosology and Classification of Mood Disorders

Dan Blazer

Duke University School of Medicine, Duke University Medical Center, Durham, USA

The mood or affective disorders are a group of disorders characterized by disturbance of mood and accompanied by a partial or complete change in mood or affect that is either manic (or hypomanic) or depressed (or mildly dysphoric). These disorders are classified in both the ICD[1] and the DSM[2] diagnostic systems in the three-digit rubric (296.xx in DSM-IV and F30.x–F39.x in ICD-10). With some exceptions noted below, the nosology of mood disorders in ICD-10 and DSM-IV is appropriate for the classification of mood disturbances in older adults. The classification of the disorders will therefore be described below, with specific comments related to older adults.

It should be noted at the outset of this chapter that DSM-IV is unchanged since the second edition of this text. A new version, DSM-V, is due for publication in 2012. ICD-10 has been instituted since the second edition, yet many changes in ICD-10 and the desire to bring the classification systems into closer concert were anticipated in the chapter from the second edition. It should also be noted that, despite the many advances in the pathophysiological investigation of late life mood disorders and new studies of therapies (pharmacological, psychological and social), DSM-IV and ICD-10 classifications have been accepted by investigators and clinicians alike. Some suggestions of new syndromes, such as 'depression in Alzheimer's Disease', have emerged and will be discussed briefly though none of these are widely employed.

MANIC EPISODE (F30, 296.4–7)

A manic episode is characterized by an elevated mood that is unrelated to the patient's circumstances. This elevated mood usually varies from an expansive or irritable syndrome to an almost uncontrollable excitement and psychotic agitation. Changes in mood are accompanied by increased energy, a decreased need for sleep, a decline in normal social inhibitions, as well as inflated and grandiose ideas, which frequently become delusional. Older persons can experience a typical episode of mania as well as hypomania (a less severe elevation of mood) but are more likely to suffer a so-called 'irritable' or 'angry' manic episode. Joviality and elation are replaced by irritability and agitation (as described elsewhere in this text). Nevertheless, older persons who suffer manic episodes usually meet both ICD-10 and DSM-IV criteria, even when the predominant symptoms are irritability and anger, as other diagnostic criteria are met.

ICD-10 defines a hypomanic episode as a disorder characterized by a persistent mild elevation of mood, increased energy and activity, and usually marked feelings of well-being and both physical and mental efficiency. Increased sociability, talkativeness, over-familiarity, increased sexual energy and a decreased need for sleep are often present but not to the extent that they lead to severe disruption of work or result in social rejection. Older adults, however, often experience irritability and anger as with a full episode. A parallel diagnosis is bipolar II disorder in DSM-IV.

DEPRESSIVE (F32) OR MAJOR DEPRESSIVE (296.2, 3) EPISODE

A major depressive episode is characterized by a depressed, disinterested or irritable mood, associated with the loss of interest or pleasure in all or almost all activities, accompanied by a number of other symptoms. These additional symptoms include a reduced capacity for enjoyment, reduced interest in surroundings, difficulty concentrating, lethargy, sleep disturbances, appetite disturbances, decreased self-esteem and self-confidence, and frequent ideas of guilt or worthlessness. Although older persons are somewhat less likely to report a specific decrease in their mood, they almost always describe a loss of interest in usual activities (anhedonia) in the midst of a major depressive episode. The categories of severe depressive episode in ICD-10 and major depressive episode in DSM-IV are very similar. DSM-IV and ICD-10 permit the diagnosis of a minor depressive episode (in the appendix of DSM-IV and categorized as mild in ICD-10); that is, a depressive episode which fulfils some of the symptom criteria for a major depressive episode and/or dysthymia and which lasts two weeks or longer. The more severe consequences of a depressive episode, such as a successful suicide or a retardation that progresses to stupor, would be characteristic of a severe but not a mild depressive episode in ICD-10.

Older persons who suffer a complicated, severe depression are easily diagnosed according to both ICD-10 and DSM-IV criteria. Problems do arise, however, when the episode experienced by older persons is accompanied by a severe medical illness or significant cognitive impairment. The frequency of psychobiologic symptoms in more severe depressions renders the distinction between symptoms of depression and symptoms of physical illness/functional impairment difficult in the midst of a depressed mood associated with medical illness. The current nosology is not helpful in disaggregating mood disorders from either the symptoms of physical illness or normal psychological reactions to physical illness. Some have suggested that a unique criterion for older persons with depression and cognitive impairment should be instituted (but this is yet to be included in

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

any extant diagnostic system). The co-morbidity of depressive symptoms in cognitive disorders such as dementia, Parkinson's disease and small strokes renders such an approach potentially useful in improving the current nosology. Two examples are presented below.

'Vascular depression' has been proposed as the diagnostic entity secondary to vascular lesions in the brain and appears to increase in frequency with age[3]. The clinical presentation may differ from major depression, even if only in subtle ways. Elders with vascular depression exhibit impairment in set shifting, verbal fluency, psychomotor speed, recognition memory and planning (executive cognitive function), a 'depression–executive dysfunction syndrome' characterized by psychomotor retardation, and reduced interest in activities. Vascular depression is associated with an absence of psychotic features, less likelihood of a family history, more anhedonia and greater functional disability when compared with nonvascular depression.

Others have proposed a depression of Alzheimer's disease[4]. The criteria are as follows. In persons who meet criteria for dementia of the Alzheimer's type, three of a series of symptoms that includes depressed mood, anhedonia, social isolation, poor appetite, poor sleep, psychomotor changes, irritability, fatigue or loss of energy, feelings of worthlessness and suicidal thoughts must be present for the diagnosis to be made.

BIPOLAR (F31, 296.4–7) AND UNIPOLAR DISORDER (F32, 296.2, 3)

In both ICD-10 and DSM-IV, individuals who present with a history of recurrent mood disorder (at least two), in which mood and activity were profoundly disturbed and at least one of the episodes was manic, are classified as suffering from bipolar mood disorder. Bipolar disorder usually has an early age of onset, although it can have its onset later in life, and the categorization is useful in older as well as younger persons. Bipolar disorders are classified as manic (the individual is currently in a manic episode), depressed (the individual is currently in a depressed episode and has at least one well-authenticated manic episode in the past) or mixed (the individual's current episode involves a full symptomatic picture of both manic and depressed episode, except for the duration requirement of two weeks of depressed episodes). Symptoms are often intermixed or rapidly alternating within hours or days in the latter category.

Bipolar II disorder (F31.8 and 296.89) is characterized by at least one hypomanic episode and at least one episode of major depression. These disorders are probably more common among older persons than the more classic bipolar disorder described above. Older persons frequently experience depression and occasionally mania secondary to medical illness or medications, categories that are specified in DSM-IV as mood disorder due to a general medical disorder and substance-induced mood disorder. Common examples of causes of these secondary mood disorders in the elderly include hypothyroidism, Parkinson's disease, chronic obstructive pulmonary disease, various forms of cancer, alcohol, β-adrenergic blockers and L-dopa. Mood disorders with a seasonal pattern are less frequent in the elderly[5].

Individuals who never experience an episode of mania or hypomania but nevertheless suffer episodes of major depression are generally classified as 'single-episode' or 'recurrent'. Most depressive disorders are recurrent; that is, distinct episodes of major depression followed by distinct episodes of normal functioning may be the exception rather than the rule. For this reason, additional diagnostic categories have been instituted in the nosology to disaggregate the classification of the natural history of depressive episodes. In ICD-10, a category of 'recurrent severe depressive disorder' (F33.3) is analogous to the DSM-IV category of 'major depression recurrent' (296.3). Recurrent mild depressive disorder (F33.0) is categorized in ICD-10 by repeated episodes of depression, the majority of which fulfil the description given for mild depressive episode above. These recurrent mild episodes may or may not be associated with environmental stress and may be either acute or insidious in onset. Recovery is usual, although not always complete.

Cyclothymia is included in both DSM-IV (301.13) and ICD-10 (F34.0). According to ICD-10, cyclothymia is a persistent instability of mood involving numerous periods of mild depression and mild elation. The instability usually develops early in adult life and pursues a chronic course, although at times mood may be normal and stable for months. Cyclothymia is difficult to establish without a prolonged period of observation or an unusually good account of the subject's past behaviour. In DSM-IV, cyclothymia must persist for at least two years to be diagnosed and involve numerous hypomanic episodes.

Yet another phenomenon has emerged in the study of the natural history of depression – rapid cycling[6,7]. Rapid cycling is the occurrence of four or more episodes of depression or mania per year, with either two weeks of normal mood between episodes, or a shift directly from mania to depression, or vice versa. Others have classified rapid cycling as involving either mixed mood states, or frequent mood fluctuation without discrete intermorbid periods, or involving 24- or 48-hour cycles of mood disturbance. Rapid cycling occurs in persons regardless of age, although there may be some tendency for individuals to decrease their propensity to rapid cycling with increased age. Rapid cycling appears to be more common in individuals with bipolar disorder than unipolar disorder, but it is not limited to individuals with bipolar disorder. Rapid cycling is a specific type of bipolar mood disorder in DSM-IV (296.8) and major depression (311). Research criteria are proposed in the appendix of DSM-IV-TR.

DYSTHYMIA (F34.1, 300.4)

Dysthymia is a category included in both ICD-10 and DSM-IV. Dysthymia is a chronic depression of mood that does not fulfil the description and guidelines of mild recurrent depressive disorders (in ICD-10) and is characterized by periods of days or weeks at a time when patients feel tired and depressed, where everything is an effort and where nothing is enjoyed. They 'brood and complain', sleep badly and feel inadequate, but are usually able to cope with the basic demands of everyday life. This description is similar to the description of dysthymia in DSM-IV, where the essential feature is a chronic disturbance of mood, involving a depressed mood for most of the day and more days than not for at least two years (the two-year minimum duration is not a criterion in ICD-10 but rather is to last at least several years). In addition, individuals suffering dysthymia suffer many of the symptoms of the more severe depression but with less severity, such as poor appetite, insomnia, low energy and low self-esteem. Older persons often meet criteria for a dysthymic disorder (in terms of duration of symptoms) when diagnosed with major depression. It is difficult to determine, however, whether the dysthymic disorder is a separate entity or whether it is part of the same syndrome which 'waxes and wanes' in severity. Recent studies have suggested that dysthymic disorder may exist most often in the elderly as an entity not associated with major depression. Dysthymic disorder has usually been equated with depressive neuroses, as described in earlier versions of both the ICD and DSM diagnostic systems,

which assumes that the depressed mood results from psychoneurotic and stress-related difficulties.

Yet another category that has been suggested is minor or mild depression. Criteria for minor depression can be found in the appendix of DSM-IV and variants can be found in the Research Diagnostic Criteria and in ICD-10 (F32.0). There is virtually no data to substantiate a specific entity for minor depressions, except that persons who experience minor depression (that is, symptoms less severe than major depression for at least two weeks, according to DSM-IV) exhibit a similar risk factor profile and are at much greater risk for developing major depression over time. There have been a number of studies of minor depression among the elderly. The renewed interest in minor depression once again brings the categorical vs. continuum controversy to the forefront in the phenomenology of depression.

ADJUSTMENT DISORDER WITH DEPRESSED MOOD (F43.2, 309.0)

In the DSM-IV system of classification, an adjustment disorder is a reaction to an identifiable psychosocial stressor that leads to maladaptive reactions, including impairment in occupational functioning and symptoms that are in excess of normal and expected reaction to this stressor. The maladaptive reaction may take many forms and an exaggerated depressed mood is one of the forms.

Symptoms of adjustment disorder with depressed mood include tearfulness and feelings of hopelessness. By definition, the maladaptive reaction can persist no longer than six months, does not meet criteria for other disorders and does not represent uncomplicated bereavement.

ICD-10 includes the category of adjustment disorder (but depressed type is not specifically coded) and the clinical form may take the characteristic of a 'prolonged depressive reaction'; that is, a mild depressive state occurring in response to prolonged exposure to a stressful situation but of a duration not lasting six months. The categories of adjustment disorder are therefore very similar for both diagnostic systems. In theory, the stressor may include physical illness and therefore this category is most relevant to depressive episodes in later life. A lack of acceptable longitudinal data on the association of depressive symptoms with physical illness renders it difficult to determine whether older persons do recover from the depressive episode, which often accompanies a physical illness, within the six months required by the diagnostic category of adjustment disorder.

CONCLUSION

In general, the current classificatory systems of both DSM-IV and ICD-10 work relatively well for classifying older persons suffering from mood disorders. A number of distinct exceptions must be recognized, however. Categories such as dysthymic disorder, adjustment disorder and minor depression in DSM-IV do not appear to be adequate, and therefore more exploration of the ICD-10 construct of mild depression (but possibly not utilizing the specific diagnostic criteria of ICD-10) would appear in order. A major problem with the current classification systems is the inability to take into account co-morbidity, especially co-morbid depression and physical illness. Co-morbid depression and physical illness is a grossly unstudied area, compared to the clinical relevance of the condition. To what extent do our current classification systems accommodate individuals suffering mild or even severe depressive symptoms in the midst of physical illness? In addition, depression is often co-morbid with other psychiatric symptoms, especially anxiety disorders and somatic complaints. Neither ICD-10 nor DSM-IV adequately accommodates the co-morbid psychiatric syndromes that are frequently seen in older adults.

Finally, when classifying mood disorders many individuals suffer a depressed mood in late life that is not disordered. Uncomplicated bereavement is an expected accompaniment of older persons who experience a significant loss in old age. In addition, other older persons may become demoralized, given the current circumstances in their lives. Such persons should not be classified in a disease-oriented classification system. Nevertheless, these human experiences are not to be ignored by the clinician working with the older adult suffering a mood disorder.

Genetics of Affective Disorders

Carolina Aponte Urdaneta and John L. Beyer
Duke University Medical Center, Durham, NC, USA

INTRODUCTION

With the completion of the Human Genome Project, the field of genetics has vastly changed. Even our current definitions of disorders and treatment of diseases are anticipated to evolve pending the interpretation of our new genetic data[1]. However, rather than just narrowly looking at genetic associations in persons with affective disorders, the contributions obtained from the wider body of research examining the genetic basis of psychiatric disorders need to be interpreted in the context of environmental influences and the heterogeneous nature of these disorders[2,3]. This is especially true for late-life disorders, in which simple Mendelian genetics do not apply, and multiple genes each likely play a small role, together with co-morbid illnesses, earlier life insults and environmental factors[4,5].

Genetic studies can be classified into linkage studies, gene–disease association studies (looking at specific single nucleotide polymorphisms (SNPs)), and the more recent genome-wide association studies (GWAs). Other more classic forms of genetic studies include familial aggregation studies, twin studies, adoption studies, and linkage studies of an illness with a genetic marker. Finally, an area of recent intense research that may soon show significance in late-life psychiatric disorders is that of copy-number variations (CNVs). Findings have suggested that CNVs may cause disease due to genomic rearrangements that result in altered number of copies. These disorders have primarily been associated with neurodevelopmental and neurodegenerative disease processes[6,7], a classification in which late-life affective disorders could well be included.

In this chapter, we will review the current understanding of genetic influences in late-life affective disorders. However, before looking at specifics, it is important to highlight the intricacies of examining the associations of genetic variations with complex diseases such as late-life affective disorders; researchers have had difficulty replicating associations[8]. Therefore, many of the findings reviewed here may be considered suggestive, but not fully verified. It will be up to future research to clarify and reveal the developing story of genetic influences in late-life mood disorders.

LATE-LIFE AFFECTIVE DISORDERS

As with affective disorders in the early and mid-life ages, late-life mood disorders are quite heterogeneous. Age of onset appears to be an important clinical variable in the genetic study of affective illness. Therefore, two groups of affectively ill elderly patients are usually differentiated: those who had an early onset of illness with continued symptoms or episodes in their later life, and those who had a late onset of illness (usually defined as a first onset after the age of 60 years)[9]. When differentiated by age of onset, late-onset depressive disorders have qualities suggesting that they may be genetically different from early onset forms, including clinical differences in expression and non-conformity to expected genetic models[10].

For example, basic genetic models propose that diseases with strong genetic influences are most often found in earlier onset and/or more severe forms of an illness. However, late-onset affective syndromes are typically among the most severe and most refractory to treatment[11,12]. Further, many studies have consistently found that patients with late-onset depression and bipolar disorders have less familial aggregation of mood disorders than those with the early onset affective disorders[13–18]. Also, late-onset mood disorders are also less likely to display the gender disparity present in early onset mood disorders[13]. These considerations challenge our models of genetic influence for late-life affective disorders.

Two explanations have been proposed for the age-related variation in genetic influence for affective illnesses: multifactorial inheritance and increased phenocopy expression with age. Multifactorial inheritance (also called polygenic inheritance) suggests that inheritance patterns are a result of a combination between multiple interacting genes and environmental factors. Examples of traits that have multifactorial inheritance include stature, intelligence or blood pressure[10]. According to the multifactorial theory, the onset of an affective disorder results from the additive effects of several genetic and environment factors. One could also assume that early onset illnesses probably result from greater genetic loading, while late-onset illnesses may have less genetic loading but increased occurrence of environmental events with age.

The second explanation, increased phenocopies, may explain the limited specificity of the affective disorders diagnosis. Both bipolar disorder and major depressive disorder are syndrome diagnoses; that is, the diagnosis is based on the presence of a collection of observed symptoms (phenotypes) rather than an etiological cause. In this theory, late-onset affective illness is a collection of phenocopies. Phenocopies are illnesses with a characteristic phenotype but different underlying causes.

It has long been known that depressive syndromes are very common in neurological disorders such as Parkinson's disease, Alzheimer's disease and stroke; more recently added to this list would be the proposed subtype of depression called 'vascular

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

depression'[19,20]. Taking these into account, the age-related variation in late-life affective disorders may be explained by increasing phenocopies in older adults who have late-onset affective disorders. Patients with early onset affective disorders (which would include elderly patients with previous diagnosis of affective disorders) may be, therefore, more likely to have a genetic cause. As research sharpens our understanding of these diseases, the 'heterogeneous' group of affective disorders will be differentiated into various subtypes, each with a more specifically defined course, prognosis and treatment. Each new subtype will also suggest new ways that genes and the environment may contribute to the expression of the illness.

There is one further consideration in studying genetic contributions to late-life affective disorders. This is the fact that not all subjects with higher or lower genetic susceptibility may reach the developmental age of expression. Competing causes of death must be taken into account (i.e. individuals at high risk of developing a disorder may not express the disease symptoms during their lifetime). This in turn means that the actual risk of developing a disease is decreased when other causes of mortality are in play[21].

GENETICS OF LATE-LIFE DEPRESSION

First-degree relatives (parents, siblings, offspring) of depressed adult patients are twice as likely to develop depression as those in the general population[22–26]. In two twin studies of adult populations, the relative risk for monozygotic twins to develop depression was 1.9, while the risk for dizygotic twins was 1.2[27,28]. Adoption studies have suggested that certain environmental influences, especially parental loss and parental alcoholism, may be predictors of depression[29]. Heritability, therefore, is estimated at around 40% in the adult population[30]; however, it has also been estimated to be lower in the elderly[31,32]. Evidence of only limited heritability (16%) was found in a sample of elderly reared-apart and reared-together Swedish twins studied for characteristics of depression[4]. In contrast, a sample of Danish twins 75 years of age and older revealed that depression symptomatology is moderately heritable in late life (approximately 35%)[5]. Moreover, both studies consistently implicated environmental factors as the major source of variance in depression symptoms among the elderly.

Large-scale family linkage studies of major depression to chromosomal loci have been conducted focusing predominantly on early onset major depression, with some consistency of findings[33]. In the area of candidate genes mainly drawn from monoamine theory of depression, study findings have suggested that 44 base pair deletions or insertions in the serotonin transporter (*SLC6A4*) may result in dysfunction or reduced expression of the transporter and, possibly, depressive symptoms or major depression[34,35]. In the same area, the gene *SLC6A4* has been associated in several studies with increase risk for depression induced by life stresses[35,36]. However, caution is still warranted about these associations because, as in repeated cases of genetic association findings in psychiatric disorders, several studies have failed to replicate the findings on *SLC6A4* and stress reactivity[37,38]. Still, *SLC6A4* variations may be implicated in functional effects[39]. As with most findings, further research is required.

Other candidate genes that have been proposed and received attention in the field of late-life depression are the genes associated with brain-derived neurotrophic factor (*BDNF*), tryptophan hydroxylase 2 (*TPH2*), and *APOE* (apolipoprotein E). Studies in *BDNF* and *TPH2* genetic associations have reported mixed results[35,40,41]. Since one of the major complications of Alzheimer's disease is the development of a major depressive disorder, researchers have been especially interested in the *APOE* genes. Research has suggested that the presence of one of the *APOE* alleles may predispose patients to the development of major depression[42]. Other researchers have not supported this finding[43–45].

GENETICS OF LATE-LIFE BIPOLAR DISORDER

Bipolar disorder has been widely recognized as having a strong genetic component[46]. Heritability has been estimated at over 80%[47]. Depending on which particular study is cited, first-degree relatives of adult bipolar patients may have a 3.7 to 17.5% risk for developing bipolar disorder[22–26]. The risk of bipolar disorder diminishes in second-degree relatives (grandparents, grandchildren, aunts, uncles) of bipolar patients, though still elevated over the general population. The average concordance rate for bipolar disorders in monozygotic twins is 60%, while the concordance rate in dizygotic twins is 12%. This five-fold greater rate of concordance strongly indicates the importance of genetic factors in the familial aggregation[48].

Large samples for genetic analyses have been obtained by combining family data sets. These studies have found consistent evidence of a linkage region on chromosome 6q. Other regions that seem to be implicated include chromosomes 4q and 8q[46,49–51]. Associations with the schizophrenia risk genes D-amino acid oxidase activator (*DAOA*), disrupted in schizophrenia 1 (*DISC1*), neuregulin 1 (*NRG1*) and catechol-O-methyltransferase (*COMT*) have been reported[46,47,52,53]. Meta-analyses of bipolar disorder genetic association studies have also identified small effect sizes for *BDNF, MTHFR*, and *SLC6A4*[54]. However, even these candidate genes appear to explain a small proportion of bipolar disorder's heritability since the odds ratios for individual susceptibility variants typically are less than 1.5. Specific associations for genetics in late-life bipolar disorder are unknown.

CONCLUSIONS

Late-life affective disorders are genetic complex diseases, resulting from the interplay of multiple genes, environmental factors, comorbid illnesses and life stressors. This complexity makes the results obtained from the various studies difficult to interpret and replicate. Furthermore, translating the findings into clinically useful data that results in advancements in treatment is at this point still elusive. This is especially true given that these diagnoses are syndromal, not necessarily clearly and cleanly elucidated, and therefore likely to represent a conglomerate of diseases (each with its own genetic make-up). Moreover, most of the research to date, including that discussed in this chapter, is not specific to late-life affective disorders but also to early onset affective disorders. Despite the biases and difficulties mentioned above, genetic research in late-life affective disorders remains a very exciting field of study, where new advances and breakthroughs are paving the way for future research in this area. With the advent of GWAs, there is increased hope that susceptibility loci will be identified, and that the ultimate identification and characterization of affective disorder susceptibility genes will clarify the biological mechanism of the disorders and lead to new treatment strategies.

Environmental Factors, Life Events and Coping Abilities

Toni C. Antonucci and James S. Jackson

Institute for Social Research, University of Michigan, Ann Arbor, USA

Understanding physical and social environmental factors, life events and coping abilities in the lives of older people is best accomplished by applying both a life-span and a life-course perspective. The life-span framework allows one to incorporate information about individual experiences over the life course, the successes and failures that individuals have coping with these experiences, the tangible and human resources that have or have not been helpful, as well as the organizational or societal events that have influenced their development[1]. Thus, understanding how the elderly cope with environmental factors and life events must also be considered within a dynamic family and friendship context that is multigenerational, influenced by ageing, cohort differences and historical events [1,2].

These intersecting contexts are characterized by exchanges which are perceived as either reciprocal or non-reciprocal over time. These transactions have been described as being of three types: those earmarked by the anticipation of linear downward transfers, i.e. from older to younger generations; those characterized by curvilinear exchanges, from the middle to younger and older generations; and resource-based exchange networks, which assume that resources will be exchanged based on availability rather than generational lineage membership. Akiyama *et al*.[3] have argued that cultural and resource differences affect how generations exchange goods and services. But this argument can also be extended to expectations based on lifetime affective relationships and competencies. These resource exchanges also contribute to the individual's experience of the physical and social environments, life events they encounter and their coping capacities and abilities. Each model predicts a certain expectation or resource availability. The degree to which individuals have positively experienced these exchanges will directly affect their successful adaptation to old age.

It is clear that individuals vary in their ability to cope with the stresses and strains of life. As individuals age, it has been assumed that they are faced with more negative experiences, that the environment in terms of both physical and psychological characteristics becomes more difficult. One therefore seeks to understand the mechanisms individuals use to cope with these events.

Education has been linked to health, a well-documented finding indicating that those with higher levels of education enjoy better health. However, Antonucci *et al*.[4] showed that this relationship can be attenuated for specific groups and levels of support; less-educated men enjoyed the same good health as men with higher levels of education if they had key social supports. Less-educated men with larger networks, emotional, financial and sick care support from a child have better health than less-educated men without these supports. Interestingly, these findings were not found for women. The findings can be interpreted as illustrating the protective potential of social relations, though the gender differences highlight the complexity of the relationships.

Another important question is whether as people age they become better able to cope with relationships over time. Research thus far, although cross-sectional, suggests this is the case at least for most relationships[5]. Social relations with parents, children and friends do tend to decrease in negativity over time. Spousal negativity, however, remained stable over time, well into old age. It appears that part of the successful coping strategy seemed to be reduced contact with the 'difficult' party. This is less easily accomplished with a spouse living in the same household. Strained spousal relationships can be devastating, since they tend to be one of the most significant long-term relationships of adulthood, understanding what factors allow an individual to cope with stressful spousal relationships is important. Birditt and Antonucci[6] examined relationship profiles of married people. They were able to demonstrate that married individuals with two high-quality relationships had higher well-being, if one of these was a best friend, regardless of whether they reported a positive relationship with their spouse. However, if the married individual did not have a best friend, quality of spousal relationship was singularly and significantly related to well-being. Thus, as previous research has shown, while spousal relationship is an important predictor of well-being, the potentially negative influence of a poor spousal relationship can be offset by other significant and high-quality relationships.

Coyne and Downey[7] argue that people evidencing depressive symptoms generate a negative exchange loop for their support network. The life-span perspective is useful because individuals do not suffer isolated single depressive episodes, but rather a series of depressive episodes over time. Network members may come to recognize the negative aspects of these episodes and as Coyne and Downey argue, subsequently distance themselves from the individual in crisis. It is speculated that knowledgeable network members recognize this crisis as one of many that have negative consequences. In an effort to protect themselves from the unsuccessful

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

and frustrating experience of attempting to be helpful, network members may ignore, isolate or abandon the individual in crisis. This is most likely to happen, unfortunately, when the individual has a history of being maladaptive. Thus, in the case of the individual in need, but with a history of depressive episodes or other series of crises events, it may be difficult to activate a support network. On the other hand, for individuals who have a more successful history of coping with crises, their support networks are likely to respond to a crisis with both affective and instrumental support.

Recent work suggests that it is vital to consider the realistic viability of various coping behaviours[8,9,10]. Socioeconomic status (SES) and the challenging nature of physical and social environments, especially in large urban areas, simultaneously help to afford greater opportunities for engaging in what we have termed 'negative' coping behaviours (e.g. smoking, drinking alcohol and drug use) and fewer opportunities for relying on positive coping alternatives, a traditional focus of the coping literature. Studies report that lower SES individuals have a more limited set of coping resources at their disposal compared to those with more income or education[10]; these findings suggest that some coping choices may not be readily available to poor populations, particularly those living in urban centres. Limited access to exercise and public recreation facilities and perceived poor neighbourhood safety have been linked to reduced physical activity levels and increased obesity in lower income neighbourhoods[11,12]. Lower levels of education, unskilled and semi-skilled versus professional occupations and lower levels of income, have all been associated with lower levels of emotional support, less contact with friends and lower frequency of disclosing problems[13].

At the same time, people of low SES and traditionally disadvantaged ethnic minority populations are more likely to smoke, use alcohol and be obese[14,15]. They are more likely to live in close proximity to liquor stores[16]. They are also more likely to have limited access to healthy foods, putting them at greater risk for obesity and obesity-related diseases[15,17]. This suggests that the physical and social environments characterizing the urban poor may facilitate certain negative coping mechanisms that are effective at relieving psychological symptoms of stress over more positive behaviours that may be less accessible to these populations, especially in middle and older ages[8,9].

Comprehending the effectiveness of potential stress-reducing strategies has important implications for understanding the epidemiology of chronic diseases that are more prevalent among low SES and certain race and ethnic groups. A variety of coping strategies may help reduce the body's response to chronic stressors; some linked to those having negative health consequences and others linked to more neutral or positive health outcomes. It is clear that more research needs to be conducted to understand the role of positive coping behaviours in alleviating the physiological responses to stressful events among different social and economic groups and at different ages and at different points in the life course[2].

Although it is clearly true that some people experience more crises than others, it is not always the case that those who experience a great many crises are the ones overwhelmed by them. The same environmental conditions or life events which might devastate one person may have much fewer negative effects on another. As noted above we have some information about risk factors or vulnerabilities, but we actually know very little about what makes some people capable of coping with stress and others incapable of coping with the same events. Among the explanatory hypotheses which have been offered are personality characteristics, supportive interactive exchanges, self-concept and self-efficacy. We are not at a point where there is clear evidence in support of one explanatory concept over another and it may, of course, be some combination of these influences. Nevertheless, a series of studies by Taylor and his colleagues[18] offers interesting insights about the interactive basis of coping strategies. In their studies of men recovering from uncomplicated myocardial infarction (MI), they found that wives who believed in their husbands' ability to recover were more likely to have husbands who did recover. It is especially interesting that these husbands were no less disabled by their MI than others in the study. The researchers were able to experimentally augment the wife's view of her husband's potential for recovery, which in turn directly affected the husband's actual recovery. This series of studies, replicating the impressions of many clinicians, dramatically demonstrate that individuals can be fundamentally influenced in how they face life conditions and events which confront them. The mechanisms through which these influences occur are not well understood. Bandura[19] has argued that the relevant characteristic is self-efficacy. Whether self-efficacy is the critical variable or not, it is clearly evident that 'objective' facts or events are influenced by very 'subjective' factors.

Social support is not always or solely considered a coping ability or strategy. In fact, it may be best considered as a resource that individuals may call upon if needed to cope with particular environmental stressors. Moreover, successful coping is the ability to activate the kinds of support needed to meet the needs of a specific situation and to help the individual achieve a positive affective disposition. We know that people vary in their ability to develop a supportive entourage or network; in their ability to mobilize or activate this network once established; and in their ability to benefit from this support. We can best understand these differences as indications of how older people differentially experience their environments and life events; and how they cope with these experiences.

Once again it is critical to recognize the life-span and life-course contexts because the individual old person confronts a specific event with a history of either positive or negative coping experiences. A related issue is the question of how frequently the individual experiences crises and at what points in their lifetime. The now classic work of Brown and Harris[20] established both the lifetime vulnerability of people who experience the loss of significant intimate others early in their lives and their frequent lack of healthy, positive adult intimate relationships. Others have also established the influence on depression and overall affective well-being of negative relationships with close supportive others.

The life-course and life-span perspectives[1,21] emphasize that people evolve throughout their lifetime and become more heterogeneous with age. As people grow older the separate experiences of their lifetime combine uniquely to shape the individual. There is every reason to believe that this is especially important to the question of how individuals cope with the challenges of old age. Although major theoretical and empirical questions have not been resolved, research concerning social support as a coping strategy does provide insights into how people manage the stresses and strains that they face in late life. It has been suggested that an individual's ability to cope with specific environmental conditions and life events is best understood through a consideration of the resources and experiences available to that person. One simplistic way to consider this is that successfully coping with stresses and strains in early life is the best predictor of the individual's ability to cope with stressful situations in later life. This is likely to be true, even if the exact nature of the stressful event varies. There is also reason to believe that individuals develop coping styles over their lifetime which can be seen to be generally successful and adaptive while others develop coping styles which are generally

unsuccessful or maladaptive. These coping strategies, at their best, match the environmental conditions and life events that the individual experiences. It is proabable that, although the specific nature of these experiences will change with age, an individual's ability to cope with these events is likely to show fairly stable life-span continuity. As research clearly demonstrates, however, individual coping and adaptation competency can be improved through informal and professional intervention at all points in the individual life course.

It is also important to consider the influence of non-psychiatric factors on the experience of events in old age and how one copes with stressors and stress. Jackson *et al*.[22] have noted that different racial, cultural and other socio-demographic factors fundamentally affect how a situation is experienced. If an individual is one of many suffering the same negative experience(s), the aetiology of that experience may not be devastatingly personalized. On the other hand, if everyone else in one's reference group is significantly more successful, the relative comparison can be devastating, even if 'objectively' the situation is quite positive. Similarly empirical evidence indicates that different national groups appear to vary considerably in the degree to which they respond negatively to environmental factors and life events. Recent profile analysis of social relations and relationships among different groups has suggested interesting similarities, but also differences. Using almost identical measures in the US, Germany and Japan, three sets of profile analyses were conducted. Interesting similarities and differences emerged. Cross-cultural work[23] examined social relations and mental health among older men and women in the US, Japan, France and Germany. Findings indicate that women experience more resource deficits, i.e. widowhood, illness, financial strain, than men in all these countries. In addition, the social relations of women in France and Japan were shown to offset the effects of these deficits on depressive symptoms and well-being, but this was not the case for women in the US and Germany or for men in any of the four countries. Apparently not only gender, but also the unique cultural environment, influences how well an individual copes with even the same life events.

One additional approach to understanding environmental factors, life events and coping is through the study of relationship profiles among individuals of different cultures. Studies in the US[24] and Israel[25] indicate that common network types could be conceptualized as diverse (including both family and friends), predominantly family, predominantly friends and restricted (very limited). While all four existed in both cultures there were actually two types of restricted networks in the US, those restricted to only family and those restricted to only friends. Diverse networks were associated with the highest levels of well-being, whereas restricted networks were associated with the lowest levels. Interestingly, in the US, sample individuals who might be seen as vulnerable because of the limited number of family members in their networks were shown to be less so if there were friends in the network. Among those with limited friends in their networks, however, their vulnerability was not mediated by the presence of family members. In keeping with the increased awareness of the importance of the quality of relationships, the US study also demonstrated that quality of relationship, not just the existence of the relationship, influenced mental health and depressive symptoms. Additional profile studies[26,27] in the US, Japan and Germany reinforce these findings. The same four types of clusters were found, although each country also had additional unique clusters. The frequencies of these clusters and their associations with well-being varied by country: in the US the diverse network was the most prevalent, but this was less true in Japan and Germany. Nevertheless, only in the US and Germany was there an association between clusters and well-being. In the US and Germany, the diverse networks were associated with better mental health and the restricted networks were associated with poorer mental health. The unique, country-specific clusters and associations with well-being are interesting and informative. For example, in Germany people with friend-focused supportive networks had relatively high levels of depressive symptoms, perhaps suggesting that the lack of family support cannot be compensated for among this post World War II cohort of elders. The lack of association between network type and well-being in Japan and the poor well-being among those with high levels of friend support in Germany suggests that there may be deep-seated cultural differences that require explanation.

Further work is needed to better elucidate which aspects of social support are more important as strategies to cope with chronic stressors (e.g. a large social network, or higher quality support received regardless of quantity) in specific environments. In addition, more research is needed to develop a better understanding of the physiological mechanisms through which social support may exert its mental and physical health benefits[8,9].

Finally, several researchers have shown that the size of social networks and the frequency of contact with network members change over the life course. In general, older adults tend to have smaller social networks and have less frequent contact with members than younger adults, though this depends on how social networks are assessed. It is possible that these smaller networks represent a voluntary diminution because of perceived growing time constraints, as well as an increasing awareness of their own pending mortality among elders. Research suggests that this awareness may lead older adults to build deeper relationships with a small group of friends with whom they feel emotionally close rather than maintaining a large network. These changes in the nature of social support in later life may influence its utilization and effectiveness as a coping resource over the life course among different socioeconomic and ethnic groups, but more work among diverse groups at different points in the life course is needed[4,22].

Vascular Disease and Late-Life Depressive Disorder

Robert Baldwin

Manchester Mental Health & Social Care Trust, Manchester Royal Infirmary, Manchester, UK

DEPRESSION COMPLICATING VASCULAR DISEASE

Stroke and Mood Disorder

Stroke is associated with a high risk of depression as well as pathological laughing or crying and emotionalism. These are covered in Chapter 82.

Heart Disease

Soon after a coronary event about 15–20% of patients develop depressive symptoms[1]. By two months, out of 804 patients with stable coronary heart disease (CHD), 7.1% met criteria for major depression and 5.3% for generalized anxiety disorder[2]. These rates are at least double that expected in the general population.

Diabetes

The frequency of type 2 diabetes increases with age. In a cohort of patients aged 70–79 years followed for about six years those with diabetes had an increased rate of depression which attenuated after adjustment for diabetes-related co-morbidities, although this still represented a significantly increased risk compared to controls[3]. In this study HbA1c was a predictor of recurrent depression.

Blood Pressure and Depression

Whether the prevalence of depression increases as blood pressure rises is controversial. Rabkin *et al*.[4] found a three-fold higher frequency of major depression in 452 patients treated for hypertension whereas Jones-Webb *et al*.[5] found no association between resting blood pressure and self-rated depression in 4352 young subjects. Scalco *et al*.[6] suggest that a link between depression and hypertension may be mediated by hyperreactivity of the sympathetic nervous system. There is also a potential link between low blood pressure and depression. An inverse relationship between low diastolic blood pressure (below 75 mmHg) and depressive symptoms (such as fatigue, pessimism and sadness) was shown in a study of 846 elderly men without a psychiatric diagnosis[7].

Vascular Depression

Central to the notion of vascular depression is that vascular brain disease may predispose to depression, precipitate it or perpetuate it[8]. Features include reduced depressive ideation, more psychomotor retardation, poor insight, executive dysfunction (see below), greater disability and often an age of onset over 60. Magnetic resonance imaging (MRI) has shown higher rates of hyperintensities in the deep white matter and basal ganglia compared with control subjects, an effect seen most in late-onset cases[9]. Epidemiological studies confirm that the severity and location (especially in the basal ganglia) of white matter lesions (WMLs) seem to be causally related to late-life depression[10,11]. Pathological data show that WMLs in the brains of depressed patients are more likely to be ischaemic compared to those seen in the brains of non-depressed subjects[1].

A clear-cut association between the symptoms of vascular depression and common cerebrovascular risk factors (such as hypertension, smoking, hyperlipidaemia and diabetes) has not been shown and the vascular depression hypothesis has its critics. McDougall and Brayne[12] analysed 13 studies comparing depressive symptoms in subjects with and without co-morbid vascular conditions and concluded there was insufficient evidence to agree an operational definition of vascular depression. However, Sneed *et al*.[13] applied the statistical technique of latent class analysis to two naturalistic clinical trials of treatment in late-life depression. WML burden was the most accurate indicator of vascular vs. non-vascular depression. This internal consistency is important for confirming vascular depression as a distinct entity.

Chronic hypoperfusion (rather than small vessel infarction) may be another cause of vascular depression. Hypoperfusion might be secondary to hypotension (as discussed above), damage to blood pressure regulating mechanisms or arterial stiffness and/or failed compensation by the brain[14]. Brain hypoperfusion is not readily detectable by 'bedside' measures of cerebrovascular function other than perhaps by assessing postural hypotension.

The 'Depression–executive dysfunction syndrome' is an important feature of vascular depression[15]. Deficits involve executive tasks (planning, initiation and task persistence) and speed of information processing[16]. Clinically, these patients present with slow inefficient thinking, patchy memory impairment and are often apathetic.

DEPRESSION AS A RISK FACTOR FOR VASCULAR DISEASE

A number of studies have demonstrated that depression is a risk factor for cardiovascular and cerebrovascular events. However, the quality of evidence has been variable, for example fully accounting for factors which might explain such an association (such as severity of cardiac disease and vascular risk factors) markedly attenuates the association.

Stroke

Whether depression is a risk factor for stroke is controversial. In the Framingham study[17] participants aged 65 or below with raised depression scores on a rating scale were four times more likely to experience a stroke or transient ischemic attack compared with those of the same age without depression, after controlling for smoking status and education. The effect was not seen among those who were 65 or older. A positive association between the presence of depression and the risk of stroke across the entire adult age range was, however, found in another study[18].

Wouts *et al*.[19] reported that patients with baseline cardiac disease and depression were most at risk of later stroke and that there was a dose–response relationship: greater severity and chronicity of depression increased the risk. This may reflect the synergistic effect of depression and vascular disease or it may be that depressive symptomatology merely reflects the severity of underlying vascular disease (reverse causality).

Heart Disease

A meta-analysis concluded that depressed mood moderately increases the risk of myocardial infarction, coronary heart disease and cerebrovascular diseases by about the same amount (odds ratio between 1.43 and 1.63)[20] and adversely affects the prognosis of CHD to about the same degree[21]. The evidence for depression as an *independent* risk factor for vascular events has been sufficiently robust for the American Heart Association to recommend screening for depression in cardiac patients[22]. As a risk factor for cardiovascular disease, depression may rank somewhere between active and passive smoking[23]. However; adjustment for baseline factors, especially left ventricular function, substantially attenuates this association.

A Dutch epidemiological study of older adults showed that cardiac patients with minor (subthreshold) depression had a relative risk of subsequent cardiac mortality of 1.6 rising to 3.0 for those with major depression, after adjustment for confounding factors[24], an effect replicated by Ariyo and colleagues[25]. Negative effects on cardiac outcome are seen whether or not subjects are healthy at baseline and can last for many years[26] but generally manifest themselves within the first year after an acute myocardial infarct[22].

Diabetes

For diabetes, again there is some evidence that depression is a risk factor for diabetes but this may apply mainly to the non-insulin dependant type[27], the commonest form in older adults. The risk though is only modest once other factors (for example lifestyle) are accounted for. The occurrence of diabetic complications and poorer glycaemic control are more likely in depressed subjects because depression undermines motivation (Figure 75.1). Painful neuropathy may be another factor in triggering depression. Diabetes can cause small vessel pathology in the brain that leads to subcortical encephalopathy, not unlike that seen in vascular depression. This may lead to both cognitive impairment and depressed mood.

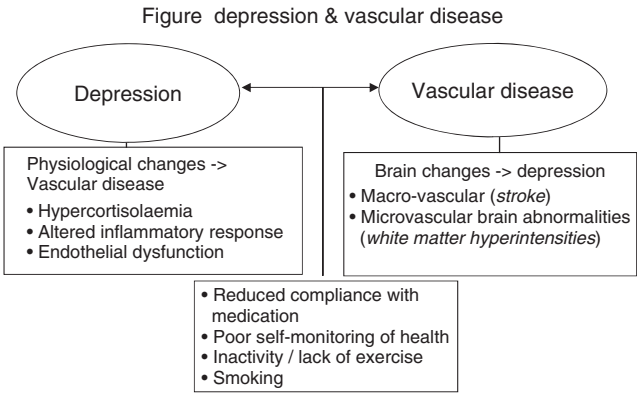

Figure 75.1 Depression and vascular disease

Hypertension

Some evidence suggests that depressed people have higher resting blood pressure than non-depressed people[6]. This may be because depression reduces medication conpliance, but one study of normotensive, non-elderly subjects followed over several years showed that high levels of depressive symptoms doubled the risk of hypertension[28].

Cholesterol

Low cholesterol may reduce serotonin available to the brain, although there is no convincing evidence which links cholesterol and depression via vascular disease. One study of statins did not demonstrate that lowering cholesterol increased depression[29].

POSSIBLE MECHANISMS OF CAUSATION

The relationship between depression and vascular disease is two-way (Figure 75.1) and there are aetiological factors which may be shared, such as genetic risk and lifestyle factors.

Genetic Mechanisms

In a study of older, middle-aged patients with late-onset depression a higher prevalence of the homozygous or heterozygous forms of the C677T mutation of the methylenetetrahydrofolate reductase enzyme (MTHFR) was found compared to those with early-onset depression[30]. This enzyme system is relevant to homocysteine, B_{12} and folate metabolism. A high level of homocysteine has been implicated in depression and in vascular disease[31]. No convincing role has been identified for the apolipoprotein E (*APOE*) gene in late-life depression.

Autonomic Dysfunction

Autonomic imbalance is associated with major depression and leads to sympathetic over-activity and/or parasympathetic under-activity,

with decreased heart rate variability, downregulated beta-adrenergic receptor function and decreased baroreflex sensitivity, making the diseased heart more susceptible to arrhythmia. Autonomic imbalance contributes to hypertension and atherosclerosis and is an independent risk factor for early cardiovascular mortality[32].

Platelet Dysfunction

A number of studies have found subtle changes in one or more platelet markers such as increased plasma platelet factor 4, beta-thromboglobulin and fibrinogen suggesting enhanced platelet activation. Platelets seem to be more activated in depressed patients with heart disease than in depressed patients without. The current evidence that antidepressants improve platelet function in depression is inconclusive, but it is known that selective serotonin re-uptake inhibitors (SSRIs) can normalize platelet hyperactivity[33].

Neuroendocrine Abnormality

Dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis and hypercorticolism are two well-known factors seen in major depression and associated with hippocampal damage and insulin resistance. The latter is a feature of the metabolic syndrome (abdominal obesity, hypertension and triglyceride abnormality) which is associated with increased cardio- and cerebrovascular disease as well as hypercoagulation, enhanced inflammatory responses and possibly endothelial damage (see below). The metabolic syndrome may be an intermediary linking depression to vascular disease.

Endothelial Dysfunction and Subclinical Atheroma

The vascular endothelium produces local vasoactive agents including nitric oxide, a vasodilator, and the peptide endothelin, a vasoconstrictor. Endothelial dysfunction is thought to precede and predict atheroma. In non-elderly subjects endothelial function was impaired irrespective of the presence of vascular risk factors[34]. Using carbon dioxide inhalation to assess vasomotor reactivity in the middle cerebral artery, depressive symptoms were associated with lower reactivity, which is a risk factor for cerebrovascular disease[35]. Tiemeier *et al*.[36] also found that carotid artery distensibility and pulse wave velocity (measures of arterial stiffness) were significantly associated with late-life depression. Lastly, the same group assessed coronary calcification and found that for every standard deviation increase in extracoronary atherosclerosis there was a 30% increase in depression[37].

These studies do not prove that depression causes vascular damage as causality could be in either direction. In a study of 324 adults, mean age 60.6 years[38], measures of carotid intima media thickness (IMT) to detect subclinical atheroma showed that baseline depressive symptoms were associated with a significantly greater three-year worsening in carotid IMT, even after adjusting for potential confounding factors. Similar conclusions were reached in a study of participants aged over 65[39], while another study of women showed that it was those with recurrent depression who were most at risk of subclinical atheroma[40]. Again this is not proof but it is strong evidence that depressive disorder is bad for a person's arteries.

Inflammatory Responses

Inflammatory markers include C-reactive protein (CRP), interlukin-6, tumour necrosis factor (TNF) and fibrinogen. In a two-year study, Frasure-Smith *et al*.[41] investigated the relationship between depression and inflammatory markers. Elevated depressive symptoms and raised CRP two months after an acute event were overlapping risk factors for later cardiac events in men. Carney *et al*.[32] demonstrated that fibrinogen was most associated with altered heart rate variability in depressed CHD patients and proposed that this could be attributable to deficits in parasympathetic modulation of immunity and coagulation. In contrast, another study found that major depression was associated with lower levels of CRP, fibrinogen and interleukin-6[42]. Nevertheless, pro-inflammatory cytokines are known to be expressed in the brains of those with late-life depression[43].

Behavioural and Psychological Factors

Lifestyle factors in depression include a reduced likelihood of taking medication such as antihypertensives and antidepressants, inactivity, lack of exercise, smoking and excessive alcohol intake. Clearly these can act as intermediaries between depression and vascular disease (Figure 75.1). It is also possible that patients with vascular disease subtly recognize that something is wrong before it becomes clinically apparent, thereby triggering depression.

Treatment

The presence of WMLs, especially when numerous, severe in extent or strategically located (as in the basal ganglia) is of relevance to poorer outcomes for depression in later life[44]. One study has shown that in patients with late-life depression nimodipine (a drug with vasoprotective properties) when combined with antidepressant medication led to a reduction in time to remission and a longer time before recurrence compared to placebo augmentation[45]. This needs to be replicated before vasoactive drugs can be recommended. Likewise, statins can improve vascular function[46] but it is not known whether they benefit depression. Omega 3 fatty acid is a promising treatment for vascular disorder but a study of two dosages in patients with late-life depressive symptoms did not show benefit to depression over placebo[47].

There is no evidence that antidepressants have adverse effects on the vasculature; possibly they are protective as SSRIs reduce platelet aggregation[48]. However some SSRIs can interfere with the metabolism of some cardiac drugs. Treatment of vascular depression with electroconvulsive treatment is effective but there is an increased risk of post-treatment confusion; a recent trial showing that repetitive trancranial magnetic stimulation (rTMS) was moderately effective in older patients with clinically defined vascular depression is of interest[49].

Apathy is common in both depression and vascular disease and amphetamines have been used to treat it. There are data showing that augmentation of an SSRI with methylphenidate can improve response rates in late-life depression[50] and that problem-solving treatment for the dysexecutive syndrome associated with depression is effective[51].

Metyrapone reduces adrenal cortisol synthesis. Broadley *et al*.[52] gave this drug to 30 depressed subjects (mean age 40) and 36 control subjects, showing that cortisol levels reduced in the depressed group and endothelial function improved. More innovative studies like this are needed.

CONCLUSION

The relationship between depression and vascular disease is two-way; that is, depression may lead to vascular disease and vascular

disease may trigger depression. The overall burden of vascular disease seems to be the best predictor of subsequent depression[53]. Clinical trials are needed to study whether drugs with vasoprotective properties can improve outcomes in depressive disorder. These will not be easy to conduct but in the meantime the management of depression should encompass the optimum treatment of both affective disorder and vascular disease.

Mood Disorders in Parkinson's Disease

John V. Hindle

Senior Clinical Lecturer in Neurodegenerative Diseases, School of Medical Sciences, University of Bangor, North Wales, UK, Consultant Physician Care of the Elderly, Llandudno Hospital, Llandudno, Conwy, UK

INTRODUCTION

Parkinson's disease is the second commonest cause of chronic neurological disability after stroke. The prevalence of Parkinson's disease increases with increasing age and in the United Kingdom is ~150 per 100 000 population with an incidence of 10.8 cases per 100 000 population. The mean age of onset of Parkinson's disease is in the seventies. The diagnosis is based on the presence of bradykinesia, rest tremor, rigidity and loss of postural reflexes, all of which are likely to be asymmetrical. It is now recognized that Parkinson's disease is much more than a motor disorder, having a spectrum of non-motor symptoms, which may occur prior to the onset of the motor signs. The non-motor symptoms of Parkinson's disease may have more impact on long-term quality of life than the motor symptoms[1]. Non-motor symptoms include autonomic impairment (e.g. constipation, sweating, urinary problems, dribbling and dysphagia), psychiatric problems (e.g. depression, dementia, psychosis), sleep disturbances (e.g. sleep behaviour disorder), sensory disturbances, nutritional problems and problems of balance and falls.

This chapter will focus on depression in Parkinson's disease, which is the most common psychiatric non-motor symptom of Parkinson's disease. Depression in Parkinson's disease is associated with a poor quality of life, excess disability and carer stress, and treatment of depression can reduce functional disability[2].

DIAGNOSIS

Depressive symptoms are common in Parkinson's disease, especially in elderly patients. Recognition of depression in Parkinson's disease can be confounded by the symptoms of Parkinson's disease itself. It is not clear whether the symptoms of depression in Parkinson's disease differ from those of depression in persons without Parkinson's disease. Some have suggested that patients with depression in Parkinson's disease have less guilt and sadness, whereas others have shown no difference when compared with patients with major depression. Anhedonia, or the lack of ability to enjoy, may be a clinical feature of Parkinson's disease and a key symptom of depression in Parkinson's disease. Tearfulness and emotionalism can occur in Parkinson's disease in a similar manner to stroke and must not be confused with depression. Clinicians should be aware of the difficulties in diagnosing mild depression and should have a low threshold for the diagnosis in Parkinson's disease.

Depression in Parkinson's disease probably represents a spectrum of mood disturbances from mood changes before Parkinson's disease motor symptoms through to depression associated with dementia. DSM-IV criteria may not adequately capture the spectrum of mood disorders seen in Parkinson's disease. A broader definition of mood phenotype to include greater levels of psychological distress and particularly anxiety may be more appropriate in Parkinson's disease. DSM- IV criteria for depression have been modified for depression in Parkinson's disease by a consensus group to be more inclusive of symptoms, to include subsyndromal depression, to specify the timing of assessment and to use informants in those who are cognitively impaired[3]. These modified criteria have been validated prospectively[4].

In a prospective cohort study of mood states in Parkinson's disease it has been shown mood disturbance can be divided into depression plus anxiety, depression alone, excessive worry and normal mood[5].

A variety of rating scales have been used to assess depression in Parkinson's disease although they may reflect the presence of depressive symptomatology rather than depressive illness. For screening, the Hamilton Depression Rating Scale (HDRS), Beck Depression Inventory (BDI), Hospital Anxiety and Depression Scale (HADS), Montgomery and Asberg Depression Rating Scale (MADRS) and the Geriatric Depression Scale (GDS) have been shown to be valid. For measurement of severity of depressive symptoms, the HDRS, MADRS, BDI and Zung Self-Rating Depression Scale (SDS) are recommended. The HADS and the GDS include limited motor symptom assessment and may, therefore, be most useful in rating depression severity across a range of Parkinson's disease severity[6]. The HDRS is based on a structured interview whereas the self-rated GDS takes 5 minutes to complete, has been validated against the HDRS and is used commonly in United Kingdom practice in older patients.

EPIDEMIOLOGY

People who are prescribed anti-parkinsonian drugs are more likely than controls or diabetics to be prescribed antidepressant drugs. Recent prescription of antidepressants is associated with an increased risk of developing Parkinson's disease since depression can be a premorbid sign of early Parkinson's disease[7]. A prevalence meta-analysis showed the weighted prevalence of major depressive disorder was 17%, and that of minor depression 22% and dysthymia 13%. Clinically significant depressive symptoms were present in

35%[8]. In a study of mood disorders in Parkinson's disease in the United Kingdom the prevalence of major depression was 2.8% and minor depression was 7.7% although there was a high prevalence of up to 80% of worry and tension[5]. Depression is often unrecognized. In a survey of 1000 patients, 50% reported depressive symptoms but only 1% identified themselves as depressed[9]. This may be because people do not believe themselves to be depressed unless they feel sad. Similarly doctors can miss depression, in the majority of cases.

Age, psychosis and depression in Parkinson's disease increase mortality, with a relative risk of 2.7 in patients with depression in Parkinson's disease compared with those without depression, with the increased risk not due to suicide. The prevalence of depression is not related to disease duration. The five-year cumulative risk of depression onset is around 10%. Depression in Parkinson's disease has a chronic course, and in one study, 56% of patients with major depression at baseline still had major depression at follow-up, while by combining major and minor forms, depression was chronic in 89% of cases[10]. Minor depression can lead to major depression in 11% of cases over a year and major depression will lead on to minor depression in 33% of cases and will remain chronic in the majority of cases[11].

DEPRESSION IN PARKINSON'S DISEASE AND COGNITION

It is unclear whether cognitive impairment in Parkinson's disease is a risk factor for depression or vice versa, or whether the two sets of symptoms represent a depressive–executive syndrome. Depression in Parkinson's disease may be similar in nature to depression associated with the depression–executive dysfunction syndrome of later life, which is associated with a slow or poor response to antidepressants. Depression and dementia combined may represent a subtype of Parkinson's disease[12]. Studies comparing depression in Parkinson's disease with depression without Parkinson's disease have shown similar cognitive deficits in both conditions, with reduced verbal fluency and attention deficits in depression and problems of abstract reasoning and set shifting in depression in Parkinson's disease. Patients with depressive pseudodementia respond to cueing in a similar manner to Parkinson's disease patients with subcortical dementia, which suggests that similar neural pathways are involved. Defining and diagnosing depression in Parkinson's disease in the presence of dementia are problematic since most rating scales are unsuitable. The Cornell Scale for Depression in Dementia has been used in research but takes 30 minutes to administer and may not be practical for screening in clinical practice[13].

AETIOLOGY

It is still unclear how much the depression in Parkinson's disease is due to the biology of the disease or is the result of psychosocial effects of chronic disease. An organic basis for depression is supported by a number of factors. Depression has been shown to be common in early disease, impairing activities of daily living and increasing the need for symptomatic therapy for Parkinson's disease[14]. One case–control study has shown that initiation of any antidepressant therapy may be associated with a higher risk of Parkinson's disease in the two years after the start of treatment, which suggests that depressive symptoms could be an early manifestation of Parkinson's disease, preceding motor dysfunction[7]. The early pathological stages of Parkinson's disease (Braak stage 1 and 2) with pathology in the brainstem linking to the limbic system before the onset of motor symptoms may be associated with depression and anxiety. Depressed patients are more likely to develop Parkinson's disease than they are to develop osteoarthritis or diabetes, suggesting some common underlying aetiological factors. At diagnosis, 9.2% of Parkinson's disease patients have a background history of depression compared with 4% of controls, again suggesting a link between depression and Parkinson's disease[15].

There is a possible familial aggregation of unipolar depression and Parkinson's disease. Female gender, young onset, akinesia, postural and gait problems and right hemi-Parkinson's disease have a significantly higher risk of depression in Parkinson's disease. Depression is more pronounced in 'off ' periods, possibly due to the deregulation of the locus caeruleus similar to that found in rapid cycling bipolar affective disorder. Positron emission tomography (PET) studies of depression in Parkinson's disease have shown reduced cortical serotonin (5HT) binding and reduced limbic noradrenaline and dopamine but no correlation with basal ganglia dopamine levels[16]. Abnormalities of the mesencephalon on MRI and transcranial ultrasound, frontal cortical under-activity on PET scans, and reduced caudate metabolism all suggest an organic basis for depression in Parkinson's disease.

Cerebrovascular disease is an important determinant in the aetiology of depression, especially in the elderly, and may also be an important contributory factor to the development of depression in the elderly Parkinson's disease patient.

There is no good evidence for a direct correlation between disease severity and depression. There is, however, considerable disadvantage and handicap associated with a chronic neurological disorder. Some workers have gone so far as to suggest a mainly psychosocial model for depression in Parkinson's disease. A particular pattern of negative beliefs and worries described as metacognitive style may increase the risk of depression in Parkinson's disease[17]. It is difficult to attribute functions of the human mind to purely neurochemical and structural changes, and intuitively it seems most likely that depression in Parkinson's disease has a major organic predisposition interacting with psychosocial factors influencing its presentation.

MANAGEMENT

The general principles of management of depression in chronic physical health problems are outlined in the guideline *Depression with a Chronic Physical Health Problem* published by NICE[18].

Psychological Therapies

Provision of support, advice and counselling to both patients and carers may be all that is needed in sub-syndromal and mild cases. A clear explanation that depression is a common intrinsic part of Parkinson's disease is needed in order for patients and carers to accept appropriate help and treatment. Support groups can provide an informal form of group therapy. Counselling and support can be provided for patients and carers by social workers and counsellors with a special interest in Parkinson's disease. In the United Kingdom the Parkinson's disease nurse specialists have a key role in the provision and coordination of these support services in the management of depression. Cognitive behavioural therapy (CBT) can benefit mild or moderate depression in the elderly but there have only been small open studies of CBT in patients with depression in Parkinson's disease[19]. Group-based cognitive therapy or computerized cognitive

therapy has not been studied in depression in Parkinson's disease. Bright light therapy has been shown to have a positive effect on mood and motor function in a small study[20]. Exercise interventions may help function in Parkinson's disease but the effects on mood have not been well studied [21].

Drug Treatments

There is insufficient evidence from randomized controlled trials of the safety or efficacy of any antidepressant in depression in Parkinson's disease[22]. In a meta-analysis of the treatment of patients with depression in Parkinson's disease compared with elderly depressed patients without Parkinson's disease, the newer antidepressants were well tolerated in depression in Parkinson's disease. Patients with depression in Parkinson's disease may benefit less from antidepressant treatment, particularly SSRIs, than do elderly patients without Parkinson's disease. The meta-analysis showed a positive effect for depression treatment in patients with depression in Parkinson's disease whether with active drug or placebo[23]. A large placebo effect because of the expectation of reward may be found in Parkinson's disease and this may be caused by placebo-induced dopamine or serotonin release in depression. This placebo effect may be an important consideration in future strategies for the management of depression in Parkinson's disease and emphasizes the need for placebo-controlled trials. In a veterans' study of the impact of a diagnosis of Parkinson's disease on depression treatment the presence of a Parkinson's disease diagnosis had little impact on the frequency and type of antidepressant treatment.

Efforts to improve the care of depressed Parkinson's disease patients should focus on improving recognition, ensuring adequacy of treatment and evaluating the efficacy of existing antidepressants[24].

Dopaminergic Treatment

The first option in the drug treatment of depression in Parkinson's disease is to ensure optimal dopaminergic treatment. Mood elevation and anxiety reduction can be demonstrated using levodopa infusions, and therefore smoothing out fluctuations may be important in the control of depression in Parkinson's disease. Optimization of dopaminergic therapy could include the addition of a non-ergot dopamine agonist. Direct-acting dopamine agonists acting on the D3 receptors (e.g. pramipexole) in the limbic system may have an antidepressant effect, and this may be due partly to an effect on psychomotor retardation. Pramipexole has compared favourably with sertraline[25]. Catechol-*O*-methyltransferase (COMT) inhibitors may have a similar effect through enhancement of dopaminergic transmission and reduction in motor fluctuation, but this has not been studied in trials. Older reviews suggested that selegeline may be effective; however, later evidence-based reviews have not confirmed this.

Serotonin Re-Uptake Inhibitors

A favourable side effect profile possibly makes selective serotonin re-uptake inhibitor (SSRI) antidepressants the first-line treatment in depression in Parkinson's disease, although trial evidence for efficacy is limited[23]. There is a theoretical risk of increased parkinsonism with SSRI antidepressants, and some case reports exist of akathisia, tardive dyskinesia and dystonia, but there is no clinical evidence that these effects are significant. Possible increased suicide risk need to be considered, especially when treating younger patients. The pattern of liver enzyme induction varies from one SSRI to another, and this may influence the choice of drug. There is no trial evidence that the SSRI antidepressants help symptoms of low mood outside a depressive illness in Parkinson's disease. A generic SSRI such as sertraline may be the best choice for efficacy and tolerability since it has low propensity for interactions[18].

Combined Re-Uptake Inhibitors

The noradrenaline and serotonin combined re-uptake inhibitors may have a role in depression in Parkinson's disease but have yet to show advantages over SSRI drugs. Venlafaxine, a serotonin and noradrenaline re-uptake inhibitor (SNRI) has an anxiolytic effect with a rapid onset of action in the elderly at 1–2 weeks although these effects have not been demonstrated in depression in Parkinson's disease. Mirtazepine, a derivative of mianserin, is a noradrenaline and specific serotonin antidepressant (NaSSA) which may have a rapid onset of action. Theoretically this profile of neurotransmitter action may be useful in depression in Parkinson's disease. Mirtazepine may produce weight gain which can sometimes be used to good effect in depression in Parkinson's disease. There are only a few uncontrolled reports using reboxetine or nafazodone and no studies of duloxetine in patients with depression in Parkinson's disease[18].

Tricyclics

An evidenced-based review suggested that amitriptyline should be considered in the non-demented patient with depression in Parkinson's disease[26]. A trial comparing the short-term efficacy of the predominantly noradrenergic tricyclic desimipramine with citalopram showed a significant improvement in depression at 30 days with a more rapid onset of effect at 14 days with desimipramine. This effect was outweighed by the side effects of desimipramine which can include increased tremor in Parkinson's disease[27]. Other studies show that imipramine is most effective in patients with rigidity and nortriptyline may improve Parkinson's disease. In elderly patients, the anticholinergic side effects of these drugs, including confusion, hallucinosis, urinary retention, blurred vision, faecal impaction and dry mouth, reduce their tolerability. Since anticholinergic drugs are now avoided by most experts in the treatment of Parkinson's disease[22], tricyclic antidepressants are usually reserved for situations where other antidepressants have failed.

Other Drug Treatments

Moclobamide, a reversible monoamine-oxidase A (MAOA) inhibitor is used rarely in depression in Parkinson's disease. Some have combined MAOA inhibition with MAOB inhibition, showing enhanced antidepressant activity with no hypertensive effect. High-dose SSRI regimes have not been studied in depression in Parkinson's disease and are only weakly supported by trial evidence outside Parkinson's disease. From experience the combination of an SSRI in the day and mirtazepine at night may be useful in resistant depression in Parkinson's disease.

Other High-Intensity Therapy of Depression in Parkinson's Disease

Electroconvulsive therapy (ECT) has been shown to be effective in the treatment of depression, motor fluctuations and drug-induced

mania. Motor symptoms, especially rigidity, have been shown to respond and relapse more quickly than depression, the response being greater in the elderly. In a randomized controlled trial, repetitive transcranial magnetic stimulation (rTMS) has been shown to improve depression in Parkinson's disease to the same extent as fluoxetine[28]. The effects on depression may last only two weeks, and concurrent antidepressants are needed. In future rTMS may be a useful alternative to ECT since it has a more focal effect, reducing adverse cognitive symptoms and avoiding the need for a general anaesthetic, in addition to improving motor function. Stimulation over the motor cortex can reduce motor slowing and improve cognition in elderly Parkinson's disease patients. rTMS requires further evaluation, but has a promising future role in the treatment of depression in Parkinson's disease.

Summary of Management of Depression in Parkinson's Disease (Figure 76.1)

Treatment should take into account a patient's needs and preferences. People with depression in Parkinson's disease should have the opportunity to make informed decisions, including advance decisions and advance statements, about their care and treatment, in partnership with their practitioners[18]. It is important to consider both Parkinson's disease-related and non-Parkinson's disease-related

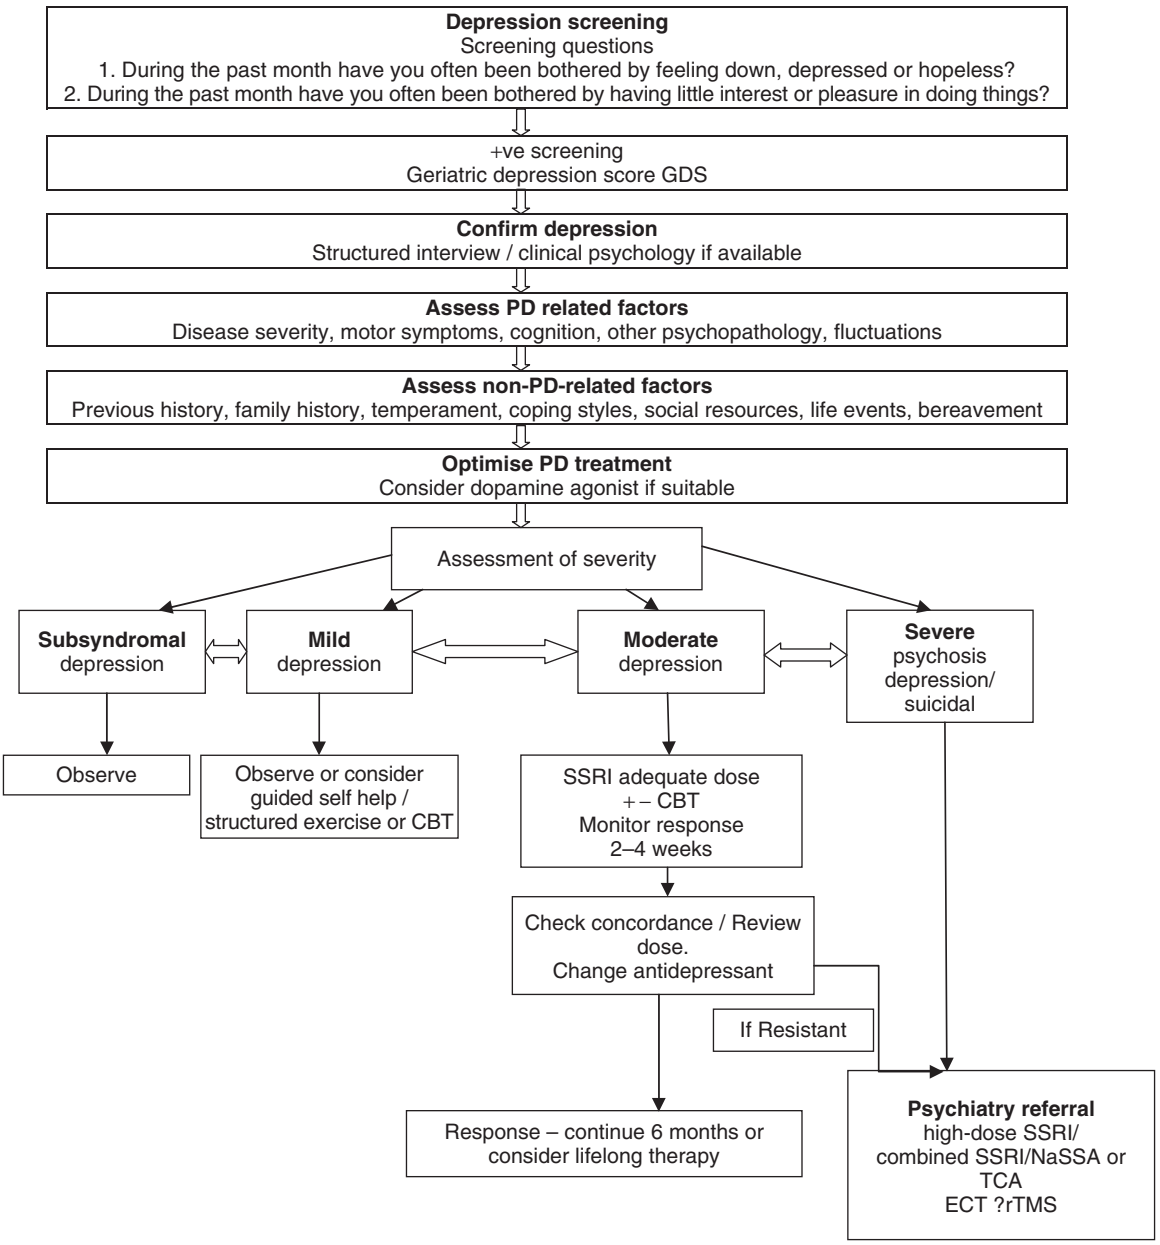

Figure 76.1 Depression screening. PD, Parkinson's disease; CBT, cognitive behavourial therapy; SSRI, selective serotonin re-uptake inhibitor; NaSSA, noradrenaline and specific serotonin antidepressant; TCA, tricyclic antidepressant; ECT, electroconvulsive therapy; rTMS, repetitive transcranial magnetic stimulation

factors. Parkinson's disease-related factors include reviewing and managing disease severity, motor symptoms, cognitive impairments, other disease-related psychopathology, and reviewing psychiatric side effects and fluctuating response to medications[29].

Non-Parkinson's disease-related factors include obtaining insights into previous psychiatric history, family history, temperament, coping styles, social resources and life events which all contribute to the aetiology of depression and may also significantly affect its management[29].

Two screening questions could be used and then if the person responds positively to these a rating such as the GDS completed. Once depression is identified a stepwise collaborative approach to management is based on an assessment of severity and response to interventions[18]. Both the number and severity of symptoms, as well as degree of impairment determine the severity of depression. A clinical assessment of severity of depression, into subsyndromal, mild, moderate and severe based on DSM categories as per the NICE guidelines may help with management decisions[18]. Stepped care encompasses intervention ranging from support, low intensity psychosocial interventions, and medication through to ECT and inpatient management.

In subsyndromal and mild cases a watch and wait approach may be appropriate. Counselling or CBT may be considered in mild cases. In moderate depression, the first step is to optimize dopaminergic therapy and to consider the use of a dopamine agonist if the patient is suitable. If there is no improvement, a trial of an adequate dose of a SSRI antidepressant should be considered with careful monitoring of the patient's mood and motor function. The presence of anxiety may influence the choice of a more sedative antidepressant such as mirtazepine. There is a small risk of producing a serotonin syndrome (hyperpyrexia, agitation, confusion) when selegeline is combined with tricyclics or SSRI antidepressants. The response to an antidepressant is best reviewed after 2–4 weeks of a therapeutic dose[18]. If there is no response after this period, a change of antidepressant can be considered. Patients should be seen on a regular basis at intervals of 2–4 weeks in the first three months and at longer intervals thereafter, if response is good. Antidepressants are usually continued for six months after remission. Two or more episodes of depression have been considered an indication for long-term treatment, but the chronic nature of depression in Parkinson's disease suggests that lifelong therapy may be needed in most cases. Referral to a psychiatrist should be considered if there is a severe depression with psychosis – especially if insight is lost, if there is medication failure in chronic depression or if there are suicidal ideas. The development of suicidal ideas or life-threatening complications, such as refusal to eat, should be taken seriously, and ECT may be considered.

Epidemiology of Depression: Prevalence and Incidence

Ruoling Chen[1] and John Copeland[1,2]

[2]*Division of Psychiatry, University of Liverpool, UK*

INTRODUCTION

The most common geriatric psychiatric disorder is depression. Depression in older people has become a serious health-care issue worldwide. But it is often ignored, and thus opportunities are lost for prevention and early treatment. Blazer in his introduction to this section in the second edition of this book states, 'Many symptom checklists have been used to estimate the burden of depressive symptoms in community populations. The results of these studies are remarkably consistent, with the range of significant depressive symptoms estimated to be 10–25%'. He quotes from 10 studies. In order to update information on prevalence and incidence of depression, we have now been able to review 38 studies of prevalence and 10 of incidence appearing in the English language during the last 10 years. Blazer continues, 'Lower prevalences of major depression have been found in more rural samples with an estimate of less than 1% in a North Carolina rural sample, whereas urban studies have typically estimated higher prevalence. The prevalence of dysthymic disorder is generally higher than that for major depression, approximately 2–8%, depending on the instrument used in the survey'.

The problem that Blazer highlights including the diverse case-finding methods causing difficulties in drawing comparisons has substantially increased since the second edition. Most of the studies reviewed used at least one of the following instruments to diagnose depression, including those clinically based, replicating a psychiatrist's diagnosis using ICD-10, DSM-III,-R DSM-IV criteria, CSNMD (clinically significant non-major depression) applied to the results of case-finding instruments, others to the results of psychiatrists' clinical examination, CIDI and GMS-AGECAT (Geriatric Mental State-Automated Geriatric Examination for Computer Assisted Taxonomy), and those based on scale cut points such as GDS-30, 15-item GDS (score >5), EURO-D scale, CES-D (Center for Epidemiological Studies Depression Scale). Although there is some correspondence between these methods, precise comparisons are difficult to make. There is also the problem of the type of selection of samples, whether or not they were purely community based, that is to say people living in their own homes or also in residential accommodation, or included hospital admissions, especially in those countries where hospitals still accommodate large proportions of patients. Are the samples randomly selected and what were the dropout rates? Was a one-stage method of identification used or a two-stage method with loss due to death, illness or refusal between stages (a particular problem in the calculation of incidence rates). Studies report their samples, grouping the data in different ways. Most do not state the kind of case they are trying to identify. The majority are likely to be interested in cases suitable for intervention but use DSM or ICD criteria aimed specifically at improving reliability between psychiatrists, and therefore likely to lead to a narrower more sharply defined concept of a case than would be acceptable to most clinicians who, as a consequence, are tempted to invent their own 'subsyndromal' cases for treatment. Nevertheless, in spite of these difficulties it may be possible to draw broad conclusions.

Blazer warns: 'One of the major tasks facing psychiatric epidemiologists studying depression cross-nationally in the elderly is to explain the residual depressive symptoms in community samples not easily captured by the usual diagnostic categories' and goes on to quote the 34 studies of the prevalence of late-life depression where the prevalence varied from 0.4% to 35%[1]. Arranged according to diagnostic category, major depression was relatively rare (weighted average prevalence of 1.8%), minor depression more common (weighted average prevalence of 9.8%) while all depressive syndromes deemed clinically relevant yield an average prevalence of 13.5%. Depression was more common among women and among older people living under adverse socioeconomic circumstances.

Below, we review 38 studies of the prevalence of depression and 10 of incidence across the world, published over the last 10 years, divided by continent and whether clinically-based diagnosis was used or scale cut scores.

PREVALENCE OF DEPRESSION IN EUROPE (TABLE 77.1)

The EURODEP study[2] (1999) reported the prevalence of depression in nine countries in Europe, which had all used the GMS-AGECAT assessment and computerized differential diagnosis. This instrument was designed to facilitate large epidemiological studies in older people where psychiatrists could not be employed for screening every

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

case. A case was defined as one requiring some form of intervention. This package was prepared before DSM-III and ICD-10 revisions but AGECAT cases of depression have been shown in a number of studies to equate with major depression, dysthymia and 'depression not otherwise specified'.

In the EURODEP study[2] all subjects were aged 65 or over, randomly selected or total samples in the community except for the Dublin centre which sampled a general practice, to yield a total of 13 803 individuals. Substantial differences in the prevalence of depression were found, with Iceland having the lowest level at 8.8%, followed by Liverpool 10.0%, Zaragoza 10.7%, Dublin 11.9%, Amsterdam 12.0%, Berlin 16.5%, London 17.3%, Verona 18.3% and Munich 23.6%. There was no constant association between prevalence and age. A meta-analysis of the pooled data on the nine European centres yielded an overall prevalence of 12.3% (95% CI, 11.8–12.9%); for women 14.1% (95% CI, 13.5–14.8%) and for men 8.6% (95% CI, 7.9–9.3%).

Using Clinically Based Diagnosis

DSM-IV criteria. Prevalence of major depression in France. Ritchie *et al*.[3] randomly recruited 1873 non-institutionalized persons aged 65 and over from the Montpellier district electoral rolls to assess current and lifetime depression symptoms using the Mini-International Neuropsychiatric Interview. Cases identified were re-examined by a clinical panel. Major depression was found to be 3% and lifetime prevalence 26.5%. A level consistent with many other studies.

GMS-AGECAT. Como (personal communication) reported the findings of the random community study of participants aged 65 and over in Tirana, Albania, which formed part of the EURODEP study but entered at a later date. Prevalence levels of depression were 19.3%. This is the first EURODEP study from a Muslim state in Europe. de Jonge and colleagues found levels of depression in the second Zaragosa study of persons aged 55 and over of 11.2%[4]. McDougall *et al*.[5] reported the prevalence of depression in the Medical Research Council Cognitive Function and Ageing Study (MRC-CFAS), and the prevalence of depression and depressive symptoms in those living in institutions[6]. The MRC-CFAS is a population-based cohort comprising 13 004 individuals aged 65 and above from five sites across England and Wales. A stratified random sub-sample of 2640 participants were interviewed by GMS-AGECAT, showing that the prevalence of depression in those living at home was 9.3% (similar to the 9.2% in an earlier Liverpool study ($n = 5222$)[2] and for those living in institutions was 27.1%. The prevalence increased if subjects with concurrent dementia were included. This is of interest because such cases of dementia are often excluded in surveys of depression but may require treatment for depression. Also, such exclusion may give a spurious impression of a fall in the proportion of people with depression with increasing age as the prevalence of dementia escalates. Depression was more common in women (10.4%) than men (6.5%) and was associated with functional disability, co-morbid medical disorder and social deprivation.

Using Scale Scores

EURO-D based prevalence in 10 European countries. Castro-Costa *et al*.[7] administered the EURO-D with score ≥ 4 to cross-sectional nationally representative samples of non-institutionalized persons aged 50 years and over ($n = 22\,777$) across 10 European countries – Denmark, Sweden, the Netherlands, Germany, Austria, Switzerland, France, Spain, Italy and Greece – as part of the SHARE study. The distribution of gender and age did not differ between countries. Educational levels were lowest in the Latin countries (France, Italy and Spain) and in Greece. The highest country-specific depression prevalence rates were found in France (33.7%), Italy (33.7%) and Spain (36.8%), with a 9% difference between the lowest of these (33% in France) and the next lowest (24% in Greece). Prevalence in the remaining countries was 18–19%. Heterogeneity between countries was statistically significant ($p < 0.001$). The pattern and extent of between-country differences were not affected by direct standardization for gender, age, education, verbal fluency or memory. But the SHARE data are limited by the relatively low proportion of households and individuals responding. This may, unfortunately, represent a secular trend in more developed countries. The net effect may be an underestimation of the true prevalence of depression[8,9].

The EURO-D scale was developed in order to include more centres in the EURODEP study. It was shown to have strong conceptual validity and high internal consistency when applied to data from 21 724 subjects. EURO-D scores tended to increase with increasing age, unlike the levels of prevalence of depression. Women had generally higher scores than men, and widowed and separated subjects were higher than those who were currently or never married.

GDS in the Netherlands. Stek *et al*.[10] assessed the prevalence of depression and correlates from a representative sample of 599 community-based 85-year-old subjects with a MMSE >18. The prevalence of depression, as measured with a GDS-S score of 5 points or more, was 15.4%, not very different from the EURODEP level for Amsterdam of 12.0%.

CES-D in the Netherlands. Van't *et al*.[11] assessed the prevalence of depressive symptomatology and risk indicators in 2850 participants aged 75 years or more in the PIKO study. The prevalence of depressive symptoms was 31.1% across all participants.

PREVALENCE IN THE AMERICAS (TABLE 77.2)

Using Clinically Based Diagnosis

DSM-IV. One study[15] in the United States examined the current and lifetime prevalence of depressive disorders in 4559 non-demented individuals aged 65 to 100 years. This sample represented 90% of the elderly population of Cache County, Utah. The researchers employed DSM-IV criteria for major depression, dysthymia and subclinical depressive disorders using a modified version of the Diagnostic Interview Schedule. The point prevalence of major depression was 4.4% in women and 2.7% in men ($p = 0.003$), similar to the level (3%) found by Ritchie *et al*.[3] in France using similar criteria. Other depressive syndromes were surprisingly uncommon (combined point prevalence, 1.6%), and the current prevalence of major depression did not change appreciably with age. They also estimated that lifetime prevalence of major depression was 20.4% in women and 9.6% in men ($p < 0.001$) (Ritchie 26.5%), decreasing with age.

In Quebec, Preville *et al*.[16] used the 'Enquete sur la sante des aines' study, conducted in 2005–6, to obtain a representative sample ($n = 2798$) of community-dwelling older adults. Of this sample, 12.7% met the criteria for depression, mania, anxiety disorders or benzodiazepine dependency. The 12-month prevalence rate of major depression was 1.1% (again demonstrating the low levels found with these criteria) and the prevalence of minor depression was 5.7%.

Table 77.1 Prevalence of depressive symptoms in community samples of older adults in Europe

Author	*Sample*	*n*	*Screening method*	*Findings*
Clinically based diagnosis				
Como (personal communication)	Random community sample in Tirana, Albania (65 years and over) part of the EURODEP Consortium	1239	GMS-AGECAT	19.3% depression
de Jonge *et al*.[4]	Second random community sample in Zaragoza, Spain (55 years and over)	4803 (M2771, F2032)	GMS-AGECAT	11.2% depression, 2.7% men, 9.3% of women
Ritchie *et al*.[3]	Community sample in France (65 years and over)	1873	Mini-International Neuropsychiatric Interview DSM-IV criteria	3% for major depression (26.5% with major depression lifetime prevalence)
Intorre *et al*.[12]	Community sample in Rome, Italy (70–85 years)	359 (M167, F192)	Mental health assessment	9% men, 19% women with possible depression
McDougall *et al*.[5]	Five centre community samples MRC CFAS (England and Wales) (65 years and over)	2640	GMS-AGECAT	9.3% depression (95% CI, 7.8–10.9%) living at home
Score cut point				
Stek *et al*.[10]	Community sample in the Netherlands (85+) MMSE >18	500	GDS-S (score 5 or more)	15.4% depression (no age, gender or racial difference in prevalence) 25% of participants who were seen by their GP with depressive symptoms
Jansson *et al*.[13]	Twin pairs in Sweden (50+, mean 72) female monozygotic (MZ), Male MZs, Female DZs, Male DZs, opposite-sex DZs)	959 (123, 90, 207, 109, 430)	CES-D	16% men, 24% women (clinically significant depressive symptoms)
Wilson *et al*.[14]	Community sample living alone in their own home in UK (80–90)	376	GDS (score 5 or more)	21% depression
Castro-Costa *et al*.[7]	Community sample in 10 European countries (50+)	22 777	EURO-D (score 4 or more)	The prevalence of symptoms higher in the Latin ethno-lingual group 33.7% France; 33.7% Italy; 36.8% Spain other countries in between these and 24.0% Greece
van't *et al*.[11]	Community sample in the Netherlands (75+) the PIKO study	2850	CES-D (score 16 or more)	31.1% depression

ICD-10, SCAN. Two studies were conducted in Brazil, and one study in Peru, Mexico and Venezuela. Costa *et al*.[17] investigated the prevalence and correlates of common mental disorders with semi-structured interviews administered by a psychiatrist. During the study, a two-phase population survey of 392 persons aged 75 years and over were screened for depression and mental disorders using the General Health Questionnaire (GHQ-12) and Geriatric Depression Scale (GDS). In the second phase, 20% were evaluated using the SCAN to generate ICD-10 diagnoses. The prevalence of depressive episode was 19.2% with no effect of gender or age. Lay-administered interviews were thought to underestimate the prevalence of mental disorders in older people and they recommended one-month prevalence as more appropriate for the oldest-old given patchy recall of distant experiences.

DSM-IV. Xavier *et al*.[18] described the prevalence of minor depression as 12% of the oldest-old in a random representative sample ($n = 77$ subjects) aged 80 years and over from the Brazilian rural southern region using DSM-IV criteria. A small but interesting study which was found to be consistent with others quoted here concerning younger age groups.

DSM-IV and ICD-10 GMS-AGECAT. Investigating the prevalence in five locations in Latin America, Guerra *et al*.[19] conducted a one-phase cross-sectional survey of 5886 people aged 65 and over from urban and rural locations in Peru and Mexico and an urban site in Venezuela. Depression was identified according to diagnostic criteria, and scale scores with EURO-D cut-off point. DSM-IV major depression prevalence varied between 1.3% and 2.8% by site (consistent with other sites in Europe and North America), ICD-10 depressive episode between 4.5% and 5.1%, GMS-AGECAT all forms of clinical depression between 30.0% and 35.9% (high, because of the low level of education stage one of the algorithm was used, i.e. level of depression in all participants regardless of other diagnoses such as dementia), and for EURO-D depression between 26.1% and 31.2%. The prevalence of EURO-D depression was in a similar range of 24–36.8% in Latin countries in Europe. The prevalence of DSM-IV major depression was lower than that in men in the United States (4.4% in women and 2.7% in men). The authors of this important study (part of 10/66 Dementia Research Group) from low and middle income countries draw several conclusions, 'the population attributable prevalence fractions suggest that 13.6% of the prevalence of severe disability in Peru, 32.4% in Mexico and 31.7% in Venezuela could be independently attributed to depression'; 'a strong and independent association between subsyndromal depression and an established criteria of relative severe disability, 15 or more disability days in the past month, would appear to indicate that DSM-IV and ICD-10 diagnostic criteria might indeed be missing a substantial proportion of clinically significant cases. We have also demonstrated... that the true population burden of depression is significantly under estimated by these very narrow diagnostic definitions'; 'late-life depression in Peru, Mexico and Venezuela is similar to that seen in Europe'.

Using Scale Scores

Alvarado and colleagues[20] in the SABE (Salud Bienestar y Envejecimiento) study interviewed a sample of 10 661 persons aged 60 and over in seven Latin American and Caribbean countries using the GDS. They found the prevalence of depression varied from 0.4–5.2% in men and 0.3–9.5% in women. They concluded that current socioeconomic conditions and health status as well as functional disabilities mainly accounted for gender differences in prevalence.

PREVALENCE IN ASIA – CHINA AND TAIWAN (TABLE 77.3)

Using Clinically Based Diagnosis

GMS-AGECAT studies in mainland China. In urban communities, the prevalence of depression was 2.2% – about five times lower than that of older people in Liverpool including older people of Chinese origin[22] – but in poorer rural communities depression was higher at 6.0%[23]. Could these low levels be due to failure to recognize cultural ways of expressing depression? This would seem unlikely because the GMS-AGECAT diagnosis, as in other studies, was formally validated by local psychiatrists using a translated version and comparing their diagnosis with one provided by computer. Chong *et al*.[24] and Chen *et al*.[25] investigated the one-month prevalence of clinically significant depression in 1500 subjects aged 65 years and older, randomly selected from three communities of urban and rural elderly in southern Taiwan. One-month prevalence of depressive neurosis and major depression were 15.3% and 5.9%, respectively. These results reflect similar differences in prevalence rates from Europe and North America found in surveys of younger adults.

CIDI. In a Beijing study[26] involving urban and rural regions, the overall 12-month prevalence of depression was 4.33% (2.65% in men, 5.83% in women). The overall lifetime prevalence was 7.83% (4.65% in men and 10.66% in women).

Using Scale Scores

CES-D. The prevalence of depression was 9.5% (6.7% men and 11.7% women) in a two-centre study by Pan *et al*.[27]: north China (Beijing) 14.9% rather different from south China (Shanghai) 4.1% ($p < 0.001$). These also appeared to be low rates for a *CES-D* study.

GDS (≥ 8). In Hong Kong, three urban random community samples were undertaken by Li *et al*.[28] examining obesity and depression among 18 750 men and 37 417 women aged 65 or over in health centres using the 15-item Chinese GDS (CGDS; ≥ 8) found 4.9% depression in men and 7.9% for women ($p < 0.001$). Since attendance at the health centre was voluntary severe depressive symptoms may have been under-represented. Chi *et al*.[29] using the same instrument with a random community sample of 917 people aged 60 and over found depression levels of 11.0% men and 14.5% women, a prevalence rate not dissimilar to that in the United States, England and Finland. The same scale was used by Chou *et al*.[30] in a representative community sample of 1903 Chinese aged 60 and above, finding prevalence rates for the oldest-old of 31.1%; for those aged 70–79, 22.4% and for those 60–69, 19.1%. Chiu *et al*.[31] compared depression in urban and rural elders finding that 20.1% of urban elders and 12.8% of rural samples were classified with depressive symptoms. Tsai *et al*.[32] using stratified random sampling of 1200 elderly participants from northern, middle, southern and eastern regions of Taiwan found the prevalence of depression to be 13%, within the range of previous findings 4.9–20.1%[28,31].Overall, the prevalence of depression based on this scale and cut-off point in Taiwan and Hong Kong lay between 4.9–31.1% – an apparently large geographical disparity.

The GMS-AGECAT prevalence of depression was higher in rural than that in urban mainland China, while in Taiwan the urban sample had a relatively higher prevalence of depressive symptoms than that found in rural elders[31].

Table 77.2 Prevalence of depressive symptoms in community samples of older adults in North, South and Central America

Author	*Sample*	*n*	*Screening method*	*Findings*
North America – Clinically based diagnosis				
Steffens *et al*.[15]	Community sample in Cache County, Utah (non-demented; 65–100 years)	4559	Diagnostic Interview Schedule	2.7% men, 4.4% women (major depression), prevalence did not change with age. 1.6% with other depressive syndromes 9.6% men, 20.4% women (lifetime depression, decreasing with age)
Heo *et al*.[21]	Community sample – nationally representative survey data from 2006 BRFSS in US (18+ years)	188 292	Doctor diagnosed	15.7% depression; 11% men, 20.6% women (117% increase from year 2005–50 in older people)
Preville *et al*.[16]	Community sample in Quebec	2798	DSM-IV	12.7% depression (12-month prevalence: 1.1% major depression, 5.7% minor depression)
South and Central America – Clinically based diagnosis				
Xavier *et al*.[18]	Community sample of Italian descent in rural Southern Brazil (80+)	77	DSM-IV	12% minor depression (frequency greater in women)

PREVALENCE IN OTHER ASIAN COUNTRIES (TABLE 77.3)

Using clinically Based Diagnosis

GMS-AGECAT with ICD-10, DSM-IV. Rajkumar *et al*.[33] investigating 1000 participants aged over 65 years from a rural south Indian community using the Geriatric Mental State, ICD-10 and DSM-IV diagnoses of major depression within the previous one month found 12.7%.

GMS AGECAT with DSM IV. Suh[34] with a community sample of 1241 persons in Korea aged 65 and over found 10.5% depression.

GMS AGECAT. With the community sample of 1156 people aged 65 and over in Nakayama, Japan, Ikeda *et al*.[35] found a level of depression of of 5.8% (AGECAT) and 4.3% (DSM IV) (personal communication).

GMS AGECAT (Arabic version). Ghubash *et al*.[36] investigated the prevalence of depression within a random sample of households representing the United Arab Emirates national population. They screened 610 UAE nationals aged 60 years and over, irrespective of the age of other individuals in each household. The researchers found 20.2% with depression at syndrome case level. An important study and the only one so far from Arabic countries. More studies are required from the Islamic world as a whole.

Using Scale Scores

GDS-15 cut-point 5/6. Wada *et al*.[37] used this scale to assess depression in a 2695 community sample aged 60 and over living in five rural Asian towns. They found 29.0% of depression overall. Indonesia was 33.8%, (sample size 411), Vietnam 17.2% (379) and Japan 30.3% (1905). Malhotra *et al*.[38] using the same scale and cut-off point with an 1181 community sample of Sri Lankans (aged 60 years and over) found a prevalence of depression of 27.8% overall (24.0% men, 30.8% women), lower than in Indonesia and Japan and higher than in Vietnam. In Japan, Niu *et al*.[39] assessed depression in 1058 community-dwelling Japanese individuals aged 70 years and over using the 30-item Geriatric Depression Scale with two cut-off points: 11 (to include most clinical depressions) and 14 (severe depressions) yielding 34.1% and 20.2%, respectively.

GDS (Korean). The majority of studies have rarely examined both urban and rural populations simultaneously. Kim *et al*.[40]

Table 77.3 Prevalence of depressive symptoms in community samples of older adults in Asia

Author	*Sample*	*n*	*Screening method*	*Findings*
Clinically based diagnosis				
2. Chong *et al*.[24]	Community sample in Taiwan (65+)	1500	GMS-AGECA	5.9% major depression (one month) 15.3% depressive neurosis high

Malhotra *et al*.[38]	Community sample in Singapore (60+) of elderly Sri Lankans	1181	GDS-15 (score ≥6)	27.8% depression 24.0% men 30.8% women

investigated 485 urban-dwelling and 649 rural-dwelling participants within Kwangju, South Korea for depression. No differences rural/urban were found, findings being consistent with other studies in China.

GDS Thai (TGDS). Thongtang *et al*.[41] using in addition the Thai Mini Mental State Examination (TMSE), screened 1713 elderly people in 35 communities from four districts finding a prevalence of depression of 12.7% (8.2% depression alone (5.4% men, 9.6% women) and 4.5% depression with cognitive impairment (2.8% men, 5.5% women).

PREVALENCE IN AFRICA (TABLE 77.4)

Using Clinically Based Diagnosis

CIDI DSM IV. Gureje *et al*.[42] estimated major depressive disorder in a representative sample of 2152 people aged 65 years and older by sampling households in the Yoruba-speaking areas of Nigeria. Twelve- month and lifetime prevalence estimates of major depressive disorder were 7.1% and 26.2%, respectively. The 12-month prevalence estimate of major depressive disorder was higher than the rate of 1.1% in the study in Quebec[16].

Using Scale Scores

GDS. Baiyewu *et al*.[43] undertook a two-stage study. The community-based samples aged 69 years and over were first screened for dementia, 2627 individuals in Indianapolis of whom 17.2% underwent clinical assessment including GDS and 2806 in Ibadan with 21.6% having clinical assessment. Prevalence of depression was estimated using weights indicated by the sampling stratification. The prevalence of mild and severe depression was similar for the two sites: 12.3% and 2.2%, respectively in Indianapolis and 19.8% and 1.6% in Ibadan. However, Ibadan men had significantly higher prevalence of mild depression than Indianapolis men. Poor cognitive performance was associated with significantly higher rates of depression in Ibadan.

PREVALENCE IN AUSTRALIA

Using Clinically Based Diagnosis

DSM. Snowdon and Lane[44] re-examined the data from a 1985 survey of 146 elderly people living at home. Depression and cognitive impairment were also assessed in a local hostel ($n = 42$) and nursing home ($n = 74$). DSM diagnoses were made by an old-age psychiatrist. In the nursing home, 23 residents could not respond to interview questions and were considered to have severe dementia. Subjects in all three settings were followed up after four years. They found that seven community subjects (4.5%, 95% CI 1.3–8.3%) and three in residential care fulfilled criteria for major depression. The estimated total prevalence of depressive disorders among older people in Botany was between 13.0% and 13.6% (4.6% major depression, 3.6% dementia with depression, 5.4% other depressive disorders).

INCIDENCE OF DEPRESSION IN OLDER PEOPLE

In the original chapter for the second edition of this book Blazer wrote, incidence studies of depression in the elderly are extremely rare in the literature. Two studies provide some estimate of incidence, however, Rorsman *et al*.[45] estimated incident depression from the Lundby cohort in Sweden among 2612 individuals evaluated in 1957 and later in 1972 (i.e. 15-year incidence) until the age of 70. The cumulative probability of suffering a first episode of depression was 27% for men and 45% for women, a very high incidence figure in this cohort (especially compared to lifetime prevalence figures, reported in other studies, of less than 15%). The annual age-standardized first incidence for depression, all degrees of impairment included, was 0.43 for men and 0.76 for women. Incidence appears to decrease in the studies as individuals aged, especially for men. Eaton *et al*. (1997)[46] estimated the incidence of major depression over 10 years for the ECA cohort from Baltimore. They found an overall estimated annual incidence of 3.0 per 1000 per year, with a peak while subjects were in their 30s, a smaller peak when subjects were in their 50s and a definite lower incidence in the elderly. Prodromal symptoms were present many years before the full criteria for major depression were met, further linking the minor and major depression. Foster *et al*. (1991) estimated the incidence of depression in long-term care facilities. In a cohort of 104 new admissions followed for a year, they found an incidence of 14%. One-third of these new cases were diagnosed as major depression, two thirds as minor depression.

In the last 10 years, nine important studies on the incidence of depression in older people have been conducted in the Netherlands, UK, London, USA, Austria, Thailand and Republic of Korea. Depression was diagnosed in these studies by using the 15-item GDS?score >4 or 5)? the 10-item CES-D (score >8)? the Geriatric Mental State, SDS (Zung self-rating depression scale) and the Thai Geriatric Depression Scale (TGDS). Participants were generally community-dwelling older people or patients registered with primary care practices participating in community-based cohort studies.

Incidence Rate

After one-year follow-up: Thongtang *et al*.[47] assessed 1713 elderly people in 35 communities from four districts in Bangkok using the Thai Geriatric Depression Scale (TGDS) and the Thai Mini Mental State Examination (TMSE). The point incidence (one year) of depression was 1.58% in men and 5.68% in women[47].

After two-year follow-up[46,47]: out of 521 people aged 65 years and over from an East Asian population, incident depression was found in 63 (12% or 6% per year). In Austria, 331 non-demented and never-depressed individuals were followed up for 30 months, by which time 31.4% had developed a subsyndromal, minor, or major depressive episode. In a prospective cohort study with index assessment and two-year follow-up of patients initially aged 65 years and over registered with two south London practices ($n = 1164$), the incidence of depression was 8.4% (4.2% per year)[50].

An eight-year follow-up[51]: A study of a cohort of 5653 community-dwelling elderly free of dementia was conducted in the Netherlands. For depressive syndromes, the incidence rate was 7.0 (95%CI 6.0–8.3) per 1000 person-years which was more than doubled when episodes of depressive symptoms were included. The rate was almost twice as high for women compared with men. The incidence did not appear to change with age.

During a follow-up period of 15 years, depressive symptoms in 464 men aged 64 to 84 years were assessed by the Zung self-rating depression scale (SDS). The cumulative incidence for depressive symptoms was 44%[52].

Among the oldest old, depression is frequent[13,14]. In a population-based prospective study, depressive symptoms were annually assessed in 500 people aged 85 years or above with the 15-item GDS, using a cut-off of 4. During a mean follow-up of 3.9 years, the annual risk for the emergence of depression was 6.8%.

Of 376 participants aged between 80 and 90 years, who lived alone and followed-up for one year, the annual incidence of depression was 12.4%, with the depression identified by GDS of 5 or more.

RISK FACTORS

Risk factors for incidence of depression 'Dispositional optimism' predicted a lower cumulative incidence of depressive symptoms with an odds ratio of 0.23[52]. Poor daily functioning and institutionalization predicted depression[13]. Subsequent development of clinically significant depressive symptoms was associated with baseline increased scores in depression (OR 1.68, 95% CI 1.21–2.34)[14].

Family factors

Risk factors associated with prevalence depression include not living close to family and friends (OR 2.54, 1.44–4.47)[14]. Having severe

troubles with relatives and pre-existing cognitive impairments may enhance the probability of developing a late-onset depression[49].

Vascular depression hypothesis

The vascular depression hypothesis suggests that age-related vascular diseases and risk factors contribute to late-life depression. A study of 1796 elders ages 70–79 without depression at baseline were followed-up to assess two-year incidence of elevated depressive symptoms, defined as a score >8 on the 10-item Center for Epidemiologic Studies Depression (CES-D) scale. After adjustment for demographic data and physical and cognitive functioning, increased risk of depressive symptomatology remained associated with several vascular conditions, including metabolic syndrome and its components, coronary heart disease, a positive questionnaire for angina, and high haemoglobin level. Cumulative vascular risk based upon a composite of 10 vascular diseases and risk factors was independently associated with incident elevated depression at two-year follow-up after controlling for demographic data, physical and cognitive functioning, and selected co-morbid medical conditions. These results provide support for the vascular depression hypothesis in demonstrating an association between vascular conditions and risk factors and subsequent risk of depressive symptomatology. The authors suggest older adults with vascular conditions and risk factors require close monitoring of depressive symptoms[53].

CONCLUSIONS

From all this data there emerge certain conclusions. There are major differences between classification schemes. There is a difference between clinically based diagnosis, whether by humans or computers, and those derived from scale scores. The latter tend to be higher if only because they usually include all participants regardless of diagnosis. They give an estimate of morbidity and co-morbidity, and point to a level of suffering in a community. There is a major difference between diagnostic classifications ostensibly aimed at improving reliability between psychiatrists, so necessary in the 1960s and 1970s in the USA and now elsewhere, and diagnostic classifications such as GMS-AGECAT, which aim to identify cases for intervention. Clearly the evidence is now strong that these are quite different types of cases[54]. Those persons concerned with relieving suffering rather than cutting back on health resources need to take up this cause and those responsible for international classification systems may need to reassess their aims. Has the time come to move from improving reliability between doctors to acknowledge that in vast areas of the globe doctors are not particularly active or apparent and that guidance on suitability for intervention must have a higher priority? That after all is what it is about. No longer is it sensible to hide under the shield of 'they may have symptoms, but do they have disability'? Many excluded from the classifications do have serious disability.

The increase in the number of studies in Asia and South America is gratifying but we need more studies in Africa to persuade governments that mental illness, the hidden illness, is behind much human disability and is treatable.

Neuroimaging in Geriatric Depression

Faith M. Gunning

Institute of Geriatric Psychiatry, Department of Psychiatry, Weill Cornell Medical College, USA

OVERVIEW

Geriatric depression is a complex and heterogeneous syndrome that likely has multiple environmental and biological determinants. Among these, structural and functional abnormalities in specific cerebral networks likely confer vulnerability that increases the likelihood of developing geriatric depression. The aetiology of such brain abnormalities may be diverse and likely results from processes commonly occurring in older adults including cerebral ageing, vascular, inflammatory, autoimmune and endocrine processes[1].

Significant effort has been devoted to characterizing alterations that occur in the brains of elderly depressed patients. In this chapter, we discuss work using a number of different neuroimaging modalities to advance our understanding of the neurobiology of late-life depression. In addition, when data exist, we will examine the question of how these neuroimaging correlates of late-life depression relate to specific features of the illness, including the presence of cognitive deficits and the course of the illness.

VOLUMETRIC STUDIES

Volume reductions are often present on T1-weighted magnetic resonance imaging (MRI) in the brains of elderly depressed patients in select frontal, limbic and subcortical regions. These regions include the anterior cingulate cortex, the orbitofrontal cortex, the neostriatum, the hippocampus and the amygdala[2–11]. The anterior cingulate cortex and orbitofrontal regions demonstrate the most consistent alterations. MRI-based parcellation of prefrontal regions in elder depressed patients confirms that relative to elderly control subjects, there are significant attenuations of grey and white matter in the anterior cingulate cortex and the gyrus rectus, as well as reductions of grey matter in the orbitofrontal cortex[12].

In addition to the presence of volumetric differences between elderly depressed patients and non-depressed individuals, there is evidence that specific clinical characteristics of the illness may be related to volumes of select regions[2,7,13–15]. For example, reduced amygdala volumes have been reported in recurrent depression[15]. In addition, one of the early studies to use voxel-based morphometry (VBM), revealed that smaller hippocampal volumes in elderly depressed patients were associated with greater number of years since first depressive episode[13]. Furthermore, apathy has been associated with smaller volume of the right anterior cingulate cortex in elderly subjects, although this may not be specific to depressed patients[16]. Finally, antidepressant medication itself may impact regional brain volumes. Lavretsky and colleagues[7] observed that orbitofrontal grey-matter volumes were larger in patients with geriatric depression who had been treated with antidepressant medication relative to drug-naive patients, although these volumes were smaller than those of age-matched controls.

Although most of the volumetric studies in late-life depression have focused on specific regions of interest (ROIs), a study by Andreescu and colleagues[2] applied an automatic labelling pathway technique to 24 ROIs to examine the relationship of volumes of grey-matter regions in elderly depressed patients to age of onset and duration of illness. Relative to non-depressed subjects, elderly depressed patients had smaller volumes in 17 of the ROIs examined. Both shorter duration of illness and later age of onset were correlated with smaller volumes of parahippocampal and inferior parietal ROIs. However, a later age of onset was also correlated with smaller volumes of several frontal and temporal ROIs, the cingulum and the putamen. These findings were interpreted to support the hypothesis that small volumes in late-life depression may be more related to neurodegenerative changes than the result of a toxic stress response[2].

In cross-sectional studies of geriatric depression, poor performance on tasks of episodic memory and executive functions have been associated with reduced volume of the hippocampus and select prefrontal regions[8,17]. In one study of late-life depression, volumes from specific ROIs within the prefrontal cortex were calculated and related to performance on a battery of executive measures[17]. Poorer performance on tests of response inhibition was associated with smaller anterior cingulate volumes, whereas poorer performance in nonverbal inductive reasoning tasks were associated with smaller gyrus rectus volumes[17]. Longitudinal studies of the hippocampus, indicate that smaller hippocampal volumes predict MCI and subsequent dementia[8,9].

There is little published data about the relationship of MRI volumes to response of late-life depression to treatment. However, in one study of elderly non-demented depressed patients, the relationship of remission status following treatment with escitalopram and volume of subregions of the anterior cingulate cortex was evaluated. Regional anterior cingulate volumes were manually outlined (dorsal, rostral, anterior subgenual and posterior subgenual) on high-resolution T1-weighted images. Analyses revealed that patients who failed to remit following escitalopram treatment had smaller dorsal

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

and rostral anterior cingulate grey-matter volumes than patients who remitted, whereas subgenual cortical volumes did not differ between the groups[18].

Volumetric differences in elderly depressed patients tend to be small and the relationship to clinical variables, when significant, tend to be modest in strength. More sophisticated shape analysis and/or 3D surface mapping may be used to better localize structural abnormalities in late-life depression[4]. For example, the caudate nucleus was examined using traditional volumetry and a 3D brain-mapping technique in a group of patients with late-life depression and non-depressed elderly comparison subjects. Relative to comparison subjects, depressed subjects had significantly lower mean caudate volumes bilaterally. Furthermore, the 3D maps localized these reductions in volume to the caudate head and volume reductions were correlated with depression severity[4]. Another study used shape analysis to examine the amygdala in a small group of healthy elderly individuals and elderly depressed individuals. Although no significant volumetric differences were found for either amygdala, regions of specific shape variation were detected. The most notable difference was contraction of the amygdala in depressed patients relative to comparison subjects in a region associated with the basolateral nucleus[19].

A number of methodological issues must be considered when interpreting morphometry studies. The specific neurohistological processes that account for the observed volume reductions in late-life depression cannot be distinguished. In addition, manual ROI morphometry is quite time consuming and a lack of standard guidelines used for delineation of ROIs across laboratories may contribute to differences between studies. VBM can overcome some of these weaknesses because of the relative ease with which it can be carried out, as well as its ability to examine the entire brain at once. However, VBM studies of ageing brains may be particularly problematic because of the requirement that MR images are transformed from native space to standardized stereotaxic space and this space is most often defined by a template that reflects a young, healthy brain. Approaches that apply templated ROI maps to MRI data in native space may increase both reliability and validity of findings from VBM studies.

Even within the context of the limitations of morphometry, the studies to date reveal a pattern of frontostriatal and limbic abnormalities, with some evidence that such abnormalities may be associated with the clinical presentation and perhaps even the course and outcome of the illness. In future studies, advancements in techniques (e.g. shape analysis) may facilitate more precise localization of structural anomalies in late-life depression.

WHITE MATTER INTEGRITY IN LATE-LIFE DEPRESSION

White-Matter Hyperintensities

Traditionally, the most common method to study white-matter abnormalities on MRI has been the examination of white-matter hyperintensities (WMH). These WMH are typically observed in T2-weighted sequences and are taken to indicate white-matter damage. They can be discrete, or punctate, or may appear more confluent with the lateral ventricles.

WMH are more frequent and severe in older depressed individuals than in age-matched controls and occur most often in subcortical grey-matter regions and frontal white-matter projections[10,20–26]. Even in cognitively intact individuals, WMH are often associated with subtle cognitive deficits, particularly executive dysfunction and slowed processing speed[27–30]. Furthermore, in elderly depressed patients, increases in WMH volumes at longitudinal follow-up predict the development of dementia, especially among non-Alzheimer type dementias[31].

Some studies suggest that WMH also may influence the course of affective symptoms in late-life depression. For example, longitudinal CHS data found that large cortical white-matter lesions and severe subcortical lesions were significant risk factors for developing depressive symptoms[9]. Furthermore, WMH burden and subcortical grey-matter hyperintensities have been associated with response to both ECT[32,33] and antidepressant treatment[32,34] although disagreement exists[35,36]. One report indicated that basal ganglia lesions predicted failure to respond to antidepressant monotherapy with a sensitivity of 80% and a specificity of 62%[37].

Neuropathological correlates of WMH in brains of elderly depressed individuals provide rather compelling support for a vascular contribution to the pathophysiology of late-life depression. In a study of neuropathological correlates of WMH in 20 depressed patients and 20 elderly comparison subjects (see[38–40]), all of the deep WMH examined in the depressed subjects showed evidence of ischaemia compared with less than a third of deep WMH in control subjects. Whereas large deep WMH were usually ischaemic in both groups, punctate lesions were typically characterized by ischaemia in depressed patients but not in controls. Periventricular WMH were characterized by ependymal loss, varying degrees of demyelination and cerebral ischaemia with no differences in pathological correlates detected between patients and controls[41]. Furthermore, in the depressed subjects, the ischaemic DWMH showed a striking predilection for the dorsolateral prefrontal white matter[40].

The methods of quantifying WMH are characterized by some of the same limitations as morphometry studies. That is, there are a number of different WMH rating scales and these scales vary widely in reliability and sensitivity. Also, postmortem studies of WMH suggest that such white-matter abnormalities reflect a number of pathological processes; however, MRI scans do not always allow a reliable discrimination among the underlying processes. Although recent advancements in measurement (i.e. volumetric measurements and regional WMH measurements) partially address these limitations, the introduction of newer MRI techniques to examine white-matter integrity may help to achieve not only better differentiation between true white-matter lesions and spurious findings, but will also help to identify the location of white-matter abnormalities and perhaps clarify their underlying causes.

MRI STUDIES OF MICROSTRUCTURAL WHITE-MATTER ABNORMALITIES

Diffusion Tensor Imaging

Diffusion tensor imaging (DTI) offers a promising approach for the examination of cerebral white-matter integrity in geriatric depression. DTI measures the magnitude and direction of self-diffusion of water. When no barriers to such diffusion are present, diffusion occurs equally in all directions (i.e. it is isotropic). However, when barriers to this diffusion are present, the diffusion tends to follow the long axis of those barriers (i.e. diffusion is anisotropic). Barriers to diffusion in the brain include cell membranes, myelin sheaths and white-matter fibre tracts. Diffusion anisotropy can be quantified by

a number of different metrics, including fractional anisotropy (FA). FA, which ranges in value from 0 to 1, is a measure of the strength of the directional dependence of diffusion and generally reflects the organization of fibre tracts. In regions with dense, highly organized fibres (e.g. the corpus callosum) FA values are the highest.

Commensurate with the morphometry findings of reduced volumes of select frontostriatal and limbic regions, DTI studies reveal that depressed elderly patients exhibit compromised integrity (i.e. reduced FA) of the white matter of prefrontal regions and the anterior cingulate[42,43], perhaps within the context of more subtle, widespread white-matter abnormalities[44]. A study that explored the relationship of diastolic blood pressure and FA in elderly depressed patients revealed significant associations between FA and diastolic blood pressure throughout the anterior cingulate and in multiple additional frontotemporal and frontostriatal white-matter regions[45]. These findings, albeit preliminary, suggest that reduced microstructural integrity of frontal-subcortical white matter may be one of the mechanisms by which high blood pressure, a known vascular risk factor, confers vulnerability to geriatric depression.

Regarding cognitive correlates of FA in geriatric depression, one study has examined the relationship of FA in depressed elders to performance on an executive task[46]. Response inhibition, one aspect of executive function that has been shown to predict antidepressant response[47], was assessed with the Stroop colour-word task. Voxelwise correlational analysis revealed significant associations between FA and Stroop colour-word interference in multiple frontostriatal-limbic regions, including white matter lateral to the anterior and posterior cingulate cortex and white matter in prefrontal, insular and parahippocampal regions.

In addition to a relationship between FA and response inhibition, there is evidence that lower FA in distributed cerebral networks is associated with poor antidepressant response of geriatric depression[48], although some disagreement exists[49]. Furthermore, a preliminary study of the association of the serotonin transporter gene status to both FA and response to antidepressant treatment indicated that depressed elderly S-allele carriers had lower FA than L homozygotes in frontolimbic brain areas, including the dorsal and rostral anterior cingulate, posterior cingulate, dorsolateral prefrontal and medial prefrontal regions[50]. S-allele carriers also had a lower remission rate than L homozygotes, introducing the possibility that the risk for chronicity of geriatric depression in S-allele carriers may be mediated by frontolimbic white-matter compromise.

Magnetization Transfer Imaging

Magnetization transfer ratio (MTR) is another method that can be used to study white-matter integrity in geriatric depression. MTR imaging provides information about the macromolecular structure of cerebral white matter based on the interaction of the normally observed tissue water signal with protons contained in large macromolecules (including myelin). Macromolecular structures in the brain (e.g. myelinated axons) are ordinarily not detected by MRI because of their extremely short transverse relaxation times. However, protons bound to them can be selectively excited using off-resonance radio-frequency pulses. To achieve MTR contrast, two MR sequences are used. The first is a proton density (PD) weighted sequence, which reflects the total water signal. The second uses an additional pulse prior to the basic proton density sequence and serves to null the signal from water molecules that are associated with macromolecules. The percent contrast difference between the two image sets is usually expressed as the magnetization transfer ratio: MTR = (M0 – MSAT)/M0. Reduced MTR reflects reduced macromolecular volume fraction. Studies conducted in neurodevelopment and multiple sclerosis suggest that DTI and MTR may provide complementary information about white-matter integrity with DTI mostly reflecting organization of fibre tracts and MTR being particularly sensitive to myelin and axonal integrity[51,52].

Kumar and colleagues[53] were the first to demonstrate the use of MTR in geriatric depression. Their results from a small study of elderly depressed patients suggest that, relative to their elderly counterparts, older depressed patients have lower MTR in the genu and splenium of the corpus callosum, the neostriatum and the occipital white matter. In a larger study of elderly patients with major depression and elderly non-psychiatric comparison subjects, we reported lower MTR in multiple left hemisphere frontostriatal and limbic regions, including dorsolateral, dorsomedial, dorsal anterior cingulate, insula, periamygdalar, subcallosal, posterior cingulate and regions lateral to the lentiform nuclei[54]. However, there have been no studies published to date that have reported the relationship of MTR to features of depressive illnesses in the elderly.

FUNCTIONAL NEUROIMAGING STUDIES

Functional neuroimaging studies in late-life depression reveal a pattern of abnormal activation of frontolimbic regions, generally characterized by hypoactivation of specific dorsal cortical regions and hyperactivation of select limbic regions. One of the first published reports of task-related activation in geriatric depression, reported results of a PET study that compared cerebral blood flow during a word activation task between elderly patients with severe depression and normal elders. During the word activation task, hypoactivation of the dorsal ACC and the hippocampus was detected[55]. This finding of attenuated activation of the dorsal ACC during a verbal fluency task was later replicated by another group in an fMRI study of older depressed individuals in remission who had experienced multiple previous episodes of depression[56]. In depressed elderly patients, relative to age-matched controls, Aizenstein and colleagues[57] reported decreased prefrontal activation in addition to increased caudate activation in response to an explicit sequence learning task.

Emerging evidence from functional neuroimaging studies suggests that select frontolimbic structures are not only abnormally activated in late-life depression, but these abnormalities are related to clinical features of the illness. For example, in a preliminary study of late-life anxious depression, subjects completed an executive control task. Relative to elderly depressed patients, elderly subjects with anxious depression produced a significantly greater and more sustained signal in the dorsal anterior cingulate, posterior cingulate and lateral prefrontal cortex. These preliminary results not only suggest specific activation patterns unique to anxious depression but also demonstrate the utility of using fMRI to examine the neurobiology of clinical subtypes of late-life depression[58].

Regarding the relationship of illness state to frontolimbic activation, an fMRI study of elderly depressed patients using an emotional oddball task reported that relative to healthy comparison subjects, the elderly depressed patients demonstrated attenuated activation in select frontolimbic regions, including the right middle frontal gyrus and the cingulate, as well as the inferior parietal cortex. Activation in the middle frontal gyrus appeared depressive state-related, whereas attenuated activation in the posterior cingulate and inferior parietal regions persisted in the remitted subjects, consistent with a disease-related alteration[59].

In a study examining the relationship of cerebral activation to course of illness, acutely depressed patients exhibited hypoactivation of the ventromedial prefrontal cortex in response to the emotional evaluation of negatively-valenced relative to positively-valenced words. However, this hypoactivation normalized after several months of uncontrolled antidepressant treatment[60]. Furthermore, in a controlled, antidepressant treatment trial, during a cognitive control task elderly depressed patients demonstrated hypoactivation in the dorsolateral prefrontal cortex and diminished functional connectivity between the dorsolateral prefrontal cortex and dorsal ACC prior to treatment[61]. Although this hypoactivity in the right dorsolateral prefrontal cortex subsided after successful antidepressant treatment, the reduced functional connectivity between the dorsal ACC and the DLPFC persisted.

Taken together, the functional neuoroimaging results indicate that abnormal frontolimbic activation is present in elderly depressed patients during the depressed state and these abnormalities may normalize, at least in part, in response to antidepressant treatment.

MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) provides important information about the neurochemical environment. Different molecules have unique MR spectra that can be quantified by taking the area under the signal curve. In most cases, the values are not absolute, so it is customary to take ratios of the measure of interest to some standard metabolite, for example choline.

Kumar and colleagues[62] used MRS to examine biochemical abnormalities in left frontal WM and bilateral anterior cingulate grey matter of elderly depressed patients. They observed higher choline to creatine as well as myoinositol to creatine ratios in the white, but not grey, matter of patents relative to age-matched comparison subjects. Results from a follow-up MRS study suggested that cognitive performance was associated with levels of metabolites as measured by 2D MRS in healthy controls, but not in patients with geriatric depression[63]. There was a significant difference in the overall pattern of associations between the four measured metabolites and verbal learning and processing speed in elderly depressed patients compared to elderly controls. The weaker relationship between metabolites and specific cognitive domains in patients with late-life major depressive disorder was interpreted by the authors to suggest that cognitive performance in geriatric depression may be associated with biochemical changes in frontostriatal circuitry.

In a recent study of elderly depressed patients and age-matched control subjects, MRS spectra were acquired from voxels that were placed in the left frontal white matter, left periventricular white matter and left basal ganglia. Results indicate that elderly depressed patients had significantly lower NAA/creatine ratio in the left frontal white matter and higher choline/creatine and myoinositol/creatine ratios in the left basal ganglia when compared with the control subjects. Furthermore, the myoinositol correlated with global cognitive function among the patients[64].

Most recently, MRS was used to examine biochemical correlates of response to antidepressant treatment[65]. Using a 3D chemical shift imaging sequence, tissue-specific differences in markers of energy metabolism, including high-energy phosphate compounds (beta and total NTP, PCr) and pH, were examined in 13 older adults with major depression pre and post 12 weeks of treatment with sertraline and 10 age-matched controls. Total NTP was reduced in the white matter, but not in the grey matter, in the depressed group prior to treatment depression group. Intracellular pH was higher in the grey matter of subjects with pre-treatment depression but similar to levels of controls after treatment[65].

Although there are only a handful of published reports that have used MRS to examine the neurochemical environment in geriatric depression, this appears to be a promising technique that, especially if used in combination with other measures of tissue integrity (e.g. DTI), is likely to be a quite powerful tool to advance our understanding of the neurobiology of late-life depression.

CONCLUSIONS AND FUTURE DIRECTIONS

For more than two decades, scientists have taken advantage of the remarkable capacity of neuroimaging to visualize and quantify patterns of cerebral abnormalities in psychiatric illnesses. As with many features of psychiatric illnesses, MRI observations are notable for the variability of findings between studies. However, when considering evidence from multiple MRI modalities across the numerous studies that have been performed, a general pattern of findings has emerged. This pattern is characterized by compromise in the structure of select aspects of frontostriatal and limbic networks coupled with hypoactivation of cortical regions critical for cognitive control and hyperactivation of limbic structures involved in emotional reactivity. Both structural compromise and abnormal activation in frontolimbic systems appear to be associated with poor response to antidepressants. These findings that relate MRI indices to antidepressant response raise the possibility that structural abnormalities may interfere with the normalization of frontolimbic activity in individuals who fail to respond adequately to antidepressants. While each neuroimaging technique alone has limitations, the concurrent application of more than one technique yielding complementary information can increase the information gleaned from future neuroimaging observations and significantly advance our understanding of the pathophysiology of depression in the elderly.

Clinical Features of Depressive Disorders in the Elderly

Davangere P. Devanand and Steven P. Roose

Division of Geriatric Psychiatry, New York State Psychiatric Institute, and the College of Physicians and Surgeons, Columbia University, New York, USA

Late-life depression refers to depressive syndromes in people who are older than 60–65 years. Depression causes considerable personal suffering and adversely affects family members and other caregivers. In elderly subjects, depressive syndromes are often associated with chronic medical illnesses that can precipitate depression. Conversely, the presence of depression can worsen the outcomes of many medical disorders and promote disability. Depression occurs commonly in a variety of other neuropsychiatric syndromes, including mild cognitive impairment, dementia, stroke and Parkinson's disease.

In the elderly, the fear of ageing and its effects are common. Older adults commonly state that since they are getting old it is normal to feel depressed. This view is often shared by family members and even health care providers. However, the vast majority of elderly individuals are not depressed, and therefore depression should not be considered a normal part of the ageing process.

Many elderly patients describe their mood accurately as depressed or anxious, but some tend to deny and suppress it and they come to clinical attention only at the insistence of family members. Somatization is common in older patients, particularly gastrointestinal symptoms like constipation. Some patients are unsure if they are depressed because they have begun to feel less energetic and lose interest in activities in the absence of a clear-cut depressed mood. Some of these patients have dysthymia or minor depression. In the elderly, one important distinction to make is whether the first depressive syndrome began in late life or whether it represents a pattern of recurrent depression throughout adulthood, because the underlying aetiology may differ in these two types of patients. Premorbid personality does carry into old age, but its impact on the presentation of depression varies considerably. Personality itself may change with ageing and life experiences. Psychological changes in the elderly may be environmentally determined, but may also be based on changes in neurobiology; for instance, catecholaminergic neurons in the locus coeruleus decay markedly with ageing and this change may be related to the rarity of late-onset anxiety disorders and lower prevalence of major depression in the elderly population.

PREVALENCE

Depressive syndromes are common in late life[1] and represent the leading cause of poor functioning and disability worldwide that has an overall adverse impact comparable to cardiovascular disease[2]. A low proportion of clinically depressed elderly individuals seek help and typically they present to primary care practitioners. However, primary care physicians correctly diagnose only a minority of depressed patients and consequently few patients receive treatment for this illness. An even smaller proportion is referred for psychiatric care.

Epidemiological studies indicate that among the elderly, milder sub-threshold depressive syndromes may be more common than major depression, which ranges in prevalence from 1 to 3%[3]. However, the rate of major depression changes significantly depending on the setting. Studies of patients in medical clinics report rates of 10% for major depression; in non-psychiatric hospital in-patients the rate increases to 15–25%, and it is even higher in nursing homes[4]. These studies primarily used assessment instruments and diagnostic criteria that were developed for and/or validated in a younger population, and it is not known whether the adoption of age-adjusted diagnostic criteria would produce significantly different results.

DIAGNOSTIC CLASSIFICATION

A depressive disorder may be diagnosed by DSM-IV (or DSM-IV TR) clinical criteria only if the depressive symptoms adversely affect work, family or social functioning, or if the subject seeks or has received treatment for depression. The clinical entities in the current nomenclature identified in young adults that also occur in older adults are major depression (unipolar or bipolar, single episode or recurrent, with or without melancholia, with or without psychotic features); dysthymic disorder; and atypical depression. Disorders that are common in the elderly include mood syndromes secondary to a general medical condition, and subsyndromal depression including minor depression. Depression with cognitive impairment is a common presentation in elderly patients.

MAJOR DEPRESSION IN OLDER PATIENTS

Clinical observations and systematic studies suggest that patients with late-life major depression may well be different in important dimensions from younger adult patients with major depression. Such differences may reflect age-associated physiological changes, the changes associated with depressive illness (the ravages of a depressed life)

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

and/or the impact of co-morbid medical conditions[5–7]. For example, the differences in young versus old people may manifest in how functional impairment as a symptom of depression is expressed differently through the life cycle. Depression-associated dysfunction in childhood can present as poor performance in school or antisocial behaviour, in young adults as dissatisfaction in work or love, and for older patients as hypochondrias and increased utilization of medical resources[8].

The cumulative impact of depressive illness itself in patients with onset of illness early in life may be a critical factor. By the time a patient with early onset depression reaches age 60, they have already suffered through recurrent episodes. There is increasing evidence that the number of depressive episodes as well as the total amount of time spent 'depressed' in a lifetime is associated with less robust response to treatment and the development of chronic symptoms[6]. Furthermore, some data suggest that the cumulative time spent in a depressed state is correlated with changes in brain structure that may subsequently affect the phenomenology and treatment response in future episodes[5].

Moreover, changes in the brain that occur with age may also affect how the individual interacts with the environment, and can result in increased vulnerability to depression. Regional brain dysfunction, especially in the pre-frontal areas, is associated with instability of temperament, vulnerability to and the intensification of the experience of distress, and a degrading of coping mechanisms. Such alterations in an individual's psychic capacities may result in increased social isolation, loss of independence, and related behaviours that can precipitate, intensify, or prolong a depressive episode. Thus, by the time a patient with recurrent depression reaches late life, the consequences of the disorder itself, and maybe the impact of treatments received, will influence the presentation, psychobiology, treatment response and course of illness during late life.

Alternatively, the differences that exist in younger versus older depressed patients may indicate that late-life depression is a distinct disease entity and, despite some commonality, early onset and late-life depressive illness are significantly different in fundamental aetiological ways. An example of such aetiological heterogeneity is the distinction between the late-life patient with recurrent major depressive illness with onset of the first episode early in life, and the late-life patient with first onset of major depressive illness after the age of 60. The hypothesis that early-onset (before age 50 or 60) and late-onset depression may be, despite similarities, distinct entities is suggested by data from epidemiological, brain imaging, treatment, and long-term outcome studies[9–11]. Patients with late-onset depression have a lower rate of family history of depression, and a greater frequency of MRI abnormalities compatible with ischaemic cerebrovascular disease[10]. These lesions have been associated with symptoms of cognitive impairment, a decreased and slower response to antidepressant medication and a deteriorating course of illness[12,13].

In summary, the label late-life depression may be attached to a group of patients who share some commonalties but who, nonetheless, suffer from a heterogeneous group of disorders that differ in aetiology, pathophysiology and prognosis. Indeed, some of these disorders may be relatively unique to older adults.

Diagnostic Features of Major Depression in Late Life

Whatever the reason, and whether in a medical or psychiatric setting, the age-associated changes in the presentation of depression undoubtedly contribute to the problem of under-diagnosis and inadequate treatment of depression in late-life patients. In general, older patients report fewer emotional symptoms, for example depressed mood, and present with more cognitive/somatic symptoms, for instance sleep disturbance, fatigue, pain and memory or concentration difficulties. In fact, the older-age depressed patient may never complain of, or indeed may deny, being 'depressed'. This presentation of late-life depression has been labelled 'depression without sadness'[14]. Thus, if when making a diagnosis a physician adheres strictly to DSM-IV criteria, than depressive disorder may well be omitted from the differential diagnosis for an older patient presenting with non-specific physical complaints.

Diagnostic Criteria for Major Depression in the Elderly

Despite the compelling evidence that late-life depression and older people are different, the diagnostic criteria for unipolar depression in DSM-IV are not adjusted for age[15]. One of the five required symptoms must be either (i) depressed mood most of the day, nearly every day; or (ii) markedly diminished interest or pleasure in all, or almost all activities. The other symptoms that are counted to the total of five, but not required, are: (iii) significant weight loss, or decrease or increase in appetite nearly every day; (iv) insomnia or hypersomnia; (v) psychomotor agitation or retardation; (vi) fatigue or loss of energy; (vii) feelings of worthlessness or excessive or inappropriate guilt; (viii) diminished ability to think or concentrate, or indecisiveness (older patients with depression often have mild cognitive impairment, including disturbances in attention, speed of mental processing, and executive function); (ix) recurrent thoughts of death, suicidal ideation with or without a plan.

Though there are no separate diagnostic subtypes unique to late life, there are some considerations that are more relevant to late-life depressed patients than younger patients with the same disorder. The DSM-IV precludes the diagnosis of major depression if it can be established that the symptoms counted towards the diagnosis of depression are a direct physiological effect of a different medical disorder. However, this rule is not supported by evidence, and to the contrary, studies have suggested that the inclusive approach (i.e. if a symptom is present it is counted towards the diagnosis of depression) is justified[16].

There is also the belief that unipolar major depression with psychotic features may be a more frequently occurring subtype in older than younger patients. Psychotic depression occurs in 20 to 45% of elderly depressives hospitalized for psychiatric care, and in 3.6% of elderly depressives living in the community[17].

VASCULAR DEPRESSION

Hickie *et al.*[12] hypothesized that there may exist a vascular depression subtype that is unique to late life; he wrote that 'cerebral vascular insufficiency in elderly people leads to major changes in their subcortical and basal ganglia structure. The resultant late-onset depressive disorders are characterized by deficits in functions that are dependent on intact cortical striatal connections (e.g. psychomotor speed), as well as subcortical hyperintense lesions and reduced basal ganglia volumes.' The hypothesis emanated from studies that reported that patients with late-onset major depressive disorder (MDD) had higher rates of hyperintensities on MRI compared to patients with early onset MDD[10,12,18]. The patients with late-onset depression and hyperintensities also showed deficits on neuropsychological testing including, but not limited to, deficits in executive function[18,19]. Thus,

structural brain damage secondary to ischaemia creates a vulnerability to MDD that may be precipitated by negative life events or other stresses. Given that vascular disease of sufficient severity is the cause of the ischaemia, this form of depression will be significantly more prevalent in older adults[20].

Much about the vascular depression hypothesis is compelling. First, the evidence that vascular disease is the cause of the hyperintensities prominent in late-onset depression supports the hypothesis. Second, vascular risk factors, such as smoking, hypertension and high lipid levels, are prevalent in patients with late-onset depression. Actually, early onset depression is itself a very significant risk factor for both ischaemic heart disease and stroke later in life. Increased cortisol, insulin resistance and platelet reactivity, all of which can contribute to vascular damage and ischaemia, may mediate the increased risk of myocardial infarction and stroke associated with depression[7].

Diagnostic Criteria for Vascular Major Depression

Criteria for vascular depression include vascular disease, cognitive impairment, late age of onset, and depression. However, the various research groups who study this syndrome have proposed the variables in many different combinations. For example, one group considers clinical and/or laboratory evidence of vascular disease and depression onset after age 65 as cardinal features and executive dysfunction as secondary[21], whereas another group believes neuroimaging evidence of cerebrovascular disease to be the cardinal feature and age-of-onset over 50 as an additional secondary feature. Krishnan *et al*.[22] have further refined the notion of vascular depression, requiring only MRI evidence of cerebrovascular pathology to define it, and have referred to this syndrome as subcortical ischaemic depression. Alexopoulos has proposed a depression executive dysfunction disorder of late life that only requires executive dysfunction to meet diagnostic criteria[21,23]. Although the proposed criteria sets are important and have moved the field toward recognizing a potentially important subtype of late-life major depression, this recognition might be premature because there is no agreement on how the construct is defined. Furthermore, most studies only include patients who meet criteria for MDD; however, many patients with vascular disease have dysthymia or subsyndromal symptoms.

SUICIDAL IDEATION

Studies consistently show that elderly males, particularly white males, are the demographic group with the highest risk of committing suicide. Also, the majority of elderly patients who commit suicide have visited their primary care physician a few days to weeks before the act[24]. These findings appear to be present across countries in several continents, although there are cultural differences in the preferred method of committing suicide[25].

ATYPICAL DEPRESSION

Little attention has been paid to the atypical subtype in samples of late-life depressed patients. The term 'atypical' was originally coined to describe a group of depressed patients who characteristically present with 'reverse' vegetative symptoms such as hyperphagia and hypersomnia[26]. The diagnostic criteria and acceptance of this subtype of major depression have evolved over the past 25 years so that they are included in DSM-IV with the atypical features specifier requiring that a patient has (i) mood reactivity and (ii) two or more of the following symptoms: significant weight gain or increase in appetite, hypersomnia, leaden paralysis, or a long-standing pattern of interpersonal rejection sensitivity[15]. Studies have documented that patients with atypical depression differ from other patients with major depression in a number of parameters besides phenomenology, including biological variables, treatment response, demographic characteristics and age of onset[27,28].

There are two studies of the atypical subtype in late-life patients. The first study has many methodological limitations but is notable because it brought attention to this subtype of depression in late life. In this study, a single practitioner in a private practice reported on 358 consecutive DSM-IV unipolar (major depressive and dysthymic disorder $N = 179$) and bipolar II ($N = 179$) outpatients presenting for treatment of a major depressive episode over the last two years[29]. Depressed patients over the age of 60 had a significantly lower rate of the atypical subtype compared to younger depressed patients, 28 vs. 55% respectively ($p < 0.0001$), and also a significantly lower rate of bipolar II atypical subtype in the late-life patients compared to the younger sample, 35 vs. 67% respectively ($p = 0.01$). Furthermore, in comparison to atypical patients under age 60, atypical patients over age 60 had an older age of onset of illness (44 years vs. 23 years) and a lower rate of rejection sensitivity (55 vs. 83%).

The second study reported on an open trial of venlafaxine in late-life depressed patients with the atypical subtype[30]. The sample was 17 patients, mean age 65.6 ± 7.3 years, 77% female, mean Cumulative Illness Rating Scale-Geriatric score[31] 2.9 ± 2.8, and 43.8% of the subjects had cardiovascular disease. The mean Mini-Mental State Examination (mMMSE) was 28.6 ± 1.4. In this sample, 58% of the patients had recurrent depression and, most strikingly, 53% presented with late onset of depression (defined as first episode after age 50) and only 12% with onset before age 21. Of note, 15/17 patients completed the eight-week venlafaxine trial; intent-to-treat response rate was 65% and the completer response rate was 73%.

CLINICAL RATING SCALES FOR MAJOR DEPRESSION

Patients should be evaluated with a history and clinical evaluation, supplemented by semi-structured interviews, together with additional information from informants and referring physicians and mental health professionals. The Hamilton Depression Rating Scale (17, 21, 24 or 29 item versions) and Montgomery Asberg Depression Rating Scale are commonly used in young adults, and can also be used in elderly patients with depression. Specific instruments that address symptoms likely to occur in the elderly have been developed. The Geriatric Depression Scale[32] has been validated in older depressed patients and can be useful in the overall assessment process. The CES-D (Center for Epidemiological Studies-D) is another short instrument with both 'positive' and 'negative' symptom assessment of depression and is widely used in epidemiological studies. Both these instruments can be completed as self-reports, though interviewer ratings often add to the nature of the information obtained. Some instruments developed for use by primary care practitioners, for instance PRIME-MD, are useful for basic office screening but require follow-up with a more comprehensive evaluation if the initial screen is positive[33]. A weakness of using this type of screening approach in elderly patients is that many depressed patients do not recognize their depression as a symptom of illness or have masked depression with or without somatic symptoms. In such cases, the screen may give a false negative result. There is no objective evidence that any one of these rating instruments is superior to any other instrument in distinguishing diagnostic groups, predicting clinical

course or treatment response. Other areas of query to complete the evaluation include assessments of cognitive, nutritional and functional status, social function and general health status. Review of medications, medical work-up and laboratory assessment, if indicated, is necessary to complete the evaluation.

Depression may be reflected in behavioural changes in the elderly, with apathy, anhedonia and occasionally irritability being prominent symptoms. Although several studies show that major depression in the elderly is more likely to become chronic, it remains unclear if the likelihood of chronicity is more common in elderly patients[34]. Some older patients show partial improvement without full remission from an episode of major depression[35], but the STAR-D findings suggest that this may also be the case in many young adults[36]. While the goal is full remission, partial response without full remission remains common. In addition to antidepressant medication treatment, a variety of psychotherapies including interpersonal, cognitive behavioural and problem-solving therapy have been shown to have some efficacy, though well-controlled studies are fairly limited[37]. Other behavioural interventions include exercise and group activity involvement, but systematic controlled studies are lacking.

DYSTHYMIC DISORDER

Dysthymic disorder is a syndrome of depression of mild or moderate severity that lasts at least two years. Dysthymia is a chronic condition that may begin early in life and extend into late life, often interspersed with episodes of major depression. In these patients, the term 'chronic depression' has been used to designate the co-morbid or sequential occurrence of major depression and dysthymic disorder[38]. However, in the elderly, the majority of cases of dysthymic disorder are of late onset by DSM criteria (age of onset > 21 years), and the majority of patients have an age of onset above 50 years[39]. As discussed earlier in this chapter, there is considerable evidence that patients with late-onset (onset after 50–60 years of age) major depression are less likely to have a positive family history of affective disorder and more likely to have evidence of cerebrovascular disease and cerebral atrophy than elderly patients with early onset depressive illness. These features also appear to be present in patients with dysthymic disorder[39,40] who often have a 'pure' dysthymia uncomplicated by a history of major depression[39]. Co-morbid Axis I disorders, particularly anxiety disorders, are far more common in early onset than late-onset patients with dysthymic disorder[39,41]. The gender distribution in late-onset dysthymic disorder does not seem to have the female preponderance that is observed in most types of affective disorder. Personality disorders in elderly dysthymic patients are less common than in young adults with depression, and tend to be of the obsessive-compulsive and avoidant subtypes. Borderline, histrionic, narcissistic and antisocial personality disorders are rare in the elderly[39,42].

Co-morbid general medical conditions, cognitive disorders and frequent adverse life events, for example bereavement, can complicate the diagnosis of dysthymic disorder. Associated features may include the presence of major chronic stressors, increased physical impairment and more symptoms of anxiety. Patients with dysthymia tend to be seen in primary care settings rather than by psychiatric specialists.

DSM-IV describes the symptoms of dysthymic disorder as being similar to those in major depression, with the distinction being the presence of fewer symptoms of lesser severity. However, the DSM-IV field trials revealed a high prevalence of cognitive and social symptoms in patients with dysthymic disorder, and neurovegetative symptoms were less frequent. This led to the alternative symptom criteria for dysthymic disorder that were listed in the DSM-IV appendix. These symptoms include low self-esteem, hopelessness, social withdrawal and lack of interest, fatigue, low productivity, poor concentration and indecisiveness. These symptoms are also more common than classical neurovegetative symptoms in elderly patients with dysthymic disorder[42]. The assessment of dysthymic disorder in the elderly can benefit from the use of the Cornell Dysthymia Rating Scale that emphasizes cognitive and social and motivational difficulties[43].

The optimal treatment of dysthymic disorder in the elderly remains uncertain. Fluoxetine has been shown to have marginal superiority over placebo[44] and there is equivocal evidence on whether psychotherapy or SSRIs should be the first-line treatment[45]. Problem-solving therapy may have limited utility in dysthymic disorder and other types of late-life depression, but there appears to be considerable variability in treatment response when this therapy is not administered by experts[37,45].

OTHER SUBSYNDROMAL DEPRESSIVE DISORDERS

Subsyndromal depression is defined as the presence of depressive symptoms that do not qualify for a formal mood disorder. Subsyndromal depressive disorder tends to be a heterogeneous group of milder forms of depression with symptom patterns qualitatively distinct from more severe forms such as major depression[46]. Subsyndromal depression is often used to describe patients with occasional depressed mood in the absence of other depressive symptoms. Minor depression in elderly people is associated with functional disability, and about 25% of patients develop major depression within two years. These subsyndromal depressive disorders commonly occur in patients with co-morbid medical illness, cognitive impairment, and other Axis I and II psychiatric disorders. There have been few treatment studies in the elderly, partly because the inherent heterogeneity of this set of syndromes makes it difficult to identify consistent treatment effects. Another view is that these patients' symptoms are too mild to require treatment, but the higher than expected likelihood of progression to major depression and the possible detrimental impact of even low levels of depression on medical outcomes suggest that treatment may often be warranted.

GRIEF AND PATHOLOGICAL BEREAVEMENT

Grief, a normal psychological response to the loss of a loved one, possessions or health, or unexpected adverse events, is associated with feelings of sadness, transient somatic symptoms, weight loss and difficulty in sleeping. Symptoms are often intense for several weeks to a few months and then typically begin to improve[47]. Pathological grief refers to the persistence of symptoms of grief at the same intensity more than six months after the event, and may include acquisition of symptoms belonging to the last illness of the deceased, psychosomatic illness, greater interpersonal conflicts and social withdrawal, difficulty in concentration and other cognitive difficulties, low productivity and impaired overall functioning[48,49]. Fear, demoralization and loneliness can occur. Spousal bereavement is common in late life, and is associated with declining mental and physical health and increased risk of mortality[50]. Among elderly widows and widowers, 20% meet the criteria for major depressive syndrome two months after their loss, and one-third of these individuals develop persistent depression for a year or longer[51]. Generally, individuals who are at greatest risk for persistent depression have worse health, more

functional and social difficulties and more protracted grief than do bereaved individuals who are not depressed.

There are two schools of thought on whether grief should be treated in its early stages: some believe that it should be treated and others have the view that only persistent and prolonged grief requires intervention. The utility of antidepressant medications or psychotherapy in these contexts is not fully established, but there is some evidence for the efficacy of a specific form of therapy, complicated grief therapy, to treat patients with prolonged and disabling grief symptoms[52].

A relatively new diagnostic concept that is especially relevant to older patients is complicated grief. In this syndrome, the grief that is normally experienced during bereavement does not resolve but instead becomes persistent. The predominant symptoms of complicated grief include recurrent intrusive images of the death, bitter or angry avoidance of situations, activities, or people, intense yearning and/or longing, seeking proximity to items belonging to the deceased, feeling that life has no meaning without the deceased, self-blaming thoughts of not helping the person or not preventing the death. This syndrome is frequently co-morbid with depressive disorder; however, complicated grief itself may be mistaken for major depression. The diagnostic criteria for complicated grief are still in development and treatment studies are ongoing. For obvious reasons this syndrome has special relevance for older patients.

STRESSFUL LIFE EVENTS AND ADJUSTMENT DISORDERS

Older adults face a variety of stresses: medical illnesses, physical disability, sensory impairments in vision and hearing, loss of family and friends, loss of social supports, changes in relationships with children and significant others, alterations in living situation, and loss of income. One or more of these factors may be related to the onset of the clinical syndrome of depression. The death of a spouse is extremely stressful, as is the death of an adult child. Patients with major depression perceive significantly greater negative emotional impact of the same life events than patients with dysthymic disorder and healthy controls, particularly for interpersonal conflicts[53]. The resolution of stressful events probably depends on several factors, including genetic predisposition, prevailing early life experiences, adequacy of previous adaptive and coping mechanisms, patterns and profiles of premorbid personality and, in particular, the presence or absence of a strong support system. A specific scale has been developed to assess a range of stressful life events and their impact on mood and functioning in the elderly[53].

DEPRESSION WITH COGNITIVE IMPAIRMENT

In the elderly, depression is a major cause of suffering and disability, is often co-morbid with medical illnesses, worsens their outcome and increases mortality[2]. Cognitive deficits are common in the elderly, and often precede Alzheimer's disease (AD) and vascular dementia, which are illnesses with enormous costs. Depression and cognitive disorders are the most common neuropsychiatric disorders in the elderly; their co-occurrence may exceed chance.

Apathetic, withdrawn behaviour is common to both depression and dementia. Paucity of speech with long latency is characteristic of major depression, particularly the melancholic subtype. However, there are many symptoms common to both depression and mild cognitive impairment or early dementia: apathy, anhedonia, insomnia, agitation, irritability, memory loss and difficulty concentrating. This overlap in symptoms makes it difficult to make an accurate diagnosis and to estimate prognosis and plan treatment.

In patients with depression plus cognitive decline, the following symptoms commonly occur: difficulties in memory or thinking or concentration, forgetting of recent events, forgetting where things are located, problems in finding the right word to say, getting lost in familiar places, remembering appointments and to take medications, and difficulty in managing finances like balancing the chequebook or paying for items in a shop. These symptoms, especially financial management and remembering appointments or taking medications, may be the first indicators of dementia. The symptom of forgetting names of books and movies and people is common during the normal ageing process and by itself is not indicative of dementia.

The presence of depression of any type appears to be associated with an increased risk of converting to dementia during follow-up[54,55]. Among patients with depression and cognitive impairment, a large proportion of converters to dementia are diagnosed with AD. Autopsy studies show that elderly depressed subjects who have mild cognitive impairment or dementia often have a pathological diagnosis of AD[56].

As already described, 'vascular depression' refers to major depression with higher rates of leukoencephalopathy on MRI and executive function deficits. A number of patients with both depression and cognitive impairment have evidence of cerebrovascular disease, while others have incipient AD. Patients who present clinically with 'pseudodementia', that is, depression masquerading as dementia in its clinical presentation, were thought to be common but in fact are relatively rare[2].

The treatment of patients with depression and cognitive impairment has been poorly studied. In one study, open treatment with sertraline showed improvement in depression with minimal improvement in cognitive deficits[57], and there is preliminary evidence that adding a cholinesterase inhibitor to antidepressant treatment may lead to improvement in cognitive test performance[58]. There are no large-scale studies addressing these issues, and the standard clinical practice remains to first treat with antidepressants and then evaluate if cognition improves along with antidepressant response, even though there is little evidence to support this notion. The literature on the treatment of depression in patients with dementia, primarily AD, suggests a marginal positive effect for antidepressant medication in some studies, while other studies show no advantage of medication over placebo.

MEDICAL CO-MORBIDITY

Depression frequently accompanies other medical illnesses and is associated with considerable dysfunction and disability. Co-morbid medical illness increases the chronicity and refractoriness to treatment and it may slow recovery rates for depressed patients with various conditions, including heart disease, stroke, hip fracture and dementia.

The elderly patient typically suffers from several medical illnesses and takes a large number of medications. Benzodiazepines, steroids and anticholinergics can lead to cognitive impairment and even delirium, L-dopa and dopamine agonists prescribed for Parkinson's disease can lead to psychosis, and the use of some antihypertensives and steroids may be associated with depression.

A variety of medical disorders can first present with disturbances in mood, cognition, or psychotic features, including infections, electrolyte and metabolic imbalances, cardiovascular and cerebrovascular disease. Depression can lead to weight loss, inanition and

malnutrition. Dietary history is important in this regard; the older adult living alone may not obtain adequate nutrition and may develop vitamin and other deficiencies.

From a diagnostic classification perspective, the diagnosis of depression due to a general medical condition is given when depressed mood or anhedonia occur in patients already diagnosed with an illness that is associated with depression. A common co-morbidity is depression and cardiovascular disease, and myocardial infarction is frequently associated with depression in the short term to intermediate term.

BIPOLAR DISORDER IN THE ELDERLY

Late-onset mania is not common in the elderly, but can occur as a primary late-onset mania or secondary to dementia or stroke or other neurological insult. Labile affect is believed to be typical of vascular dementia, but it remains unclear if labile affect is more common in vascular compared to other forms of dementia. Elderly patients are prone to the neurological side effects of lithium, and systematic monitoring of lithium and anticonvulsant blood levels when anticonvulsants are used is important, though the optimal treatment strategy for elderly patients with bipolar disorder is not well established. Many younger patients with bipolar disorder are maintained on the same treatment(s) as they age, and dosage reductions and other adjustments depend on the development of side effects.

CONCLUSION

While depression in the elderly shares many clinical features with depression in young adults, there are important differences. Late-onset patients, particularly those with cerebrovascular disease, may have an illness related directly to brain pathology, and those with both depression and cognitive impairment have an increased risk of developing AD. The preponderance of subsyndromal depression, and again the large proportion among them with late age of onset, indicates that the approach to diagnosis and management should not be restricted to the major depression category. Lack of social supports and life stresses do play a role in late-life depression. The high risk of suicide, particularly in elderly males living alone, should be at the forefront of the clinician's mind when evaluating the elderly depressed patient. A comprehensive biopsychosocial approach should take into account the patient's entire history, the social context and medical issues that arise during the ageing process. Medical co-morbidity needs to be addressed, and close communication with the patient's medical providers is important in elderly patients with significant medical illness. Treatment strategies should encompass both medications and psychotherapy, taking into account the reduced tolerability and increased side effects with psychotropic medication use, and the need to emphasize behavioural and problem-solving approaches in therapy when it is utilized.

The Outcome of Late-life Depressive Disorders

THE OUTCOME OF LATE-LIFE DEPRESSION

Around the turn of the nineteenth century Kraepelin changed the face of contemporary psychiatry, primarily by systematically following up his patients after treatment. The outcome or natural history of a disorder is, since that time, decisive for any appreciation of its clinical relevance, treatment or classification, and is a cornerstone of its conceptualization. In some disorders, such as dementia, the rate of progression of the illness may vary, but the eventual outcome is fixed. Other diseases, such as diabetes or osteoarthritis, may have an extremely varied course and prognosis, but are chronic by nature. The eventual outcome of both diabetes and osteoarthritis is by no means fixed. In both disorders the outcome can vary from being a disorder that, although causing considerable discomfort, remains under control, to a debilitating and pernicious disorder. The outcome of depression is even more varied than that. Some patients suffer one episode in life, recover fully, never to run into affective trouble again. For others depression is a severe and chronic disease, omnipresent in all spheres and phases of life and dyscolouring all life's experience. The eventual outcome may vary from the depression having had a minor impact on the patient's life, to suicide. Between these extremes, every type of course and outcome of depression exists. This holds for depression at all ages. Indeed, it may well be that, given the changes that occur in later life, the variability of the outcome of geriatric depression is even more pronounced than in earlier stages of life.

Given the extreme variability of the outcome of depression and the obvious importance this has for our patients, it is surprising how poorly both our theories and our classification of the prognosis of depression have developed. Although a good many studies have been conducted to assess the naturalistic outcome of depression at all ages, this has not led to a well-developed prognostic theory for affective disorders. The primary aim of treatment is to influence the prognosis and outcome of a disorder. Although hundreds of trials have been conducted to test the efficacy of treatments for depression, this also has not led to an integrated theory of the prognosis of affective disorders. The result is that classification has remained where it essentially has been since Kraepelin's time: a purely descriptive system, categorizing what goes on while it goes on.

This chapter contains a reflection of this still rather primitive state of affairs. The first paragraph will discuss essential conceptual issues, relevant to the outcome of late-life depression. Thereafter, we will summarize the available data with regard to the naturalistic outcome of depression in older people. As will become evident, the pioneering studies in this area were conducted from specialized clinical centres, following up patients after discharge from clinical treatment. Later on, larger cohort studies were put together, following patients seen in general practice and in the community. These data will be used to test the hypothesis that the prognosis is generally more favourable in the community as compared with patients referred to specialized treatment centres. A second question is whether the prognosis of depression changes with age. To this end, results of studies conducted among older people will be compared with those in younger adults. Where possible, associations between age and the prognosis will be summarized. One of the myth's surrounding age and ageing is that later life would be an age of melancholy. This myth has been falsified many times. Although some studies do show that the prevalence of depressive symptoms increases with age, this is related to age-related risk factors and not to ageing itself. The same question will be addressed with regard to the prognosis of late-life depression. Is there an effect of age? If so, is this a result of the ageing itself, or a change in age-related prognostic factors?

A related issue is whether the variation in outcomes of depression is increased in later life. If so, the potential benefit of being able to predict the individual prognosis early on in treatment is similarly increased. First episodes of depression may arise at all ages and there are subtypes of depression that generally arise only in later life (such as vascular depression or depression associated with neurodegenerative disease). It is therefore likely that the prognosis becomes more heterogeneous in later life and that there are specific aetiological or prognostic subtypes that are especially relevant to older people. Identifying prognostic factors is therefore a further aim of this chapter.

Co-morbidity is the hallmark of geriatric medicine. Studying disorders in isolation in older people is only rarely helpful or informative. This is especially true for late-life depression. Moreover, for our patients and in terms of public health, more functional and generic outcomes such as well-being, daily functioning and social integration are essential. As these generic outcomes are the product of all the co-morbid disorders the patient has to cope with, the final aim of this chapter is to consider the role the prognosis of depression plays in the overall well-being and functioning of older people.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

OUTCOME BRIEFLY CONSIDERED

There are many ways to define and measure the outcome of depression. As is the case in most areas of medicine, the methods employed have evolved from studies retrospectively and rather loosely classifying each patient in predefined clinical criteria, to prospective studies, rigorously measuring symptom severity at multiple time points. By definition, the more often symptoms are measured, the more likely it is that change will be detected. That would mean that the more recent and sophisticated studies, employing multiple measures over longer periods of time, are less likely to find a patient in sustained recovery and also less likely to conclude that the patient is chronically depressed.

The way the outcome of a disorder is conceptualized has great impact on the way it is studied and treated. Frank *et al*.[1] described clear criteria for what may be called the episodic model of the outcome of depression. This model, which is summarized briefly in Figure 80.1 has been by far the most influential. Depression is modelled as an episodic disorder, with a clear beginning, symptomatic stage and resolution phase. If, very soon after the symptoms have resolved, the patient suffers a relapse, this is considered part of the illness episode. If the recovery is more sustained and the patient suffers a recurrence, this is then considered to be a new episode. This well-known model has many merits. First, it is an optimistic model. Regardless of age, most patients recover and treatment generally helps to speed up recovery. The episodic model has also been helpful in both organizing our thinking about the prognosis of depression and in designing studies of treatment.

However, longer term follow-up studies employing multiple measurements have shown that patients often do not follow the neat stages of development of the disorder depicted in Figure 80.1[2]. The best known example is the Collaborative Depression Study, in which more than 400 patients were followed up using detailed weekly life charts. Over 12 years of follow-up, it appeared that patients moved in and out of different levels of symptom severity and diagnostic subtypes; the symptoms often waxing and waning[2]. Using an episodic model of outcome it was reported that 70% of the patients had recovered after one year and that the mean duration of episodes was approximately six months[3]. Given the fact that these were patients referred (and motivated) for treatment in a tertiary treatment centre, the outcome was quite optimistic. However, after 12 years of follow-up, using life charts it appeared that these patients spent almost 60% of the time in a state with clinically relevant levels of depressive symptoms, severe enough to disturb both well-being and functioning[2]. The results have prompted the authors to conclude that the prognosis in depression is pleiomorphic instead of episodic[2]. When accommodating the pleiomorphic model in research, the prognosis of depression appeared less favourable than when adopting an episodic viewpoint. In practice, there are patients in whom depression follows the path of a clearly delineated episode, there are patients in whom the symptoms wax and wane over time and there are patients with a chronic course. This has clinical relevance, as the way treatment and follow-up are organized should be determined by the expected prognosis. Indeed, as was suggested by McCullough, there is good reason to consider more chronic forms of depression as a different disorder from the more benign episodic disorders[4].

When describing the outcome of late-life depression in the next section, both the parameters relevant to an episodic view of outcome (such as the duration of an episode, the percentage of patients remitting within a given time, relapse or recurrence) and those relevant for a pleiomorphic viewpoint (the average symptom severity over time, the percentage of time patients spend in a depressive state) will be discussed.

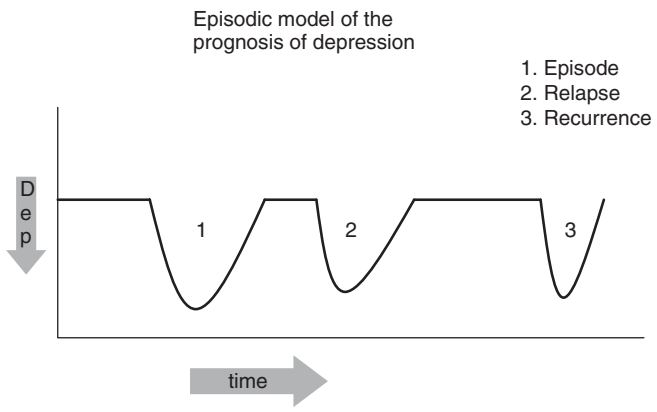

Figure 80.1 Episodic model for the prognosis of depression. From Frank *et al*.[1]

THE PROGNOSIS OF LATE-LIFE DEPRESSIVE SYMPTOMATOLOGY

Several systematic reviews have recently summarized the prognosis of late-life depression[5–7]. As was mentioned, the earlier studies were conducted as follow-up assessments of patients treated in clinical facilities. Over 20 such studies have been conducted. The outcome was often determined retrospectively in rather loosely defined clinical terms, such as the patient being well, recovery with relapses or being continually ill. Given various methodological shortcomings, Cole *et al*.[5] concluded that the majority of patients (about 60%) were well or had suffered relapses with recovery, while 14–22% were continually ill. Both Cole *et al*.[5] and Licht-Strunk *et al*.[6] in a more recent review have found poorer outcomes when studying depressed patients recruited from the community or primary care. Licht-Strunk *et al*.[6] summarized the findings of 4 primary care and 17 community-based studies that fulfilled quite rigorous methodological criteria. After a period of one year, 50–75% of patients no longer fulfilled diagnostic criteria for major depression. Taking a longer time-perspective, the available studies would suggest a rule of thirds: about one in three patients has a short-term remission, another one in three develops a chronic course, while the remaining third has a more varied prognosis, with intermittent episodes[6]. Only one study estimated the duration of episodes of major depression among older primary care patients. In a three-year follow-up of 234 older (55+) primary care patients with well-defined major depressive disorder, the average duration of an episode was estimated to be 18 months[7].

Moving from clinically defined outcomes to the more abstract pleiomorphic measures the prognosis looks even worse. In the Longitudinal Aging Study Amsterdam (LASA), which is a community-based study, 277 older depressed people were followed with six-monthly assessments over six years[8]. It appeared that almost half the sample was depressed more than 60% of the time over six years. Only one in three had a true chronic course, but another third of the patients were depressed most of the six years they were followed up, the symptoms waxing and waning over time.

Taking these results together, the prognosis seems rather good for only one in three older patients, while the majority are either

chronically depressed or have frequent, but intermittent changes in symptoms. It is striking that the data from the community and primary care suggest a less favourable prognosis when compared with data from specialized mental health care facilities. This is not what would be expected, as the more severe, chronic and hard-to-treat patients are referred selectively to specialized mental health. An explanation would be that majority of older depressed patients in the community and in primary care are not treated, while those referred for treatment do receive appropriate care[7].

MAJOR DEPRESSION, MINOR DEPRESSION AND DYSTHYMIA

Most of what is known about the prognosis of depression pertains to major depressive disorder (MDD). However, many older people with depressive symptoms do not fulfil rigorous diagnostic criteria for MDD[9]. What about their prognosis? The term 'dysthymic disorder' was introduced to replace 'neurotic depression'[10]. The underlying idea was that this would be a type of mild, but chronic depression, that was associated with personality disorders and therefore would arise early in life. What about dysthymia in later life? Is this common among older people and is it indeed a chronic, mild type of depression, that is primarily associated with personality problems?

The available data suggest that minor, or other subthreshold types of depressive symptoms, although clinically highly relevant to older people, do tend to have a more favourable prognosis than MDD. The prognosis of dysthymia appears to be worse than the prognosis of MDD. In the LASA study, data concerning the six-year prognoses of minor depression, MDD, dysthymia and double depression (MDD plus dysthymia) were compared[8]. Those with minor depression had the best prognosis (26% remission; 25% chronic course), followed by MDD (22% remission; 35% chronic course), dysthymia (12% remission; 52% chronic course) and finally double depression (only 5% remission and 77% chronic course). Dysthymia is quite common among older people (4.6% in the LASA study), has a symptom profile very similar to that of MDD and an earlier age of onset than MDD (average age at onset of 31 for dysthymia, compared with 53 for MDD)[11].

IS THE PROGNOSIS OF DEPRESSION INFLUENCED BY AGE OR BY AGE-RELATED FACTORS?

To answer this question one would like to be able to compare directly patients of different ages, recruited at similar stages of development of their affective disorder, using identical methods. As no such study is available, conclusions should be drawn cautiously as they are likely to be confounded. Given this caveat, the evidence seems to be overwhelmingly in favour of thinking that outcomes are poorer among older patients.

For instance, in a large community-based study of younger adults, the median duration of an episode of MDD was estimated to be three months, while the average duration among younger adult patients in specialized mental health has been estimated to be six months[13]. This compares very favourably with the 18 months average duration described for older primary care patients[7]. In the LASA study, direct comparisons between young-old (55–65) and older old (75–85) people is possible. It was clear that the oldest age group had a higher average symptom severity over six years of follow-up, a longer duration of symptoms and that they were almost twice as likely to have a chronic course of depression when compared with the youngest group[8].

Cole *et al*.[5] and Licht-Strunk *et al*.[6] have synthesized the data on prognostic factors for late-life depression, as described in community- and primary care-based studies. Although methodological differences among studies preclude exact estimates of the prognostic strength of different variables, some conclusions do emerge. The most consistently found prognostic factors are physical illness, impairments (such as pain, loss of hearing and loss of vision), disability and the associated impairment of daily functioning. The effect of cognitive decline and dementia on the prognosis of depression is undecided. Although one would perhaps expect that massive neurodegeneration and the resulting impairments and handicaps would be a powerful factor to prolong depression, moving through different stages of the dementia process may also act as a factor ending a depressive episode.

Another set of prognostic factors that has been studied is the experience of threatening or loss-related life events. Although these are powerful aetiological factors, there is no reason to believe that depression preceded or induced by life events has a different prognosis when compared to other types of depression. A third group of candidate prognostic factors concerns what is often called long-term vulnerability for depression. Examples are genetic factors, severe life events earlier in life, unfavourable personality traits (such as neuroticism), female gender, a lack of education or a lack of adequate social support. The uncovering of genetic subtypes predicting a more chronic course of depression would potentially be of great clinical importance, but has not as yet yielded definitive results. Studies suggest that gender, level of education and social support are not strong prognostic factors[5,6]. Both severe life events earlier in life and maladaptive personality traits have been identified as important unfavourable prognostic factors among younger adults. So far, the limited evidence has confirmed this for older adults, especially with regard to the role of neuroticism[13].

Given the available data on prognostic factors, those that have been uncovered are clearly related to age. This may explain why the prognosis of depression is worse among older people than among younger adults.

IS THE OUTCOME OF DEPRESSION MORE VARIED AMONG OLDER PEOPLE?

As described above, the available data suggest that the outcome of depression is less favourable in older adults than in younger people. This appears from data looking at the average duration of episodes, the rate of recovery, relapse and recurrence and the likelihood of chronic depression. A similar conclusion is drawn when comparing pleiomorphic indices of the outcome, such as the average symptom severity over time or the percentage of time people are depressed. Although many uncertainties remain, it appears that this less favourable outcome is at least partly explained by an increase in exposure to unfavourable prognostic factors. Depression is well known for its aetiological heterogeneity: a myriad of different aetiological factors can play a role in the development of depression. The exposure to such factors increases with age, dramatically changing the palette of risk factors involved. It is likely that the same happens with prognostic factors: the increased variability of the prognosis in part taking responsibility for the overall change in prognosis. This is important, as it would render any sweeping statement with regard to the overall prognosis of late-life depression inadequate.

With more prognostic heterogeneity, being able to reliably predict the prognosis becomes more important. Such data are becoming

available slowly. It is clear that, besides the above prognostic, several other markers that may help predict the prognosis in an individual patient are available. The most powerful group of predictors would be the severity, duration and stage of development of the depression (first episode, versus recurrent episode)[6,7,8,12]. Besides this, other clinical factors, such as co-morbid anxiety and substance-related disorders have been shown to predict the prognosis of depression[12].

Overall, the data suggest that old age psychiatry would do well to invest in identifying subgroups of depression by (i) a clinical staging of severity, duration and development of the disorder, (ii) the symptom profile, (iii) biological or other prognostic factors and (iv) treatment response. Examples are the vascular depression hypothesis, which, among other things, would suggest a poorer prognosis and less response to antidepressant therapy, and the recently coined amyloid depression, which would predict cognitive decline and perhaps also a less favourable prognosis[14].

It may be concluded that although much work needs to be done in the area of predicting the prognosis, it is highly likely that variation increases with age and that different prognostic subgroups, highly relevant to clinical work, do exist.

GENERIC OUTCOMES

Excess Morbidity

Co-morbidity between physical health and depression is salient in late life, when both risk for illness and disability rises. Depression in old age can be a consequence of somatic illness and disability but ample research also suggests that depression in the elderly leads to restricted functioning and worsening of co-morbid conditions by a variety of behavioural and biological mediators. The pathways between depression and excess morbidity are complex and bidirectional. Large-scale longitudinal studies have been carried out trying to disentangle this complex interaction. Scott *et al.*[15] recently found in their review of World Mental Health surveys that although the majority of elderly suffered from chronic physical conditions the large part had no signs of depression and anxiety. By contrast, the majority of those with mental disorders had physical co-morbidity. From another perspective findings suggest that different durations of the presence of depressive symptoms have different impact on physical health. Long-term depression had profound negative effects on illness, a short duration far less[16]. More specifically the association between depression and ischaemic cardiac illness is a frequently studied topic[17]. Depression and cardiac disease often co-occur and this association is likely to be bi-directional[18]. The presence of subclinical atherosclerosis due to exaggerated platelet function, activation of pro-inflammatory pathways and an altered HPA axis state has been suggested as an underlying mechanism[19,20].

A second field that has been studied extensively is co-morbid cognitive impairment, a clinical hallmark in old-age psychiatry because cognitive impairment is one of the immediate consequences of depression. There is a strong association between late-life depression cognitive impairment, cerebrovascular disease and progressive dementia, including Alzheimer's disease. The varied findings suggest that there are probably many pathways to poor cognitive outcomes with multiple aetiological links[14,21]. Research in this field combines data from long-term longitudinal studies with (functional) neuroimaging and biomarkers and should lead to a better understanding of these clinically very important relationships.

Suicide and Other Causes of Excess Mortality

In most countries suicide rates remain highest in old people according to the World Health Organization. In particular, older men act more decisively on their suicidal intent than women, an effect increasing with age, which could be an explanation for the large sex differences in this respect[22]. In a series of psychological autopsy studies from the United States, Scandinavia and the United Kingdom more than 70% of the elderly who died by suicide suffered from a psychiatric condition, mostly depression[23]. Persistent feelings of hopelessness and a long duration of depression and sleep disturbances were the most consistent predictors in the elderly[24]. Notwithstanding the high suicide figures in elderly men the major part of the impressive rates of increased mortality in depressed elderly cannot be explained by suicide, but is related to other causes of death, probably cardiac events in the first place. In a recent study a dose–response relationship was found for late-life depression and early death, suggesting a causal relationship[25]. There are several explanations for this pathway from depression to early death. On a behavioural level depression is generally associated with unhealthy lifestyles like smoking, use of alcohol, physical inactivity and lower compliance with medical treatment. In the elderly cognitive impairment and dieting may add to this negative cascade. Decreased heart rate variability, HPA axis dysregulation and increased pro-inflammatory activity are biological factors which probably play a part in cardiac-related death. At a subclinical level there may be depression-related illness like hypertension and endocrine dysfunctioning leading to early death. In conclusion many pathways in late-life depression lead to early death in complex interacting mechanisms[25,26].

Excess or inadequate use of service

Late-life depression is an important reason for both excess and inadequate utilization of non-mental care resources[27]. Older patients and their care providers frequently persist to attribute depressive symptoms to somatic illness or ageing effects, thus creating diagnostic confusion. In a US national sample of subjects with persistent depressive or anxiety disorder, 87% had a chronic co-morbid medical disorder, most were seeing a primary care practitioner, but only 12% were receiving both appropriate medication and counselling at follow-up[28]. In a recent Dutch general practice study, persistent frequent attendance was five times as likely to occur among persons over 65 years of age, and four times as likely when psychological or psychiatric problems were present[29]. Depression plays an especially important role in frequent attendance of the elderly[30]. Up to a quarter of elderly attend frequently, many of whom are depressed[31].

Well-being and Functioning

Older depressed patients have substantial and long-lasting decrements in multiple domains of functioning and well-being that equal or exceed those of patients with chronic medical illnesses such as diabetes mellitus[6,27]. Perhaps this strong relationship is not that surprising as depression is characterized by an absence of well-being and functioning. A prolonged lack of happiness is a key symptom for a diagnosis of major depression. To demonstrate this reciprocal relationship, positive affect, defined as emotional contentment and happiness, was directly correlated over time with social involvement and inversely correlated with negative affect (i.e. depression), instrumental activities of daily living functioning, and somatic co-morbidity[32].

CONCLUSION

All the things that characterize later life also characterize late-life depression. Older people have a lifetime of experience and ageing tends to create more variability among the processes relevant to living. Depressed older people often have a long experience with mood changes and the pathways leading to depression become more complex with age. The available data would suggest that the prognosis of depression, whichever way it is conceptualized, becomes less favourable with ageing. The data also suggest that a large part of this is due to age-related prognostic factors, and much less due to ageing per se. Depressed older people are partly 'graduates': people who have suffered repeated episodes of depression throughout life and who continue to do so when they become old. Their prognosis is a function of the long-term development of their affective disorder and concurrent circumstances or events that happen while ageing. A large minority of our patients have become depressed for the first time in later life. Among them are patients becoming depressed due to life events or circumstances, and patients who become depressed in the context of specific, age-related illnesses. The prognosis of their depression is closely related to the outcome of the underlying cause and treatment more likely to be successful if this is taken into account.

It was argued that geriatric psychiatry would do well to adopt a clinical staging of affective disorders, which should include data on (i) severity, duration and clinical stage (first or recurrent episode), (ii) relevant prognostic factors, including biological markers, (iii) data on specific symptom profiles relevant to treatment or the prognosis and (iv) data on treatment outcome. This would help to build a more definitive database on the outcome of late-life depression, while simultaneously improving treatment.

Depression only rarely occurs in isolation in older people. Although clinicians are prone to focus on the disorders they have specialized in, the more generic outcomes of disorders are likely to be more relevant to our patients than the course of one specific disorder. It was shown that depression has profound impact on most of the generic outcomes that one would consider important for the public health of older people. Although it remains difficult to tease out the unique effect that depression has on these outcomes over and above the effects of co-morbid disorders, the available data suggest that depression often plays a decisive role in tipping the balance towards unfavourable outcomes. The fact that depression remains highly treatable until very late in life should inspire us to work hard to improve both the diagnosis and treatment of depression in older people.

Physical Illness and Depression*

Mavis Evans

Elderly Mental Health Directorate, Wirral and West Cheshire Community NHS Trust, Clatter bridge Hospital, Bebington, Wirral, UK

EPIDEMIOLOGY

The prevalence of depression in the general population worldwide is usually found to be 3–8%[1–3]. The prevalence of major depression has been shown to be no higher in the elderly than the young, although these findings do not allow for the co-morbidity of physical illnesses or dementias[4]. The World Health Organization (WHO) World Mental Health surveys[5] of respondents in 10 developed countries ($n = 52\,485$) and 8 developing countries ($n = 37\,265$) showed that 12-month major depressive episodes (MDE) were significantly less prevalent among respondents aged 65+ than in younger respondents in developed but not developing countries. Prevalence of co-morbid mental disorders generally either decreased or remained stable with age, while co-morbidity of MDE with mental disorders generally increased with age. Prevalence of physical conditions, in comparison, generally increased with age, while co-morbidity of MDE with physical conditions generally decreased with age. The surveys concluded that the weakening associations between MDE and physical conditions with increasing age argue against the suggestion that the low estimated prevalence of MDE among the elderly is caused by increased confounding with physical disorders. Future studies are needed to investigate processes that might lead to a decreasing impact of physical illness on depression among the elderly.

Subthreshold or minor depressions have many different names and definitions, which causes widely differing prevalence rates to be quoted. Categorical definitions of depression do not fit well with the range of symptoms and severity seen in normal clinical practice. However, it is generally accepted that the burden of depression among the elderly is high and an accepted measure of diagnosis is necessary to allow communication with patients, relatives and professional colleagues.

'Caseness' can be considered to be the severity of depression at which the majority of professionals would consider some form of intervention appropriate. Prevalence of this degree of depression is reported as 10–15% of the elderly in the community[6,7], 15–30% of those attending primary care facilities[8,9], 15–50% of those in hospital[9–11] and 30–40% of those in institutional care[9,12].

DIAGNOSIS

Depression cannot be diagnosed unless it is first considered a possibility, neither will it be appropriately treated unless it is considered pathological. Depression may be missed when too much emphasis is placed on the presenting complaints of, for example, lethargy, anorexia or pain[13]. Depression and feelings of worthlessness may cause failure to complain of symptoms of physical illness or to ask for help. It may cause non-compliance with medication and other treatments, self-neglect or non-attendance at clinics. Alternatively, the lowering of self-esteem and decreased ability to cope can lead to increased attendance at clinics.

The lack of a concise definition for depression in the elderly makes the establishment of validity a difficult task, which can only be examined by longitudinal follow-up of patients to see what happens to their symptoms[14]. Somatic symptoms, such as lack of energy, poor concentration and weight loss, may be caused by the physical illness or ageing, not depression; even experienced clinicians may have difficulty attributing such symptoms to physical or psychiatric causes. Even feelings of life not being worth living and wishing to die are not always associated with depressed mood; poor subjective health, disability, pain, sensory impairment and living in an institution have been shown to be associated factors in the absence of depressive illness[15].

The elderly tend not to admit to feelings of depression and relatives may be unaware of the condition[16]. Somatization, 'the tendency to experience and communicate somatic distress and somatic symptoms unaccounted for by relevant pathological findings, to attribute them to physical illness and to seek medical help for them'[17], is increasingly recognized. Somatization can still occur in those with genuine physical illness. The somatic symptoms of depression are similar to those of a chronic illness, such as cancer, and it must be remembered that depression and physical illness often co-exist[18].

Hypochondriasis is a recognized symptom of depression in the elderly population[19]. However, in this age group, rigorous steps must be undertaken to exclude physical problems before ascribing symptoms to hypochondriasis or somatization[18,20]. That such patients are depressed is inferred from their good response to standard treatments for depression[21].

The 1991 National Institutes for Health (NIH) Consensus Statement on diagnosis and treatment of depression in late life concluded: 'What makes depression in the elderly so insidious is that neither the victim nor the health provider may recognize its symptoms in the context of the multiple physical problems of many elderly people.' DSM-IV allows somatic symptoms to be counted towards the diagnosis of depression if there is any possibility of psychological aetiology, a more inclusive and accurate means of diagnosis than previously.

MORBIDITY AND MORTALITY

Psychiatric morbidity in hospitals is higher than in the general population. Surveys of wards and clinics do not completely establish an association between psychiatric and physical morbidity because they may be biased for selective referral patterns: psychological symptoms can lead to help-seeking behaviour for physical illness in an individual who had previously been able to tolerate his or her physical problems. Similarly, they may influence a GP on whether or not to refer to hospital. Stress may be as important in triggering help-seeking behaviour as in triggering actual illness. In addition to the degree of distress, many other factors determine whether or not an individual will seek help, including religious and social values, socioeconomic background and personality.

Affective disorder in the elderly is strongly associated with physical ill-health[20]: 'whether or not such an illness has a direct aetiological relationship to the affective disorder, its practical importance must be considered, for it is bound to influence the course and outcome of the psychiatric condition.' Although overall medical burden appears comparable in elderly patients with bipolar and those with major depressive disorder, patients with bipolar disorder have higher body mass index and greater burden of endocrine/metabolic and respiratory disease[22].

Other studies have found that depression leads to increased mortality[23–25] over and above age effects, the prognosis worsening with severity of depression. Chronic illness, physical function and cognitive function all independently predict depressive morbidity in late life. The significance of depressive symptoms was demonstrated by their independent association with all-cause mortality at two-year follow-up[26].

Depression in the elderly may be due partly to a biological ageing process, which would directly increase mortality and morbidity[21,27]. Burvill and Hall[28] showed increased mortality in depressed elderly patients ($n = 103$, aged 60+) followed for five years if they were aged 75+, had impaired mobility or showed poor recovery with residual symptoms or chronicity. There were two peaks of increased mortality, one early in the disease and one late. Cardiovascular or pulmonary disease and malignancies were the predominant causes of death. The results are similar to those of the four-year follow-up by Murphy *et al*.[29], who also postulate that increased mortality seen in the depressed elderly (especially the men) was not caused by differences in physical health alone. They suggest:

- inadequate treatment of the depression, leading to cardiovascular complications from the antidepressant but no benefit to the patient; the depression itself can also provoke cardiac death, especially in men;
- 'sub-intentional suicide' in those who 'turn their faces to the wall';
- residual depressive invalidism, causing poor nutrition and decreased mobility; with attendant complications of susceptibility to infection, fractures, bedsores, etc., all contributing to the increased mortality.

Mortality in hospital was found to be significantly higher in those depressed but over 30% of those discharged had died within, on average, five months, whether depressed or not[30]. The authors also noted that survivors with depression consumed more health care resources than did the non-depressed survivors. Among the depressed elderly, 40% have chronic poor physical health[31]; they use and need more medical services[32,33] than the non-depressed, but also use fewer social and recreational services[32]. An association has been found between poor mental health and subsequent physical disease, suggesting that positive mental health may significantly retard the decline in physical health with increasing age[34].

Physical illness affects the capacity for independent living, resulting in altered relationships with others, lowered self-esteem and vulnerability to depression. Serious illness may be seen by some as an unpleasant reminder of mortality, bringing apprehension and fear. Continuing physical illness is a poor prognostic factor for depression, although whether this is a result of a biological relationship or the psychological strain of being ill is uncertain.

Mortality in acute medical inpatients is significantly higher in those with associated depression, although the direction of causality is not established. For example, Silverstone[35] followed consecutive admissions for myocardial infarction, subarachnoid haemorrhage, pulmonary embolus or upper gastrointestinal haemorrhage for 28 days post admission; 34% were depressed and 47% of these had life-threatening complications or died, compared with 10% of those not depressed.

PHYSICAL ILLNESS AND DEPRESSION

Mood disturbance can result from structural brain disease, alterations in neurotransmitter concentration or activity caused by drugs or biochemical disturbance. These affective symptoms may present during a physical illness or be the initial symptom of an otherwise occult physical disorder. Depression may be:

- the result of an illness, especially a painful or disabling one;
- iatrogenic (e.g. the result of steroid treatment);
- a symptom of the physical illness (e.g. hypothyroidism);
- an aetiological factor (e.g. alcohol abuse secondary to depression);
- a depressed patient adopting the sick role as a coping mechanism;
- a common aetiological factor, such as bereavement, causing both depression and physical illness; or
- coincidental.

The elderly are particularly susceptible to the side effects of drug treatment[36], especially as they are often subject to polypharmacy[37,38]. Patients with drug-induced depression often have a past or family history of depression and the drug may have precipitated the disease by affecting the levels of available neurotransmitters[37]. Depression can often be alleviated by cessation of the drug, although some patients will also require antidepressant treatment. The combination of a susceptible patient and a depressogenic drug may precipitate a depression sufficiently severe to lead to suicide[37].

Subjective rating of general health has been shown to be independently associated with depression in the elderly, including the very old[39–41]. This can lead to presentation at primary care or emergency facilities, unnecessary investigations and risk of iatrogenic disease, and lower quality of life. Recognition and treatment of the depression may lead to improvement in the patient's subjective perception of his or her health.

Physically ill depressed patients are more likely to be admitted to hospital than those who are not depressed[42]. Depressed patients have higher use of all categories of medical care, including admissions, laboratory tests and emergency department visits[33].

The presence of significant psychiatric disorder has been shown to adversely affect the course of medical admission[43,44], affective disorders in particular prolonging length of stay[45–47] (although the study by Ramsay *et al*.[48] did not confirm this) and increasing the

likelihood of admission to residential care[49]. Psychiatric intervention has been shown to increase recovery rate, reduce duration of stay, reduce the need for residential care after discharge and therefore reduce costs[50,51]. Importantly a diagnosis of major depression in older medical inpatients is independently associated with poor mental health in their informal caregivers six months later[52].

ADJUSTMENT DISORDER

Lipowski[53] has proposed that the subjective significance of an illness and its treatment (e.g. amputation, cancer), combined with the patient's personality and social circumstances, is the key to the psychological response. The variety of physical illnesses found with depression would support this view. Depression may be a reaction to physical problems; it occurs more frequently in those with increasing numbers of medical diagnoses and may be precipitated by developing new physical illnesses[23,54]. All illnesses except the very trivial involve an element of psychological adjustment. Serious medical illness is likely to be a potent psychological stressor, affecting body image, self-esteem, the sense of identity and the capacity to work and to maintain social, family and marital relationships[55]. However, the majority of people adapt their lives to the demands of their illness, maximizing their prospects of recovery and return to previous levels of activity.

In the elderly, physical illness is frequently chronic and may worsen with time. This, combined with the losses suffered by many elderly people, such as loss of status and income on retirement, loss of friends and family by death and the fear of loss of independence and dignity due to the illness itself, can lead to the adjustment disorder merging imperceptibly into a depressive illness. This can be considered secondary depression[56], the depression following or paralleling a life-threatening or incapacitating medical illness. However, the prevalence of this type of depression is unknown, as it is difficult to differentiate from depression related to other stressors and previous history. Patients with this type of depression tend to have fewer suicidal thoughts but have more feelings of helplessness, pessimism and anxiety[57].

SOMATIZED DEPRESSION

This is more common than medical illness presenting as depression, especially in the current generation of elderly, who tend to somatize their psychological symptoms, having been brought up in a society which did not encourage the expression of emotion. Somatic symptoms in the elderly may represent physical illness, depression or emotional responses to physical illness. The somatic symptoms will need investigation, but depression, if suspected, should be treated.

Pseudodementia is a specific type of masked depression. One of the most important differentiating factors is that the severity of cognitive impairment fluctuates in depressed patients, remaining constant or worsening in the evenings in dementia. Depressed patients tend not to try to succeed in tasks, giving up with 'I don't know' or 'I can't'. Demented patients will try, delighting in success but possibly becoming very distressed by failure – the so-called catastrophic reaction. Biological symptoms of appetite and weight loss, sleep disturbance and headache are typical of depression and not dementia. However, depression and dementia can co-exist and the differentiation of the two conditions is not always easy. If in doubt, a trial of antidepressant treatment will help elucidate the diagnosis. The pathognomic symptoms of masked or somatized depression include:

- diurnal variation (symptoms usually worse in the mornings);
- mild impairment of cognitive processes and concentration;
- dysthymic mood changes;
- fatigue, feeling tired, lack of energy;
- sleep disturbance (waking up early and being unable to get back to sleep); and
- an anxious sense of failure or of 'impending disaster'.

LIAISON

Consultation–liaison psychiatry has become well established as an important specialty in general hospitals on both sides of the Atlantic. In an ideal situation, psychiatrists would attend ward rounds in the general hospital, particularly on rehabilitation wards, where prevalence of depression is high and the effect on delayed discharge well documented[45–47]. However, restricted resources prevent this: psychiatric morbidity is too high for a psychiatrist to see all the patients affected – his or her main role should be educational[58], only taking an active part in the management of more difficult cases. In many areas there is increasing development of specialist liaison nurses who are able to advise on diagnosis and treatment, reducing delay before assessments. The liaison nurse is likely to be more permanent than junior doctors on rotation and can often help a patient who refuses to see a psychiatrist or whose physician refuses psychiatric referral[59]. Liaison nurses can educate general nurses in the recognition of psychiatric disorders and can in turn encourage junior medical staff to institute appropriate referral or treatment. Their development and use has been compared with that of community psychiatric nurses[60].

The most common reasons for requesting a psychiatric consultation in a general hospital are[61]:

- diagnostic uncertainty;
- recognition of a gross psychiatric disorder;
- excessive emotional reactions (e.g. fear, anger, depression);
- a patient's deviant behaviour disturbing ward or medical procedures;
- delayed convalescence (i.e. disability incompatible with observed pathology, relapse on mention of discharge);
- crisis in the doctor–patient relationship (e.g. refusing consent!);
- patient's admission of serious psychosocial difficulties;
- selection and/or preparation of patients (e.g. pre-transplant, cosmetic surgery).

It can be seen from the above list that the depressed patient, sitting quiet and withdrawn on the ward or in a home, may not be referred for a psychiatric opinion. In practice, only about 2% of geriatric patients are referred to the liaison services[62–64]. Suggested reasons for the discrepancy between liaison rate and psychiatric morbidity are as follows[62,65]:

- High prevalence of transient self-limiting psychiatric disease.
- Physician's failure to recognize psychiatric disease[66]. Many studies have highlighted the unrecognized psychiatric problems on medical wards[65] and the under-diagnosis of major depression in particular has been well documented[67].
- Medical and nursing staff may actively avoid questioning for psychological problems, due to fear of precipitating emotional distress that they have not been trained to deal with.
- The low priority of psychiatric disease compared to physical, especially in a busy medical ward with acutely ill patients.

- Poor access to, or dissatisfaction with, psychiatric services.
- Physician resistance to psychiatric consultation[50] due to stigma or under-estimating the severity or the potential for treatment.

Use of screening scales is appropriate for assessing depression in the physically ill: it is common, can be a difficult diagnosis and has significant morbidity and mortality if untreated. Care must be taken to differentiate between short-lived adjustment disorders, occurring as a reaction to the admission itself, or the crisis which precipitated it. Diagnosis in acute admissions should therefore include enquiry into symptoms before admission. If none can be elicited, the patient should be reassessed at a later date, either during rehabilitation or after discharge.

Screening scales serve a dual function[68–70] – they identify patients in need of further assessment and also serve as an educational tool if given by general staff during routine admission procedures. They emphasize the associated symptoms and signs of depression in the elderly, who may not show depressed affect and will deny feeling sad. It is important, however, that education about the treatment of depression goes hand in hand with education to recognize it, or the liaison services will be swamped.

TREATMENT

The fact that one can intuitively 'understand' why the physically ill elderly are depressed does not mean that it should be accepted as normal and treatment not attempted. Continuing physical illness is recognized as both a precipitant of depression and a poor prognostic factor, yet despite this, 80% of elderly general hospital patients are not depressed[45,71,72]. Successful coping mechanisms can prevent the emergence of clinical depression. Even in the terminal patient, depression or dysphoria can be relieved by euphoriants, such as oral or parenteral opiates, reducing the distress of patient and relatives[73] without significantly reducing the length of life remaining to the patient.

It is important that the diagnosis is not missed, as this condition usually responds well to treatment, at least initially, thus improving quality of life. Follow-up and early treatment of any relapses will further improve the prognosis. Increased self-esteem and ability to cope will reduce demand on families and possibly on services.

Even when the correct diagnosis is made, the depression may not be treated adequately, if at all: physically ill patients who are also depressed are more likely to be assigned to the 'not to be resuscitated' group, compared with those elderly who are not depressed. The lack of effort and motivation caused by depression may be regarded as 'not trying' or 'giving up' by nurses and rehabilitation staff, who withdraw from this group of patients for more emotionally rewarding non-depressed elderly subjects on the same ward.

The elderly as a group have approximately twice as many adverse drug reactions as younger adults[74]. They are frequently already on polypharmacy, so drug interactions are a real possibility. It is therefore important that physicians are advised and supported by the psychiatric services in the use of safe, well-tolerated antidepressants and other treatments to reduce the impact of this disease on both the individual and society.

Electroconvulsive therapy (ECT) is an effective treatment of depression[75,76]. The response to treatment in older people is better than in the young[77,78]. With the increasing safety of anaesthesia, very few patients, even those with severe physical disease, are unable to tolerate a course of treatment. It is more rapid in effect than medication alone, but the improvement is rarely sustained unless antidepressants are also given to prevent relapse.

A review of psychological treatments in chronic illness[79] found very little empirical evidence of benefit when therapeutic interventions were applied indiscriminately. However, some evidence was found to show benefit in patients with somatization disorders rather than physical illness, and also that brief interventions following the onset of acute physical illness reduced longer term psychological morbidity. A suggested general approach to the treatment of physically ill depressed patients is as follows:

1. Investigate and give appropriate treatment to all physical problems, either curative treatment or to minimize persistent morbidity. Explain the illness, treatment and prognosis to the patient in as much detail as he/she wishes. Make sure the explanation is understood and repeat as often as necessary.
2. Give general social support (e.g. home help services, financial assistance if relevant, or residential or nursing home care).
3. Give psychological support – encouragement, continued interest in the patient (e.g. outpatient follow-up). Support groups are often beneficial for chronic conditions such as rheumatoid arthritis, Parkinson's disease, etc.
4. Consider antidepressant therapy if the symptoms are sufficiently severe that they would be considered to warrant medication if seen in a patient without physical problems. Monitor the response to treatment; this may take 7–8 weeks[80]. If no response is seen to a therapeutic dosage of antidepressant, consider a trial of an alternative antidepressant or adjunctive treatment, or specialist referral.

PROGNOSIS

Little is known of the prognosis of psychiatric disorder identified in the medical setting[81], except that concomitant physical illness is a poor prognostic factor. Psychiatric disturbance often persists[82–84], especially in patients with a previous history of psychiatric disorder. Those with affective disorder on admission have increased mortality and make greater demands on medical, social and psychiatric services[81,85].

In one series of consecutive acute medical admissions[84], fewer than 45% of those patients with concomitant depression had received antidepressants at all, 20% had been given benzodiazepines, and less than 25% had been treated for more than one week. The authors concluded that an effective treatment for depression in elderly patients needed to be found, with widespread education of geriatricians in the diagnosis and treatment of depression.

In psychiatric patients, relapse has been linked with supervening physical illness[86]. The presence or development of cerebral or any other irreversible physical disorder indicates poor future mental health in the great majority of patients, as well as the likelihood of early death[87].

The prognosis of the physical illness, for both morbidity and mortality, is also inextricably linked with that of the depression. Increased mortality from physical illness, especially cardiovascular disease, has been reported[88,89]. This excess of deaths is significantly associated with groups who have been only partially treated (e.g. have not responded to antidepressants[90], especially in older men[91].

Explanations for the apparent association of physical illness with poor treatment outcome might include[92]:

- age as a confounding factor – most of the trials of treatment in the physically ill are in the elderly;

- medically ill patients may be given inadequate doses of antidepressants because of problems with side effects or over-cautious physicians;
- different subtypes of depression exist, some medication responsive, some not. Organic mood disorder (depression induced by physical illness or a specific organic factor) has been shown to have a worse prognosis at four-year follow-up[93].

The prognosis of depression in the physically ill elderly is therefore dependent on accurate diagnosis, intensive treatment, follow-up and early treatment of any relapses[86,88,94]. Increased self-esteem and ability to cope will reduce demand on families and possibly on services. No studies have yet convincingly identified predictors of response in physically ill populations, although pre-existing depression prior to admission with physical problems appears to predict persistent depression, rather than if the depression develops in hospital[82,95].

SUICIDE

Suicide is the most dramatic of poor outcomes, and the elderly are over-represented in suicide statistics. Although the elderly are less likely to attempt suicide, they are more likely to complete it[96,97]. The presence of physical illness, especially if associated with chronic pain and disability, increases the risk; elderly men living alone are at the highest risk. The individual's adjustment to ill-health and his or her associated feelings of hopelessness and demoralization are obviously important[98]. Many elderly suicide victims are suffering from their first episode of major depression, which is typically only moderately severe but the diagnosis is missed[99], and the potential for recovery following intervention therefore lost.

Depression has been linked to decreased compliance and to voluntary refusal of life-saving essential medical treatments[100,101]. This may reflect either conscious or unconscious suicidal motivation.

SERVICE IMPLICATIONS

It is important to note that the ageing population itself is growing older, with large numbers of very old individuals. It is this old-old group who have the highest physical and psychiatric morbidity and who make the greatest demands on services.

Undergraduate teaching programmes must be tightly integrated in order for students to develop a holistic approach to the elderly, together with an understanding of the psychosocial and economic factors that will affect presentation and treatment. Joint postgraduate meetings between the two specialties are becoming more common and should be encouraged, each maintaining their separate identities and training but working closely together in clinical practice.

Interdisciplinary research continues to grow in amount, but is mostly directed at psychiatric problems on medical wards. Little seems to be researched in the other direction, medical illnesses on psychiatric wards. All research is obviously relevant to both specialties and in practice helps to strengthen links between them.

Depression After Stroke

Peter Knapp and Allan House

University of Leeds, UK

Stroke patients have high rates of all types of depressive disorder, although estimates of the prevalence of depression within the first month of stroke vary greatly[1,2], according to the type of measure used and the way the sample was derived. A recent systematic review of observational studies suggests that the point prevalence of depression at any time in the first year after stroke is about 33%[3]. The frequency of depression is about the same whether measured soon or later after stroke, although later rates are less certain because of patient attrition in studies. Depression remits in some patients, while in others it persists: one study reported that 50% of those depressed within three weeks of stroke remained depressed one year later[4]. Depression not only affects quality of life: patients with depression after stroke may be at greater risk of mortality[5], cognitive impairment[6] and poorer functional or social recovery[7,8].

There are claims that post-stroke depression is a distinct subtype[9]. There is little unequivocal evidence to support this claim, since psychological and biological symptoms reported by patients are found in depression seen in non-stroke patients[10]. What does appear to be distinctive is the increased prevalence of uncontrollable crying (emotionality) among stroke patients. A small number of patients suffer pathological laughing and crying, a syndrome which is probably neurological in origin, in which emotional expression arises after minor provocation that often appears meaningless[11]. A more common syndrome, emotionalism, is also characterized by increased tearfulness, but is more complex. The emotional episodes are provoked by meaningful stimuli, but the crying is characterized by a lack of warning and control. There appears to be a psychological component to its origin[12]. Emotionalism is associated with an increased risk of depression[13], but patients with emotionalism may be at greater risk of psychological problems not explained by concurrent depression[14,15]. This syndrome is probably under-recognized.

Reaching a diagnosis of depression after stroke can be complicated by the presence of problems such as communicative or cognitive impairment[16]. Patients with expressive communication problems can often be assessed by the careful use of closed questions. The assessment of those with receptive communication problems or significant cognitive impairment is much more complex: a non-language-based assessment of depression shows promise but is insufficiently reliable in its present form for accurate diagnosis[17]. The use of a 'smiley faces' symbol measure has also been shown not to be a reliable screening tool[18]. Screening for depression by the use of questionnaire measures can be quick and easy to do; the main disadvantage is their low positive predictive validity: they identify many false positive cases[19]. A recent study suggests that such pencil and paper screening measures have greater validity when administered twice several weeks apart: patients scoring above the threshold on only one occasion are less likely to have a persistent depression that warrants treatment[20].

The diagnosis of depression by clinical interview might also be confused by facial palsy and a disturbance of speech prosody (rhythm in speech), both of which are relatively common after stroke and which give the patient the appearance of a person with depression[21]. The dexamethasone suppression test is not sufficiently sensitive to be used as a diagnostic tool[22].

The high rate of depression reported in some stroke research has led to the suggestion that the neurological damage is a key factor in its aetiology[23]. As a result, many studies have attempted to link depression after stroke with lesion location. A series of studies proposed, first, that patients with left hemisphere lesions were at greater risk of depression[24], and later, that those with left anterior lesions were at most risk[25,26]. Other researchers[27–29] have not replicated these findings, suggesting that patient sampling and the timing of assessment might explain the differences.

Even if lesion location is associated with greater risk of depression, the context of this relationship is important. First, it is clear that stroke patients with all sorts of lesions can suffer depression[9], so factors other than lesion location must also be at work. Second, stroke location is extremely varied[30], so those with any particular lesion (such as left anterior lesions) will be a minority of patients, making the attributable risk due to any one type of lesion small. Last, although the rate of depression in stroke patients is higher than in age-matched non-stroke controls, it is about the same as in patients with non-neurological disabling illness[21,31], suggesting that non-neurological factors are important. Relevant non-neurological aetiological factors are likely to include the threat of disability and a sense of loss.

That psychosocial factors are likely to be relevant to both the onset and persistence of depression has been illustrated in several studies. For example, one study found that depression at four months after stroke onset was commoner among those with greater disability, those who were divorced and those with higher pre-stroke alcohol intake[28]. Depression is more likely in those patients who perceive their stroke as a greater threat, and in those who have fewer psychological resources or social support to deal with that threat. Patients with previous history of depression or other psychological disorder are also at higher risk of depression after stroke[32].

Patients with depression after stroke might be considered for pharmacological or psychological treatments. A recent systematic review of the treatment trials showed limited beneficial effects of antidepressants, with moderate reduction in symptoms compared to placebo[33]. Trials are generally small with high drop-out rates and inadequate evidence on other outcomes (such as functional recovery or mortality) or adverse events. The evidence for treating emotionalism with antidepressants is rather stronger – both tricyclics and selective serotonin re-uptake inhibitors (SSRIs) have been shown to reduce the frequency of crying episodes[15]. There is no good trial evidence to draw upon in assessing whether psychological interventions are effective in treating depression after stroke[33].

Some services aim to intervene in an attempt to prevent the onset of depression after stroke. There is no evidence to support the use of antidepressants in preventing the onset of depression[34]. Three recently completed studies suggest that brief psychological interventions may be beneficial[34]. Randomized trials of motivational interviewing, care management and problem-solving therapy all showed small but statistically significant benefits. Each needs replication in further trials before these interventions can be recommended for implementation as a matter of routine, although it is encouraging that relatively brief, structured psychological interventions can show benefits. There are disadvantages to psychological management: it may be difficult to implement in patients with significant speech and cognitive impairment[35], and some patients find psychological treatments unacceptable, both before and after the treatment has started.

An unresearched question relates to the best means of structuring interventions. Evidence from other areas suggests that there are substantial benefits to be had when pharmacological and psychological treatments are delivered in an integrated approach according to standard protocols[36], when treatment is tailored to severity of depression and its response to first-line treatment, as in stepped care programmes[37] and when it is delivered in programmes of collaborative care that involve both primary and secondary care specialists[38].

In summary, depression after stroke is common, and its causes are probably multiple – biological, psychological and social – as is the case in other physical illnesses. The evidence for benefit from antidepressant drugs is accruing but remains surprisingly poor, considering their problematic side effects and how widely they are prescribed. The potential for psychological therapies is evident in several studies and its use has been under-evaluated, which is a deficit that needs correcting. The completion of several systematic reviews of intervention trials and prevalence studies has been beneficial for providing evidence for clinicians but, pending the completion of further primary research, clinicians will largely need to rely on evidence from other areas of physical medicine to inform their treatments.

Cross-Cultural Variation in the Experience of Depression in Older People in the UK

Vanessa Lawrence[1], Joanna Murray[1], Anthony Klugman[2] and Sube Banerjee[1]

[1]*Institute of Psychiatry, King's College London, London, UK*
[2]*Old Age Psychiatry, South London and Maudsley NHS Foundation Trust, London, UK*

INTRODUCTION

Depression is the most common mental disorder in later life, affecting up to 15% of those over 65[1]. Studies focused on the needs of people from minority ethnic groups suggest at least the same high prevalence of depression among south Asian and black Caribbean groups in the UK[2]. It has been suggested that ethnic elders may be more vulnerable to mental illness than the majority population and the term 'triple jeopardy' has been used to describe the combined challenge of racism, ageism and socioeconomic deprivation faced by older people from minority backgrounds[3]. Census data reveal that the proportion of black and minority ethnic individuals over the age of 65 increased from 3% in 1991, to over 8% in 2001. Therefore, it appears inevitable that the prevalence of depression in minority ethnic groups, and the challenges that this presents to health and social services in the UK will rise[2]. It is also of concern that older adults from minority ethnic groups appear to have lower levels of service use compared with the majority population[4].

There are major discontinuities in the management of depression in old age throughout the health and social care system. It is estimated that only 15% of older people with depression receive appropriate treatment from primary or secondary care services[5]. This may be a function of the inherent complexities of the illness with the presentation of depression anything but uniform. From a cross-cultural perspective, there are suggestions that Asian and black Caribbean patients have their psychological problems identified less frequently than their white counterparts[6]. Again, this may in part be explained by the variable ways in which depression is manifested and reported by different ethnic groups[7,8]. The National Service Framework for Older People has explicitly acknowledged that depression is undertreated in older people, and a key aim is to ensure the early recognition and effective management of depression across ethnic groups[9].

BARRIERS ON THE PATHWAY TO CARE

Suggestions of unmet need among ethnic elders[10] require an exploration of the potential barriers and facilitators to service use. Goldberg and Huxley (1980) described a succession of filters in the 'pathway to care' that determine whether people access mental health services[11]. Sufferers Beliefs about the nature of the condition, and what is appropriate help, may act as barriers at each of these stages, influencing whether and from whom to seek help, the idioms for expressing the condition, and the acceptability of various treatments[12]. At present, much of our data on these issues has been derived from studies focused on the needs of working-age adults[13,14]; among older adult research very few studies have examined the experience of depression across ethnic groups. In the United Kingdom, as in most health-care systems, general practitioners (GPs) are the first point of access to health care, directly providing most of the treatment for common mental disorders as well as referral to specialist mental health services. The beliefs of primary care professionals may represent a further barrier in the pathway to care influencing the recognition and management of depression in older patients[7]. Thus, it is important to consider whether the large discrepancies between prevalence, identification and treatment of depression is to be found in the attitudes and behaviour of GPs, their older patients or some combination between the two.

Levkoff and colleagues (1988) hypothesized that the most common reason for older people not to seek help from their GP was that they tended to 'normalize' symptoms of depression and attribute their condition to the ageing process rather than to disease[12]. Attributions of the causes of depression have been found to vary between different ethnic groups[14]. Bhugra (1996) found that south Asian women of all ages had a clear understanding of psychosocial aspects of depression but were not predisposed towards medical models or explanations[15]. Abas (1996) suggested that older Caribbean people construe mental disorders as secondary to other unmet needs (e.g. physical, social, spiritual)[16]. There is also evidence that south Asian and black Caribbean adults may favour self-help strategies for depression rather than seeking professional help[14]. Religious practices (e.g. prayer) have been identified as important ways of coping among minority ethnic groups living in the UK and traditional healers or religious leaders could be considered by these individuals to be a more appropriate and acceptable source of help than Western models of psychiatric care[17]. Alternatively, talking to friends and family may represent the first line of treatment[18]. Certainly, research suggests that south Asian and black Caribbean adults do not always envisage primary care consultations as an appropriate response to depression[13,19]. Negative attitudes towards antidepressants and

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

mental health services in general, may discourage help seeking within minority ethnic groups[20].

Yet depression is also under-recognized and poorly managed in primary care[5]. It appears that the stigma of mental disorder is keenly felt by older adults and feelings of shame have been cited to explain underreporting of affective symptoms by older patients[28]. Research has pointed to even higher levels of stigma surrounding depression within minority ethnic groups[17,19]. There is evidence that GPs construe presentations by south Asian patients as being dominated by physical rather than psychological complaints[7]. Odell *et al*. (1997) speculated that a tendency in south Asians to somatise their psychological distress might contribute to low detection rates[8]. However, Bhui and colleagues (2001) commented that the frequent use by GPs of 'somatic' and 'sub-clinical' labels in relation to Punjabi patients suggests that although they did not perceive there to be 'significant psychiatric disorders' they were aware of some emotional disturbance[7]. Comino *et al*. (2001) reported substantial underdetection of depression by GPs among south Asian patients, though the patients were able to identify common symptoms of anxiety and depression themselves[6]. However, there is accumulating evidence to suggest that the language used to express psychological distress is culturally informed[15,16,21]. Again it is important to emphasize that very few data deal specifically with older people with depression from minority ethnic groups. In order to generate services that are accessible and acceptable to older adults across ethnic groups, service providers need to understand the beliefs that underlie help-seeking behaviour and the likelihood of help being offered and accepted.

A CROSS-CULTURAL QUALTATIVE STUDY OF THE BARRIERS AND FACILITATORS TO CARE

In the light of the gaps in the evidence base identified above, we completed a programme of work to investigate the attitudes, experiences and beliefs of older adults from the three largest ethnic groups in the UK and primary care professionals concerning depression[22–24]. In-depth interviews were conducted with 110 older adults and 30 primary care professionals (see Table 83.1).

The data incorporates the perspective of older adults with depression (both treated and untreated) and the general older population. Each group included black Caribbean, south Asian and white British older adults; this enabled us to compare and contrast attitudes among the two largest minority ethnic groups in the UK with the majority population. A 'case' of depression was defined as a score of 7 or above on the Hospital Anxiety and Depression Scale (HADS)[25]. Treatment was not limited *a priori* to pharmacological interventions (i.e. antidepressants) but in the event no participants were receiving psychological treatments alone. We identified participants through seven primary care practices and through day centres and lunch clubs serving the black Caribbean, south Asian and white British communities. Topics for the interview guide were generated from the research literature. We used a vignette describing an older person with symptoms typical of depression as a starting point to enable us to explore the idioms used to express mental distress and attitudes toward mental illness in our sample[18,19,21]. Interviews then explored: what the word *depression* meant to participants; what participants thought might cause depression; what someone with depression should do, what help might someone with depression need; who should help them and how. The older adults were then asked to give their opinions on a range of treatments and services. Information sheets, consent forms, the HADS and the vignette were available in four Asian languages: Gujarati, Hindi, Punjabi and Urdu. Interviews were conducted in participants' homes, unless they stated a preference to be seen elsewhere, lasted around one hour and were conducted in the participants' preferred language. All were recorded on audio-tape and transcribed verbatim.

In-depth individual interviews were conducted with GPs, practice nurses and practice counsellors working in 18 primary care centres in south London. The sample was selected purposively to include professionals working in different settings (single-handed and group practices), serving areas of contrasting socioeconomic and ethnic characteristics. One-third of the participants were recruited from primary care research networks, and two-thirds were selected from information published on local primary care trust websites. Key topics explored in the interviews included: perceptions of the experience and presentation of depression in older people; perceptions of older people's beliefs about depression; cultural differences in the above. Analysis of the data was based on the grounded theory approach[26]. Three members of the research team scrutinized and coded the initial transcripts. Emerging themes were identified and labelled with codes. A constant comparison technique was used to delineate the properties of the codes and to develop categories and subcategories. As the analysis proceeded, we verified and developed existing codes and added new codes where necessary. The researchers compared their coding strategies and any instances of disagreement were discussed and resolved by the wider research team. NVivo qualitative data analysis software was used to process the transcripts. The number of interviews completed in each group

Table 83.1 Number of participants

	Older adults		
	Black Caribbean	*South Asian*	*White British*
Total	*32*	*33*	*45*
Treatment status

	Primary care professionals		
	General practitioners	*Practice nurses*	*Practice counsellors*
Total	*18*	*7*	*5*

was determined by 'saturation of data', i.e. the point at which no new themes emerged from the interviews.

FINDINGS

The themes to be presented in this chapter emerged from the analysis of: firstly, older adults' perception of the concepts and causation of depression; secondly, older adults' attitudes towards help seeking for depression; and thirdly, primary care professionals' perceptions of the experience and presentation of depression across ethnic groups. The data will be considered in relation to the existing literature.

Older Adults' Concepts and Causation of Depression

The older adults in our study felt that the ageing process had a considerable number of physical, circumstantial and emotional implications that contributed to depression. It has been suggested that there is a propensity among the elderly to 'explain away' depression as a normal part of ageing and that this prevents them seeking help for the condition[12]. However, in our study, an acceptance of the social and ageing precipitants of depression was not incompatible with the concept of depression as an illness. Roughly three-quarters of the black Caribbean elders and two-thirds of the white British participants defined depression in this way. Assigning the label 'illness' appeared to validate and legitimize the experience. Almost half of the white British and black Caribbean participants also viewed depression as a serious condition that was distinct from sadness and grief. Thus, depression was concurrently viewed by these groups as being an understandable, yet dysfunctional, consequence of old age.

It was notable that south Asian participants were least likely to identify depression as an illness or a serious condition and most likely to equate depression with 'normal' feelings of sadness and grief. The apparent incompatibility of these beliefs with the Western biomedical model of depression might make south Asian older adults less likely to seek or accept health services for depression. A further challenge to services exists in the recurring belief that emerged among south Asian and, to a lesser extent, black Caribbean participants that depression stems from a weakness or deficiency in character. This is consistent with previously reported high levels of stigma surrounding depression in these cultures[27]. Research has suggested that fear of being ostracized by peers could act as a deterrent to help seeking within minority communities[17].

The language used to describe depression also emerged as culturally influenced. A large proportion of black Caribbean participants defined depression in terms of feeling low or down, which is consistent with previous findings in younger age groups[28]. The white British participants spoke of variations in mood and feelings of hopelessness with even greater frequency, often employing metaphors of darkness to illustrate their point. The tendency of these groups to describe depression in terms of its emotional impact implies both an ability and willingness to enter into a psychological discourse. Conversely, only a small number of south Asian elders described depression in terms of hopelessness or low mood. Along with Caribbean elders, they frequently defined depression in terms of worry, with emphasis repeatedly being placed on troubles within the mind. Notably, the south Asian participants often articulated this worry in terms of 'thinking too much', a phrase previously identified as a descriptor of mental distress within south Asian younger adults[21].

Differences in attribution were found in the themes emerging from the three ethnic groups. Complaints of loneliness were the focus of the black Caribbean responses, which is consistent with the suggestion that black Caribbean older adults miss the traditional social networks that characterize Caribbean society[29]. As in research in younger adults[14], black Caribbean and white British participants tended to consider mistreatment and abandonment by partners to be a likely cause of depression. Members of the south Asian group related wider family problems to depression, which similarly accords with work in younger age groups[18]. Participants discussed the negative impact of a difficult 'home atmosphere', and they expressed concerns about the discordance in values between their children and themselves. Interestingly, members of the black Caribbean and south Asian groups made very few references to the effects of racism on their emotional well-being, which contrasts with the expressed views of a working-age adult group[14].

Over half of the white British participants cited the death of a spouse as a key cause of depression. Another major cause of unhappiness within the white British group was the feeling that they enjoyed very little contact or support from their family. Increased contact was both longed for and highly valued when received. It seems likely that this absence of family support is related to the predominant role occupied by spouses within the white British group, where loss of the spouse is likely to leave an even greater vacuum in emotional support. A large proportion of white British participants receiving antidepressants attributed their depression to bereavement, suggesting that bereavement may be used to initiate discussion about depression in this group. Research suggests that social problems may be a criterion used by GPs to make a psychiatric diagnosis[30]. In an exploration of the reasons for low treatment rates and high suicide rates in south Asian women, mental health professionals considered it advantageous to have an understanding of the cultural background and reasons why an individual may be experiencing depression[31].

Older Adults' Attitudes towards Help Seeking

Personal responsibility for coping was a recurrent theme. We found consensus across the ethnic groups that the impetus to combat depression must come from the individual. Forcing oneself to get out and engage in activities was identified as the most effective means of self-help. We found less of a focus on cognitive strategies compared with working age adults[14], suggesting that older people tend to adopt a more behavioural approach to tackling the experience of depression. Behavioural strategies that encourage efforts to interact and remain active may provide an acceptable adjunct or alternative to pharmacological or psychotherapeutic interventions. However, it remains a fact that up to one in six older adults are depressed at any one time[1] and public education campaigns must communicate that the nature of depression often necessitates help from others.

There was a tendency among south Asian older adults to identify families as a prominent source of help for depression, which is consistent with research in younger age groups[32]. The black Caribbean group placed less emphasis on the role of the family but stressed the cathartic value of discussing worries and concerns with friends, suggesting a willingness within this group to discuss emotional problems in a candid way. Our results echo the importance and acceptability of religion in helping many black Caribbean people of all ages cope with emotional distress[14,17]. Prayer was allied to the concept of self-help, and it was implied that without a true relationship with God, depression would be difficult to overcome. Seeking informal or formal help might signify insufficient faith in this context. Health-care professionals may need to work closely with religious leaders if they

are to challenge these deep-seated beliefs. Fewer south Asian participants cited religion as a coping mechanism, but of those who did, religious worship presented as an enduring and integral part of life. Participants described visiting the temple as a means of sustaining emotional well-being. In contrast to previous research[17,21] no reference was made to traditional healers as a source of help.

Research indicates that younger south Asian people tend not to medicalize emotional distress[21]. This may account for the tendency among the south Asian group within our study to view the nature of depression as incompatible with the GP's role, which they conceived as prescribing medication and making referrals. Promoting the concept of depression as a treatable medical condition might resolve this problem and legitimize help seeking. However, it is also likely to be of value to reassure older adults that it is appropriate to voice concerns about their emotional state in a GP consultation. The black Caribbean group viewed GPs as serving the additional function of listening and discussing what was on their mind. Consequently, they praised GPs for allowing individuals to discuss their worries and concerns, yet were highly critical of instances where GPs spent insufficient time with their patients or appeared to take insufficient interest. Therefore, the belief of the black Caribbean participants that GPs *could* and *should* help resulted in polarized positive and negative evaluations. Reservations about seeking help from GPs were similar across the ethnic groups; doctors were too busy and overly reliant on medication as a form of treatment. Others explained that limited GP consultation time forced them to prioritize their physical, rather than their psychological, complaints.

Psychiatrists were generally regarded negatively and many participants were conscious of the stigma attached to this profession. This was especially pronounced within the ethnic minority groups as has been reported in other studies[33]. However, experience of psychiatrists, which tended to be limited to the white British and black Caribbean groups, often predicated the more positive remarks. The idea of counselling was embraced by the black Caribbean group in particular. Their limited experience of counselling paralleled that of other groups, yet their greater enthusiasm possibly reflects the high value they place on confiding in others[33] and being genuinely 'listened to' by professionals[16]. For the south Asian group, their unease at discussing personal matters with strangers appeared to contribute to a negative view of counselling. This mirrors previous research that highlighted the pertinent issue of confidentiality within south Asian communities[18]. Medication was cautiously advocated across the groups. Participants generally felt that certain circumstances dictated its use although there was widespread concern about side effects and dependency.

Primary Care Professionals' Perceptions of Depression in Older People

All but one of the primary care professionals in our study believed that cultural differences in illness beliefs had an important influence on how older adults communicated the experience of depression. This builds upon previous cross-cultural studies of depression that have discussed the ways in which culture can shape expressions of distress[34]. A number of GPs held the view that the Western concept of depression was less recognized in some cultures. Although GPs were reluctant to make generalizations on the basis of ethnicity most admitted that it could be difficult to engage patients from minority ethnic groups in discussions about psychological problems. Professionals were of the opinion that the belief that 'non-medical' problems were inappropriate or not important enough to warrant medical attention prevented older people from all ethnic groups from talking about psychosocial difficulties in a primary care setting. However, black Caribbean and south Asian older adults were thought to be even less likely than their white British peers to disclose psychological symptoms. Moreover, and in accordance with previous research[7], GPs suggested that there was a propensity among south Asian elders in particular to express psychological distress as physical pain or concerns about heart disease. One GP commented that excessive worry about physical symptoms often masked the presence of depression and that those patients who eventually received a diagnosis usually had more severe and enduring symptoms. As the first point of contact with health care, most GPs were aware there were particular requirements for sensitive exploration of symptoms, interpretation and explanation with all older adults. Some had clear strategies for introducing the concept of depression while keeping within the patient's physical formulation of their problem. Others negotiated a treatment plan or even colluded with the patient by making the requested referral to a specialist for physical tests while initiating treatment for depression. While GPs encountered more somatic presentations of depression, practice nurses and counsellors had more opportunities to identify and explore social difficulties. People with chronic conditions were often in regular contact with the practice nurse and there seemed important possibilities in using these contacts more systematically to identify and treat depression in primary care.

The suggestion that it is a lack of 'psychological-mindedness' that leads to somatic presentation of emotional distress has increasingly been rejected within the literature and research has suggested that bodily complaints may in part indicate the use of somatic metaphors[35]. While many of the primary care professionals in our study believed that there were cultural differences in the type of symptoms presented, others believed the differences lay in the use of language and metaphor rather than the attribution of symptoms. Abas (1996) described a wide range of psychological language used by African-Caribbean elders to convey emotional distress[16]. Indeed expressions used to convey feelings of depression such as 'low spirit' and 'weighed down'[16,28] explicitly reveal low mood. Similarly south Asian patients, although tending to present somatic symptoms, have been shown to articulate their distress in psychological terms[36]. Comino and colleagues (2001) concluded that the tendency of GPs to rely exclusively on Western-based concepts and diagnostic traditions when assessing people from other cultures represented a significant detection barrier[6]. Finally, primary care staff were acutely aware of the stigma of mental disorder and had observed embarrassment, failure and shame among older patients in admitting to feelings of depression. The stigma of mental illness was thought to have more serious consequences in minority ethnic communities with a diagnosis of depression potentially bringing shame upon the family. This represented an important barrier to addressing psychosocial aspects of the illness and gaining the patient's agreement to begin appropriate treatment.

IMPLICATIONS FOR POLICY AND PRACTICE

These data have implications for policy, practice and education. The model used by older adults from all ethnic groups was more akin to a social than a classic biomedical schema. This suggests that the approach clinicians need to take in attempting to engage older people with depression in a therapeutic alliance would benefit from being framed in social as well as physical terms. Enquiries about recent

life events and losses could be used to facilitate discussion with older adults about depression. More emphasis in medical training and continuing professional development on how symptom attribution differs across ethnic groups could enable practitioners to frame their questions within an appropriate cultural framework. However, this is only a first step: clinicians need to be able to explain the interaction of the social, psychological and biological elements of causation, thus generating a shared understanding of the value of biological (such as antidepressant medication), as well as social and psychological, interventions. Recent evidence suggests that older adults incorporate medical and experiential knowledge into their model of depression[37]. However, it has also been argued that GPs should explicitly relate diagnosis and treatment options to the individual's social experience of depression if they are to have relevance beyond the clinical context in which the diagnosis is made[37]. Proctor (2008) takes this further, concluding that the acceptability and effectiveness of treatment for depression depends on the practitioners' ability to connect it to other medical and social problems of later life, which the study indicated occupy a higher priority among older adults[38].

There were striking consistencies in the barriers to care described by older people and primary care staff. Primary care professionals and older adults acknowledged that multiple health problems might prompt elderly patients to prioritize physical complaints in order to avoid 'wasting the doctor's time'. GPs considered this to be compounded by the common belief that doctors are there to deal with physical conditions rather than psychological problems. Yet white British and black Caribbean older adults displayed a willingness to disclose emotional difficulties associated with depression, which is an encouraging indication that older adults would respond to discussion with health and social care professionals about their mood. Together these data indicate that practitioners need to provide assurance that disclosure of feelings is appropriate in a medical consultation. Longer appointments might facilitate this process and enable primary care staff to address the mental health needs of older patients as a matter of routine. Practice nurses felt that they were well placed to discuss the implications of life events, family problems and other 'non-medical' crises with older patients. Given the high co-morbidity of depression in later life with physical illness[39], the increasing role of practice nurses in the management of chronic disease may provide a setting to explore psychosocial problems. The pronounced interest in counselling demonstrated by black Caribbean participants highlights the need for greater access to a wider range of treatments. Psychotherapy has been identified as a preferred treatment option among black American older adults and its provision in primary care has been associated with better depression outcomes[40]. Unfortunately, access to talking therapies remains limited among older people in the UK despite assertions that this is an entitlement for all.

The study confirms that the language and metaphors used to describe depression can be culturally influenced. Sensitivity to the 'language of depression' used by different groups (e.g. 'excessive thinking' within the south Asian group) will increase the likelihood of reaching an acceptable diagnosis and treatment plan. An understanding of cultural variation in the expression of mental illness is fundamental to good health care, and this should form a normal part of training for health-care professionals. Ethnic differences in the conceptualization and attributions of depression also highlight the need for practitioners to emphasize, particularly with patients from minority ethnic groups, that depression is not a sign of weakness and that anyone can become depressed. In turn, cultural- and language-specific public education could be directed as modifying public attitudes and understanding of depression not only to reduce stigma, but also to enable self-identification of the disorder. Lastly, the data point towards the need for education concerning the role of psychiatrists, as well as for accurate information regarding the risks of dependency and actual side effects with medication.

Treatment of Late-Life Depression In Community Settings

Carolyn Chew-Graham

School of Community Based Medicine, University of Manchester, UK

EPIDEMIOLOGY

It has been stated that 10–15% of all older people meet the clinical criteria for a diagnosis of depression[1], and major depression is a recurring disorder, with the majority of older patients having a recurrence within three years[2]. Some groups are more at risk of depression: 40% of people in care homes are depressed[3] and the community prevalence of depression in South Asian older people may approach 20%[4].

Older people have the highest suicide rate for women and second highest for men (National Confidential Inquiry into Suicides and Homicides) and is the one age group where rates have not declined. In contrast with young people, self-harm in older people usually signifies mental illness, mostly depression, with high risk of completed suicide[5].

The over-85 population of the United Kingdom will increase by 50% over the next 15 years, from 1.2 million in 2005 to 1.8 million in 2021, compared with a 30% increase in the over-65 population. In just half that time, the older black and minority ethnic (BME) population will increase by up to 170%. This is not purely a change affecting the United Kingdom – ageing is a global issue and in the United States the number of centenarians will rise from 72 000 in 2000 to 834 000 by 2050. (www.grg.org/calment.html). The concept of multiple jeopardy postulates that ethnic elders, by virtue of age, socioeconomic difficulties and minority status are at greater risk of illness, thus in greater need of health services[4].

Co-morbidities or multi-morbidities are the norm in later life. Thus emotional and physical health problems of older people are entwined and manifested in complex co-morbidity[6] and those with a physical disability have five times higher rates of depression. Although there is variation between studies, it has been estimated that up to 26% of people with diabetes also suffer from depression[7] and comparable figures have been reported for coronary heart disease[7].

Being equipped to meet these complex needs is critical in settings like primary care and residential care.

OLDER PEOPLE'S MENTAL HEALTH PROBLEMS IN PRIMARY CARE

Primary care is on the front line in dealing with older people's mental health, supporting families and managing people with complex co-morbidities. Older people consult almost twice as often as other age groups[9] and 22% of older people will have attended their general practitioner (GP) within the last two weeks and 40% may have a mental health problem. In the United Kingdom primary care is a key NHS service provider for care homes, where at least 40% of older people have depression and 50–80% dementia[3].

Depression is under-treated in older people with around 5 out of 6 older people with depression receiving no treatment at all. Only one third of older people with depression discuss their symptoms with their GP and less than half of these will receive adequate treatment[10,11]. Most people with mental health problems are managed in primary care with only 6% of older people with depression receiving specialist mental health care.

MAKING THE DIAGNOSIS

The literature suggests that diagnostic difficulties of depression in later life occur largely in relation to four areas: patient factors, practitioner factors, organizational factors and societal factors.

Patient Factors

Two-thirds of older people with serious depression have symptoms that fit poorly with current classifications of mood disorders. These classifications have been generated to reflect symptoms observed in younger people, and have inherent limitations for diagnosis of depression in older people whose presentation may differ because of ageing, physical illness or both[10]. Thus, older people can present with non-specific symptoms such as malaise, tiredness or insomnia rather than disclosing depressive symptoms[12]. Physical symptoms, in particular pain, are also common and the primary care clinician may feel they represent organic disease. Forgetfulness may also be manifest, leading to concern that the patient has cognitive impairment and early dementia[13]. Older adults may have beliefs that prevent them from seeking help for depression, such as a fear of stigmatization. They may be under the impression that antidepressant medication is addictive[11], or they may misattribute symptoms of major depression for 'old age', ill-health[13] or grief. Ethnic elders in particular do not see psychiatric services as appropriate and believe they are primarily for psychosis and violence. People across cultures often present with

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

culturally specific idioms of distress. South Asians often describe their distress using terms such as 'sinking heart' or 'gas in abdomen' (*gola*) as a symptom of distress. This may mislead the clinicians, causing them to tend to overlook the psychological distress and focus solely on the physical aspect of the presentation[15].

Practitioner Factors

Primary care practitioners may lack the necessary consultation skills or confidence to correctly diagnose late-life depression. They may be wary of opening a 'Pandora's box' in time-limited consultations and instead collude with the patient in what has been called 'therapeutic nihilism'[14]. In deprived areas primary care physicians have been shown to view depression as a normal response to difficult circumstances, illnesses or life events[16] and depression may be underdiagnosed because of dissatisfaction with the types of treatment that can be offered, especially a lack of availability of psychological interventions[14].

Organizational Factors

The trend in the United Kingdom for mental health services to be 'carved out' from mainstream medical services may disadvantage older depressed people who may have difficulties in attending different sites for mental and physical disorders[17]. New contractual arrangements for primary care provide no new incentives to offer re-configured services for older people with depression[18].

Societal Factors

The barriers described are likely to be particularly difficult for economically poor and minority populations who tend to have more ill-health and are more disabled. The National Service Framework (Older People)[18] had as its first standard the rooting out of age discrimination. However, little is known about the efficacy or implementation of the Framework at Primary Care Trust level. The 2009 Equality Bill[i] will, if enacted, make age-based discrimination in the provision of health and social care illegal for the first time in the United Kingdom. This Framework will be superseded by the New Horizons initiative[ii] which stresses the importance of well-being and resilience, prevention and early intervention. The Framework provides a focus on the mental health of older people.

THE CONSULTATION

Literature suggests that GPs experience difficulties in negotiating the diagnosis of depression with patients, including older people[14]. The Quality and Outcomes Framework (QOF) of the new General Medical Services (GMS) Contract[19] requires that GPs and practice nurses use two screening questions within the previous 15 months with patients with chronic disease in order to increase the detection of depression in patients with diabetes and heart disease:

- 'During the past month, have you often been bothered by feeling down, depressed or hopeless?'
- 'During the past month, have you often been bothered by having little interest or pleasure in doing things?'

A 'yes' to either question is considered a positive test. A 'no' response to both questions makes depression highly unlikely.

It would be logical to consider using these screening questions in consultations with other older people who are also at high risk of depression, for example:

- those with recent (<3 months) major physical illness or hospital admission;
- patients with chronic illness/long-term conditions;
- those in receipt of high levels of home care, including residential care;
- people with recent bereavement;
- socially isolated people;
- people persistently complaining of loneliness; or
- patients complaining of persistent sleep problems.

Little evidence has yet been found, however, for this approach[20].

There is some evidence[21] that a further question 'Is this something you want help with?' increases the usefulness of the screening questions in practice. It is then suggested that an assessment of severity of the depression is made by the GP using a schedule such as PHQ-9[22]. In addition it is vital that the GP explores with the patient ideas and plans for self-harm, and factors preventing the patient from acting on such ideas or plans.

Other authors question the usefulness of such a reductionist approach[23] and emphasize the value of professional judgement over the narrow use of schedules[24].

MANAGEMENT OPTIONS

Most patients with depression are managed in primary care settings, however, a substantial number of patients are not recognized, and those who are diagnosed often do not receive effective treatment[25]. There is, however, a good evidence base for the management of depression in older people. There is evidence to show that there are effective pharmacological treatments[26] but only one in four depressed older people receive effective pharmacological treatment and less than 10% a talking therapy[27] despite the fact that many people express a preference for such treatments[28,29]. Evidence for individual psychosocial interventions is presented in Chapter 87, but will be discussed here in the context of what the primary care practitioner can utilize. While a preventative approach to early prevention and detection of depression in older people is being evaluated and has a growing evidence base[30] most focus has been, and should be, on the treatment of an established, recognized disorder. Exercise is recommended by the NICE guidelines as a treatment for mild to moderate depression[31] but there is only limited evidence for this approach in elderly people[32]. Training in the use of the Internet to increase social support has been shown to reduce complaints of loneliness and depression[33] and there is recent evidence that befriending has a useful function in the management of mild depression in older people[34]. NICE guidelines[31] recommend a stepped care approach for the management of depression, although there is limited evidence for this approach, particularly in elderly people[35], and it is suggested[36] that systematic models of care dedicated to proactively managing depression as a chronic illness are required. The PROSPECT study[37] (Prevention of Suicide in Primary Care Elderly: Collaborative Trial)

[i]Government Equalities Office. A fairer future: the Equality Bill and other action to make equality a reality. 2009. www.equalities.gov.uk/pdf/NEWGEO_FairerFuture_may09_acc.pdf

[ii]http://www.dh.gov.uk/en/Healthcare/Mentalhealth/NewHorizons/DH_102135

studied the effect of a depression care manager offering recommendations to GPs according to a guideline and helping patients with adherence to medication. The IMPACT[38,39] study (Improving Mood: Promoting Access to Collaborative Care Treatment) utilized a case manager co-ordinating care and delivering a specific psychosocial intervention (behavioural activation or problem-solving treatment) with or without medication management, and liaising with both the GP and the specialist mental health services. Both studies suggest the effectiveness of such a collaborative care approach which has been shown to be acceptable to family physicians[40] and initial evidence from the United Kingdom[41] is promising. Such a service, however, is not widely commissioned in the United Kingdom as it is recommended by NICE[31] only for people with depression and chronic physical health problems.

It is vital that the GP explores the patient's view of their problem and the options that might be available to them. Thus, if antidepressants are going to be prescribed, a full discussion about these drugs, the time taken to work and the possible side effects are discussed. Similarly, a discussion about the patient's views on talking treatments or psychosocial interventions, what to expect and waiting times is vital. On-going support and review from the GP, accompanied by written information, particularly when antidepressants are prescribed, is important. In addition, the GP has a role in signposting to third sector agencies (if acceptable to the patient) and thus should be familiar with groups and local networks in his or her area.

When treatment is not leading to improvement of the patient's symptoms, it is vital that the GP considers co-morbidities, concurrent prescribing, alcohol excess, continuing loss and loneliness or a diagnosis of vascular depression[42]. At this stage, discussion with and/or referral to an old age psychiatrist is indicated.

CULTURALLY SENSITIVE INTERVENTIONS

Pharmacological and Psychological Interventions

There is little research to support any particular pharmacological therapy being specifically beneficial for ethnic elders. The general considerations about prescribing antidepressants discussed in Chapter 86 should be followed but there is a particular need for detailed explanation about the basis for suggesting medication.

Similarly, there are no culturally-sensitive psychological therapies available but again engaging the patient is critical. Abas and colleagues[43], working in the African-Caribbean community, provide a helpful framework to these issues. Consultation should be carried out with the following characteristics:

- a courteous, respectful and warm manner, along with interest in ethnicity and country of origin;
- flexibility about usual professional boundaries, for example, being prepared to share some experiences that facilitate rapport and acceptance of help;
- not offering false promises;
- offering a copy of written material (appropriately translated);
- comprehensive questions and not assuming that complaints or symptoms will be volunteered;
- acknowledging losses, both recent and chronic, including racism.

Encouraging ethnic elders to attend community and faith-based groups organized by the voluntary sector can often provide much needed social support which they are used to, but which is gradually eroding over time due to acculturation and changing family structure.

Working with the Family

The social stigma of depression causes families to deny, conceal, delay or even fail to seek treatment. This warrants public education within a cultural framework, as well as collaborative efforts by the ethnic community and health care providers. Particularly in ethnic elders from South Asia who still live in extended families it is important to keep the family 'on board'. This may seem difficult, as they may not share the viewpoint with the health provider on depression. So efforts to educate not only the patient, but also carers, becomes all the more important, particularly regarding issues around medication use, side effects and time delay in symptom improvement[44].

DEPRESSION IN RESIDENTIAL HOMES

Depression is prevalent in people in residential care homes yet usually goes undetected. Training care staff to recognize possible symptoms of depression can improve detection[45] and using a collaborative care approach to management is effective in improving outcomes[46]. Evidence suggests that using life review to people newly moved into a residential home, compared with a 'friendly visit', can prevent depression in this group of older people[47]. Other interventions such as social activation, however, have been shown to be ineffective in preventing depression[48]. The usefulness in older studies such as this, when the population in UK residential homes today may be very different to that 20 years ago, is questionable. More recent studies suggest that there are effective interventions that can be implemented in residential homes, such as group reminiscence therapy[49] and introduction of a pet into the home[50]. The role of the GP in detecting depression in elderly people in residential homes has not been evaluated, but is vital and probably limited due to current arrangements for provision of care for this group of people, who are dependent upon paid carers to request contact with their GP. Alternative models of primary care for residential homes may need to be explored.

POLICY IMPLICATIONS

Recent policy initiatives in the United Kingdom represent lost opportunities to invest and develop older people's mental health services through the National Service Framework for Mental Health[51] which excluded older people and the National Service Framework for Older People[18] which had too narrow a focus.

The publication of *Everybody's Business – Integrated Mental Health Services for Older Adults* (CSIP, 2005)[52] helpfully set out the key components of a comprehensive service for older adults with mental health needs. Regrettably though, there has been no additional targeted investment in the United Kingdom to support implementation and in the absence of clear 'must do's', performance indicators or targets, commissioners and providers find it all too easy to disregard or distort what this Department of Health guidance states.

There is a need for education at the public health level to increase community awareness of depression as a legitimate problem to take to the doctor through media campaigns and Age Concern[3], England has been active in this regard. In addition, education of health professionals in the recognition of depression in older people, a skill that requires cultural competence and different problem formulation is important, although educational initiatives alone tend to be ineffective in primary care. It is vital, then, that services commissioned are evidence-based and incorporate effective care pathways and the provision of alternative models of care, such as collaborative care,

where appropriate. There needs to be increased availability of psychological services for older people, and the Improving Access to Psychological Services (IAPT)[53] initiative may not fulfil this role, as there is evidence that GPs continue to refer younger rather than older people for talking treatments[54]. In addition, interventions need to be tailored to older people's perspectives and the social rather than the psychological emphasized.

CONCLUSIONS

Depression in older people presents a challenge for the primary care physician or GP, particularly when compounded with a patient of an ethnic minority background, when the GP may not be culturally competent, or a person in a residential home, who may not receive adequate levels of contact with the GP, such that depression remains undiagnosed. There is, however, a good evidence base for the management of late-life depression and evidence that older people would prefer the option of a talking treatment. Thus there is a need for the education of primary care practitioners so that they develop the skills to diagnoses and support people with depression. In addition, the services commissioned need to meet the needs of older people with depression.

ACKNOWLEDGEMENTS

I would like to thank Robert Baldwin (Consultant in Old Age Psychiatry at Manchester Mental Health and Social Care Trust) and Alistair Burns (Professor of Old Age Psychiatry at the University of Manchester) for their ongoing support. In addition, I would like to thank Saadia Aseem, Heather Burroughs, Pam Clarke and Jonathan Lamb, members of the AMP team (www.liv.ac.uk/amp/) for their interest in this area of work.

Electroconvulsive Therapy (ECT)*

David G. Wilkinson

Moorgreen Hospital, Botley Road, West End, Southampton, UK

> Those who decry it in the elderly are sentimental and ill-informed. ECT for suitable patients not only relieves intolerable anguish but saves lives (Pitt, 1974[1]).

Electroconvulsive therapy (ECT) is an important though controversial treatment for certain subgroups of individuals suffering from severe mental disorder. These subgroups consist primarily of patients with severe depressive disorder, catatonia, mania and occasionally certain patients with schizophrenia. In addition, depending on the co-morbidity with medical and/or neurological disorders and on the risk analysis in relation to the necessity to treat, ECT is best seen as a low-risk procedure for some patients and a high-risk one for others. ECT should be administered following valid and informed consent by the patient when appropriate and in adherence to a set of guidelines of administration procedures[2].

Despite continued opposition to its use, ECT remains a fundamental tool in the armamentarium of the psychiatrist treating the severely mentally ill. There have now been thousands of papers and articles published concerning its use and we have a wealth of accumulated wisdom, and yet the controversy continues[3].

In geriatric psychiatry there is no controversy: papers continue to confirm that in the elderly ECT is an effective treatment for severe affective disorders[4–7] and is the treatment of choice in severe delusional depression[8–11]. It is safe, despite the likelihood of multiple system disorders and medications[12]. It is well tolerated, if not always well liked[13], but does sometimes exacerbate confusion. There is no convincing evidence of brain damage or even of lasting memory impairment, particularly if brief pulse right unilateral ECT is used[14]. ECT should be considered in every patient with severe delusional depression who has either failed to respond to other treatments, or who is suffering intolerable distress, or who may die through inanition or dehydration as a result of his/her depression. It is probably for these reasons that ECT continues to be used six to seven times more frequently in the elderly than in their younger counterparts[15]. The fact that in the USA it has also been shown that early use of ECT reduces inpatient costs may have also been an influential factor in its greater use[16].

INDICATIONS

Depressive Disorders

The introduction of ECT for the treatment of severe depressive illness is one of the most dramatic developments in psychiatry. It is widely considered to be the most effective treatment for severe depressive illness compared with all other modalities including the range of pharmacological treatments. Since its introduction in the early 1930s it has undergone important development and improvement with the use of anaesthesia and muscle relaxation which rendered it more safe and acceptable. The recall of ECT in the USA in the 1970s was 'plagued by hostility to the treatment'[17] fuelled by images of barbaric, inhumane and coercive treatment. In contrast to such an approach, many national psychiatric associations and societies have promoted ECT and many countries have introduced guidelines for practice: Australia, Canada, New Zealand, UK and the USA[18]. It is, however, of considerable concern that in many third-world countries, ECT is still used without the benefit and safety of anaesthesia or modern ECT devices[17,19].

The Evidence Base

A recent systematic review and meta-analysis of randomized controlled trials and observational studies of the efficacy and safety of ECT in depressive disorders[20] reported the following findings:

- ECT versus simulated ECT – ECT was significantly more effective than simulated ECT in the reduction of depressive symptoms and no difference in premature discontinuation from treatment for patients receiving ECT and simulated ECT. Patients treated with ECT were better able to retrieve remote memories than those treated with simulated ECT and had more recognition errors immediately after treatment.
- ECT versus pharmacotherapy – treatment with ECT was significantly more effective than pharmacotherapy and discontinuation was significantly lower in the ECT group than in the pharmacotherapy group.
- Bilateral versus unilateral electrode placement – Bilateral ECT was more effective than unilateral ECT in the reduction of depressive symptoms. High-dose unilateral ECT might be as effective as bilateral ECT and causes fewer adverse cognitive effects. Bilateral ECT was associated with impairment in anterograde memory impairment within seven days of the end of the randomized phase of treatment but no long-term cognitive impairment.
- Frequency of ECT – ECT administered once a week, twice and three times a week had similar effects on depressive symptoms and no difference in discontinuation of treatment but more frequent ECT led to more cognitive impairment.
- Dose of electrical stimulus – high-dose ECT led to greater reduction in depressive symptoms, but was associated with more

*Updated by Mohammed T. Abou-Saleh

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

impairment in anterograde memory but not in terms of personal memory.
- Stimulus wave form – brief pulse and sine wave ECT were equally effective with some indication that patients receiving brief pulse ECT recovered more quickly and had better recall of word associates learned shortly before the treatment than did those receiving sign wave ECT.

A meta-analysis of the efficacy of ECT in depression deriving from 15 randomized controlled trials (RCTs) showed ECT to be superior to pharmacotherapy and simulated ECT, with the presence of psychotic symptoms predicting better response to ECT[21]. The report found no evidence for a superior speed of action of ECT or for a difference between sine wave and brief pulse stimulation. ECT has been shown to be more effective in delusional than in non-delusional depression[22,23]. A recent Cochrane Review assessed the efficacy and safety of ECT compared to simulated ECT or antidepressants in the depressed elderly[24]. Only three trials could be included and all had methodological shortcomings. The results nonetheless indicated that ECT was more effective than simulated ECT, but the comparative efficacy of unilateral over bilateral ECT and safety could not be assessed adequately.

Older age confers a greater likelihood of achieving a remission with bilateral, dose-titrated, continuation ECT in comparison with continuation pharmacotherapy[25].

The NICE Review[26] of data from 90 randomized controlled trials (RCTs) of ECT in depressive disorders (not specifically in older people) concluded that:

- real ECT (where electric current was applied) is more effective than simulated ECT (no electric current was applied) in the short term;
- bilateral ECT is more effective than unilateral ECT;
- raising the electrical stimulus above the individual's threshold supported the efficacy of unilateral ECT at the expense of increased cognitive impairment.
- ECT was more effective than antidepressants notwithstanding the variable quality of RCTs and the inadequate doses and duration of antidepressants that were used in many of the trials;
- ECT is associated with cognitive impairment, particularly in those who had bilateral ECT or unilateral ECT applied to the dominant hemisphere;
- cognitive function does not last more than six months from the administration of ECT;
- there is no evidence that ECT is associated with greater mortality than that associated with the administration of general anaesthetics. Studies that use brain-scanning techniques showed no evidence that ECT causes brain damage;
- there is no evidence to suggest that the benefits and safety of ECT are age-dependent;
- there are no complications of ECT in pregnancy but the risks should be balanced against refusing antidepressant.

As mentioned studies on the efficacy of ECT, which have largely been conducted on younger patients[8], all emphasize that ECT appears to be more effective than placebo, single-drug therapy and tricyclic/neuroleptic combinations, and that patients with more florid symptoms of recent onset fare best[27–29]. Experience with the elderly would confirm these findings. Indicators of response are perhaps less clear in the elderly, with some authors finding psychomotor disturbance and psychosis a positive predictor of response[11] and others suggesting that patients without these features can also do well[30]. That the classic distinction between neurotic and psychotic depression appears less helpful in this group as a predictor of good response is nothing new. Post[31] in 1976 stressed the practical irrelevance of any subclassification of elderly depressives, as he found that ECT rendered severe psychotic depressives fit for discharge only slightly more often than neurotic depressives. The presenting picture of apparent hysterical illness, hypochondriasis or other apparent neurotic illness may well be caused by an underlying functional psychosis, often depressive in the elderly. More recently, in a study of 163 elderly patients given ECT, it was found that 27% had predominantly neurotic depressive features and yet had a good response to treatment[4]. In fact, in the study by Fraser and Glass[32], psychic anxiety, along with the more expected features of short duration, severity of illness, guilt and agitation, was one of the symptoms correlated with a favourable response to ECT, whereas the typical endogenous features of late insomnia and diurnal variation in mood were not. Older patients with treatment-resistant depression often do respond to ECT, although not as well as non-resistant patients[33]. However, they do respond better to ECT than to SSRIs[29] and Flint[6] found that ECT was significantly superior to tricyclic/neuroleptic combinations, even when the former had been augmented with lithium. A pragmatic consensus would suggest that in the elderly a trial of ECT is indicated in any depressed patient who might otherwise be regarded as a treatment non-responder, and if the illness is severe and of short duration there is likely to be a good response, regardless of the presenting symptoms. If the illness has been present for a long time, it still may respond, particularly if there is a clear history of a recent change for the worse in a patient who had previously maintained a stable personality and had coped normally with the vicissitudes of life. Prolonged or abnormal bereavement reactions with marked depressive features not responding to antidepressants or talking therapies may need to be treated with ECT before psychotherapy or counselling can be effective. ECT may need to be given within a few months of the loss if hopelessness and suicidal ideation suggest a risk to life, and should not be withheld due to the feeling that the patient must work through his/her grief naturally, as he/she may never get that chance.

Continuation Pharmacotherapy after ECT

High relapse rates of depression have been consistently reported after remission with ECT. Five controlled trials have demonstrated the efficacy of continuation treatment with antidepressants and lithium in reducing relapse after remission with ECT[34]. Further RCTs have demonstrated the efficacy of continuation treatment with imipramine and paroxetine in relapse prevention in such patients[35]. Nortriptyline monotherapy and its combination with lithium has also been shown to be superior to placebo over six months in preventing relapses in unipolar depression following remission with ECT[36].

A recent study used a longitudinal, randomized, single-blind design to compare by survival analysis the two-year outcome of two subgroups of elderly patients with psychotic unipolar depression who were ECT (plus nortriptyline) remitters[37]. The mean survival time was significantly longer in the combined ECT plus nortriptyline subgroup than in the nortriptyline subgroup. No differences were observed between treatments with regard to tolerability. The authors advocated the judicious use of combined continuation/maintenance ECT and antidepressant treatment in elderly patients with psychotic unipolar depression who are ECT remitters.

Schizophrenia

Paraphrenia will often respond to ECT[38], although this is more likely if there are obvious depressive symptoms or delusions. A Cochrane Review assessed the evidence for the efficacy of ECT in terms of clinically meaningful benefits in patients with schizophrenia, and whether variations in the practical administration of ECT influences outcome[39]. The Review included 24 trials and 46 reports and showed the following:

- Fewer patients remain unimproved with ECT, with less relapses and earlier discharge than patients treated with placebo or simulated ECT.
- Limited data indicated visual memory impairment with ECT compared with simulated ECT.
- ECT is less beneficial than antipsychotic medication.
- Continuation ECT added to antipsychotics is superior to antipsychotics alone but is associated with more memory impairment.

There is relatively little evidence specific to the use of ECT in older patients with schizophrenia. ECT has been shown to have good short-term effects and be safe in middle-aged and elderly patients with intractable catatonic schizophrenia[40] and in treatment-resistant schizophrenia[41].

In schizophrenia, the NICE Review[26] of the data from 25 RCTs indicated that ECT may be effective in acute episodes of certain types of schizophrenia and reduces the occurrence of relapses. However, the results were not conclusive and the design of many of the studies did not reflect current practice. Moreover, there are no RCTs of ECT compared with antipsychotics. Furthermore, studies that include patients with treatment-resistant schizophrenia had not reported the use of clozapine. The Review concluded that ECT alone is not more effective than antipsychotic medication but that the combination of ECT and pharmacotherapy may be more effective than pharmacotherapy alone although the evidence is not conclusive.

ECT is certainly useful in the depressed (and usually elderly) patient with Parkinson's disease, as the motor symptoms will improve as well as the depression, and indeed, some authors advocate ECT as the treatment of choice for certain stages of Parkinson's disease, whether or not depression is a major problem[42,43]. I have given daily ECT with excellent results to a Parkinsonian patient who had developed severe paranoid delusions. His refusal to accept his medication rendered him rigid and immobile with pressure sores, he needed intravenous fluids and nasogastric feeding until he had four treatments, whereupon his physical and emotional improvement was dramatic.

Fogel[27] suggests that ECT might be more readily used in the elderly if we were more objective about its virtues as compared with the severe side effects often associated with neuroleptics, which are quite readily used in the agitated elderly patient. Extrapyramidal effects were usually the limiting factor but are not so noticeable with atypical neuroleptics. However, he postulates that the demented patient who is very agitated and screaming might suffer less indignity and fewer side effects if treated with ECT, rather than tranquillizers, as the patient may have an underlying affective disturbance manifest only by the agitation and negativism that one often sees in this condition.

Mania

Mania is another potential indication for a trial of ECT[44], particularly in the elderly, where neuroleptics may fail to control the symptoms and yet produce unsteadiness, postural hypotension or falls, and lithium may not be tolerated due to toxicity problems.

The NICE Review[26] of four RCTs indicated that ECT may be of benefit in rapid control of mania and catatonia, a suggestion that is supported by the results of observational studies. Overall, however, it concluded that the evidence for the effectiveness of ECT and for the determination of the most appropriate therapeutic strategy is inconclusive. In contrast, a recent literature review of continuation and maintenance ECT in treatment-resistant bipolar disorder reported good evidence for efficacy[45]. ECT is indicated in severe and prolonged mania (excitement, delirium, psychosis, or rapid-cycling manic states), especially when the anti-manic medications (lithium, neuroleptics) have been relatively inefficient[46]. It seems that the NICE Review has been restrictive in the studies it considered and the conclusions drawn from them. It must also be emphasized that the evidence reviewed above is not specific to elderly people.

CONTRAINDICATIONS

There are no absolute contraindications, only relative risks, in which the risks of ECT and associated general anaesthesia are weighed up against the morbidity and mortality of untreated depression. The limiting factor is whether the patient is physically fit for the light anaesthetic that ECT requires. The majority of risk factors are therefore associated with the cardiovascular system. Many people are denied treatment due to irrational caution. For example, pacemakers are not barriers to treatment; the bodily tissues, being highly resistant, prevent the ECT stimulus from reaching the pacemaker. The patient should remain insulated from the ground, however, to prevent the unlikely event of the current leaking to earth and being conducted down the pacemaker wire to the heart. Equally, myocardial infarction is not a contraindication to treatment if the depression is so severe as to threaten life; in less severe cases, an interval (governed by sentiment rather than science) of 4–6 weeks is usually recommended. The risks are greatest during the first 10 days post-infarct, and probably negligible after three months. I have treated a patient with hypothyroidism who had two prosthetic heart valves, was therefore on anticoagulants and had a pacemaker, with no special precautions or untoward effects. Patients with osteoporosis or with recent femoral neck fractures can be treated, provided an adequate muscle relaxant is given. Stroke is certainly not a contraindication, and ECT given as soon as one month after does not present a major risk to patients. There is now a growing body of literature attesting to the usefulness of ECT in treating post-stroke depression[47].

The case of deep venous thrombosis (DVT) is less clear. I have given ECT to a patient who had a DVT in his calf during his depressive illness, once he was adequately anticoagulated. In fact, the risk of pulmonary embolism seems, in my practice, greater in older severely depressed patients who are dehydrated and immobile depressive than in those receiving ECT.

Arterial hypertension is often regarded as a contraindication, as blood pressure is well known to rise during ECT. This can sometimes be controlled and the pressor response avoided by using sublingual nifedipine or short-acting b-blockers shortly before treatment[48]. Chronic glaucoma is another condition in which ECT causes fewer problems than tricyclic antidepressants; in fact, intraocular pressures are said to reduce ECT[49]. Insulin-dependent diabetes is a condition, like Parkinson's disease, which alters during ECT. Insulin requirements may decrease quite substantially during the course of ECT, so more careful monitoring of blood glucose levels is needed. It is also

necessary to avoid hyperglycaemia prior to treatment, which may significantly raise the fit threshold, and the timing of ECT administration may need consideration to prevent undue fluctuations in diabetic control.

Transient asystole occasionally occurs, for some reason less frequently in the old-old, but it is not of any long-term clinical consequence and need not prevent further treatments[50,51].

Epileptic patients on anticonvulsants should not stop their medication during ECT, as that might increase the risk of status epilepticus. However, they may need higher than usual electrical dosages to produce an adequate epileptiform response.

It is interesting that the seizure during ECT is invested with great powers of harm compared with epileptic seizures per se, which can of course occur in patients with any disease or at any time and seldom result in death. It seems understandable, then, that a seizure in the controlled conditions of the ECT room is probably even less likely to result in fatality. There is, of course, a mortality rate associated with ECT but, as noted by Fink[52], the treatment rate of 0.002% compares favourably with the rate for anaesthetic induction alone (0.003–0.04%).

ADMINISTRATION

The responses of senior psychiatrists to the process of ECT vary from those who simply prescribe six treatments and leave the administration to the newest recruit, who has often had no training at all, to the surgeon manqué who may overstate the risks and precautions in order to increase the perceived risk of his (or her) job. Clearly, the ideal path lies somewhere between, but nearer the latter than the former! ECT is the only psychiatric treatment in the elderly that involves significant medical intervention with general anaesthesia, and as such, the psychiatrist should have a clear understanding of what he/she is prescribing and regular involvement in its administration. As much attention should be paid to the prescription of ECT as to any other prescription.

A clear decision as to whether bilateral or unilateral electrode placement is wanted should be made; the ECT record sheet should be reviewed to ensure that an adequate convulsive response has occurred without excessive stimulus; treatments should not be in blocks of six, but response should be evaluated after each treatment. Provided that the illness is one with a good prognosis, treatment should be continued until the expected degree of improvement is obtained, whether that is after three or 23 treatments.

There is no evidence that the habit of giving one or two extra ECTs after full recovery is effective in preventing relapse[53]. The decision to give unilateral or bilateral ECT in the elderly is made easier by the fact that high-dose unilateral ECT does seem to produce less confusion, memory loss and headache and appears to be equally effective in many patients[54,55]. However, there is a great deal of discrepancy in the results of comparative studies, possibly due to differences in diagnosis, age and gender, together with variance in the technique of administration of unilateral ECT. The consensus seems to indicate that, for many patients, both treatments are equally effective; some patients require more right unilateral treatments than bilateral to achieve the same result and some patients who do not respond to right unilateral ECT will respond when switched to bilateral treatment. Male gender and older age are also associated with better response to bilateral treatment.

It is my practice to use bilateral treatment initially in very severe psychotic depressives but right unilateral treatment in most other cases, particularly if there is evidence of prior cognitive impairment, switching to bilateral treatment if there is no response after six to eight right unilateral treatments. Brief pulse ECT at a moderately supra-threshold stimulus (which is often only around 275–350 millicoulombs) appears to offer efficacy, with the advantage of much less memory loss and confusion than the modified sine wave stimulus, and should be used in all cases, with a record of dosage received by the patient to ensure adequate technique[56].

There is considerable debate about the necessity to use a dose titration technique to establish seizure threshold prior to treatment, with some viewing this as unnecessary and even detrimental in those patients requiring several non-convulsive stimuli. Adequate seizure response can be measured using interictal EEG monitoring. Some clinicians seem to have developed an excessive interest in stimulus intensity, seizure threshold and seizure duration. It is clear that seizure threshold will increase by about 40% during the course of ECT and the seizure duration will tend to decrease by about one-third. However, while it seems that outcome is not correlated with either seizure duration or threshold for bilateral ECT[57], it may be more important to keep the stimulus intensity above seizure threshold in unilateral treatment[58]. Seizure duration is more difficult to evaluate, as some patients regularly have brisk and brief responses with good results. The use of propofol to induce anaesthesia consistently reduces seizure duration, although apparently without affecting efficacy[59,60]. The use of caffeine prior to treatment to prolong seizure activity has been associated with improved efficacy in some patients[61]. It would seem that, as a rule of thumb, we should aim for a seizure length of around 25 s and any seizure less than 15 s or more than 120 s is likely to adversely affect response[62]. Cumulative seizure duration again seems less interesting now than it once was as a measure of the length of a course of treatment, and clinical response still seems the best measure.

There is no evidence that routine atropine premedication improves cardiac stability or lessens secretions. Theoretically it could cause confusion, but there is no convincing evidence of this either. Glycopyrrolate, which does not cross the blood–brain barrier, may be a better drug to use as a drying agent but is not widely used.

Methohexitone for the induction of anaesthesia at a dosage of 30–50 mg is adequate to ensure sleep without hangover, and muscle relaxation with a suxamethonium dosage of 20–40 mg is enough to modify the convulsion without abolishing all evidence of motor activity. If the minimum amount of anaesthetic is combined with treatment early in the morning, the patient is not required to starve any longer than usual, he/she is less likely to be dehydrated, is less likely to break his/her fast, has less time to become anxious and agitated and will recover quickly enough to enjoy a breakfast with the other patients on the ward. If this routine is combined with regular supervision of treatment by the prescribing psychiatrist, the patient will derive the maximum benefit from each treatment and the course will not be unnecessarily prolonged or ineffective. Outpatient ECT does not appear to be as effective in the elderly, except occasionally as maintenance, and consequently most patients will require admission to a specialist unit, where the effects of ECT combined with the therapeutic milieu will hasten improvement. Familiar staff administering the treatment and a well-designed ECT suite will help reduce anxiety.

MAINTENANCE AND CONTINUATION ECT

In 1990 the American Psychiatric Association task force on ECT defined continued administration of ECT over a six-month period

to prevent relapse after induction of remission as continuation ECT (C-ECT); treatment beyond six months was termed maintenance ECT (M-ECT). This was felt to be a viable form of management for selected patients.

Maintenance ECT has been used for many years: a survey of British psychogeriatricians in 1991[63] found that 20% were using it but there is little more than anecdote to support its use in the literature. Such studies as there are consist mainly of case studies and small series of hospitalized patients, all of a 'naturalistic' nature.

In a one-year follow-up of nine elderly patients, continuation treatment, even if discontinued fairly quickly, seemed to confer some lasting advantage in prevention of relapse[64], as did Petrides *et al*.'s study, looking at 33 courses of C-ECT[65]. The conclusion seemed to be that where patients have responded to acute ECT but previously failed on continuation pharmacotherapy there was compelling evidence for C-ECT and little therapeutic alternative. The four patients in this study[65] who continued with M-ECT remained well and the five who had previously stopped did not. Naturally this result is open to other interpretations, but it does suggest that C-ECT should be considered for those with recurrent depression who respond well to ECT acutely but receive no prophylaxis from pharmacotherapy. The practicalities of using outpatient M-ECT have prevented my using it more. Bringing elderly patients to hospital for outpatient ECT early in the day, from a rural catchment area some distance from the hospital, can be problematic, they soon lose enthusiasm for the treatment and consequently often withdraw consent. This is an issue recently addressed by Kim[66]. However, Schwarz's findings, that rehospitalization rates were reduced by 67% after instituting M-ECT, suggest that we should try and overcome the practical difficulties[67].

The recent NICE update of guidance on the treatment of depression[68] has recommended that further research is urgently required to examine the long-term efficacy and safety of ECT, including its use as a maintenance therapy and its use in particular subgroups who may be at increased risk particularly the elderly. This research should reflect modern techniques and the use of ECT in comparison and in conjunction with the antipsychotic and antidepressant drugs used in current practice.

CONSENT

Popular myths about ECT are always more readily believed than the reality and can be part of what the patient believes they are consenting to. Occasionally patients consent as part of their death wish. I use a video of myself administering ECT to a patient seen before and after treatment, to show anxious or interested relatives and patients; no one having seen it has then declined the treatment. There is one study suggesting that understanding is not enhanced by this method. The issue of informed consent in depressed patients is complex. As I have suggested, many care little and are prepared to do anything their doctor suggests, and patients' recollection of what was explained to them, after the ECT and when the depression has lifted, is often vague. A careful explanation should be made and recorded, and if there are doubts on either side a chance to preview the ECT room or an explanatory video may be helpful. However, it is doubtful whether the explanation of ECT is any less detailed than that of most surgical procedures and most people are willing to consent without seeing a video of the operation in question. Passive acceptance of ECT is often the case in the severely depressed but this should not prevent a full explanation, including consulting relatives if appropriate.

Involuntary ECT should never be given except within the guidelines of the relevant mental health legislation if we are to ensure the availability of ECT as a treatment option in the future. Nevertheless, depression is such a serious and debilitating illness that the chance of a cure through use of ECT should never be denied to a patient whose prognosis is favourable, simply through difficulty in obtaining actual written consent.

ADVERSE EFFECTS

As already mentioned, confusion and memory loss are often regarded as an inevitable corollary of ECT in the elderly, but this is clearly not the case and there are well-conducted studies showing no objective permanent effects on memory, and in fact this often improves as a result of improvement in the depression[32,69,70].

Nevertheless, there is no doubt that some patients who were given bilateral sine wave ECT experienced long-term, even permanent, memory loss, and bland reassurances that this or even brief pulse bilateral ECT will not cause any memory loss is foolish and counterproductive. Some patients given bilateral brief pulse ECT may have amnestic gaps, but can be assured that no lasting effect on memory function, i.e. new learning or intelligence will occur. The situation with right unilateral brief pulse ECT is different, with any subjective memory impairment being transient and undetectable six months later[71,72]. Patients with existing dementia may well show signs of memory impairment, even with unilateral ECT. This may be acceptable in view of the relief from distress and agitation and improvement in behaviour and performance.

The cognitive side effects can be minimized by reducing concomitant medications, particularly benzodiazepines, anticholinergic antidepressants and lithium[73], although a recent study found no problems with the administration of ECT and lithium[74].

Benzodiazepines, given intravenously as the seizure ends, can be of use in controlling emergent delirium, which can last for 15–30 min after treatment and be very difficult to control otherwise.

Dementia per se does not preclude the use of ECT, provided that the co-existing depression is circumscribed. A history of depression before the dementia adds weight to the decision, particularly if there was a good response to ECT previously. Other side effects of treatment, such as headache and dizziness or muscle pain, usually only after the first anaesthetic, are minimal and soon forgotten as the depression lifts.

REPETITIVE TRANSCRANIAL MAGNETIC STIMULATION (rTMS)

Repetitive transcranial magnetic stimulation (rTMS) involves focal stimulation of the superficial layers of the cerebral cortex using a rapidly changing magnetic field applied using an external coil. It does not require anaesthesia and can be performed on an outpatient basis. Treatment with rTMS usually involves daily sessions lasting about 30 min for 2–4 weeks and possibly longer. Its use in the treatment of depression has recently been the subject of NICE Interventional Procedures Guidance IPG 242. A recent meta-analysis for patients with treatment resistant depression which included 24 studies (1092 patients) meeting their inclusion criteria[75] found that active rTMS was significantly superior to sham conditions in producing clinical response, with a risk difference of 17%. However, the pooled response and remission rates were only 25% and 17%, and 9% and

6% for active rTMS and sham conditions, respectively. They concluded that further studies are required before adopting rTMS as a first-line treatment for treatment-resistant depression. The recent NICE update[68] concluded that the efficacy of rTMS depends on higher intensity, greater frequency, bilateral application and/or longer treatment durations and there appears to be no major safety concerns associated with its use.

CONCLUSION

ECT is a valuable and as yet essential tool in the treatment of depression in old age, a disease which untreated carries a significant mortality. It is interesting that in practice elderly patients who have attempted suicide are nearly all offered ECT. This is because those, albeit only very few in number, who have subsequently killed themselves during a depressive illness have all been patients who have either refused ECT or not been given it at the time of their index suicide attempt. However, while there are many compelling arguments for the use of ECT, it is not a universal panacea. ECT, like any potent treatment, should be prescribed with accuracy and its use monitored carefully by those prescribing it.

Depression in the elderly presents with protean manifestations. ECT should be part of an eclectic approach to treatment and as such will continue to relieve distress and save lives.

INTRODUCTION

Mood disorders are a major public health problem, with poor recognition, diagnosis and treatment despite the availability of reasonably safe, effective, economical treatments and the established effectiveness of continuing educational programmes for care providers[1]. The magnitude of the following problems is greater in the elderly with mood disorders for several reasons: poor recognition for most somatic and cognitive symptoms; increased physical morbidity and disability; and high mortality from suicide and other causes. This situation, however, is balanced by increased recognition that pharmacological treatments are effective and reasonably safe. There is, however, marked variation in rate, stability and direction of recovery with reliable pretreatment predictors of outcome[2]. The usefulness of pharmacological treatment for patients with subsyndromal depression, albeit to a lesser extent than major depressive disorders, has been also investigated[3].

PRETREATMENT CONSIDERATIONS

There are a number of issues to be considered before starting specific pharmacological treatment of mood disorders in the elderly[4]. With advancing age, there are important and clinically significant changes in distribution, metabolism and elimination of these drugs. The age-related increase in volume of distribution results in a longer half-life for all psychotropic drugs. Hepatic drug metabolism decreases with age, also resulting in a prolonged half-life, which may be two to three times longer than in younger patients, and the decrease in renal function with advancing age is particularly relevant with regard to lithium, which also results in two to three times higher plasma levels than those in younger patients on the same daily dose. A recent review[5] emphasized decreases in passive drug absorption, changes in the proportion of body fat (increased) and lean muscle mass (decreased) and the resultant increase in the elimination half-life of (fat-soluble) antidepressants. In addition, changes in binding proteins result in lower free levels of tricyclics but increased free levels of selective serotonin re-uptake inhibitors (SSRIs). Of particular importance, however, has been the study of the inhibitory effects of the SSRIs on the cytochrome p450 enzymes; these pharmacodynamic actions have pharmacokinetic consequences for co-administered drugs, such as tricyclic antidepressants (TCAs), which are dependent on these enzymes for biotransformation. Patients on anticoagulants in particular need close monitoring. The potential of the various SSRIs to cause significant interactions varies considerably; citalopram, escitalopram and sertraline may carry relatively low risk.

To determine the best pharmacological treatment options for individual patients requires careful consideration of a number of clinical factors, which include the following: type of mood disorder; degree of urgency for treatment; previous response to treatment; concurrent medical problems; concurrent drug therapy; risk of overdose; reasonable half-life; dosing flexibility; and affordability[6].

TREATMENT OF DEPRESSION

Older patients with depression can be successfully treated with conventional TCAs, monoamine oxidase inhibitors (MAOIs), SSRIs and atypical antidepressants. TCAs have the major limitations of anticholinergic effects, postural hypotension, excessive daytime sedation and cardiotoxicity in overdose. Their advantages, however, are their established efficacy and low cost. Among the TCAs, the secondary amines desipramine and nortriptyline have more favourable side-effect profiles, with desipramine having the fewest anticholinergic effects and nortriptyline causing the least postural hypotension[6]. The secondary amines also have the advantage of therapeutic drug monitoring, with an established therapeutic window for nortriptyline and a therapeutic plasma level of desipramine. Therapeutic drug monitoring enables the clinician to determine the minimal therapeutic dose and to monitor compliance. Nortriptyline has been well investigated for use in elderly patients, including patients older than 80 years[7] and patients who have had strokes[8].

Among the MAOIs, phenelzine has been shown to be effective in treating elderly patients with depression[9,10], particularly for patients who could not tolerate TCAs and those with resistant depression. Their main limitation is their interaction with tyramine-rich foods, causing hypertensive crisis. For this, they are superseded by moclobemide, a reversible and selective inhibitor of monoamine oxidase type A. Comparative trials in the elderly have established its efficacy compared with imipramine[11], nortriptyline[12] and placebo[13]. Moclobemide also showed benefits on cognitive function in patients who had dementia and co-morbid depressive symptoms[14].

The SSRIs, however, have provided the most important practical advance in the successful and safe management of depression in late life. This group of drugs includes fluoxetine, fluvoxamine, sertraline, paroxetine and citalopram. The SSRIs have replaced tricyclic

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

antidepressants as first-line antidepressants for older people as well as for younger adults. More recently, several other antidepressants have become available including bupropion, mirtazapine, another SSRI (escitalopram), and the serotonin and noradrenaline re-uptake inhibitors (SNRIs) venlafaxine and duloxetine[14]. The advantages of SSRIs over TCAs are the absence of anticholinergic effects, orthostatic hypotension and arrhythmia in the side-effect profiles, and their safety in overdose[7]. Comparison of fluoxetine with nortriptyline in in-patients with severe depression and heart disease showed that nortriptyline may be more effective in this population[15]. A meta-analysis of the comparative efficacy and safety of SSRIs and TCAs in elderly patients[16] showed no differences in safety and dropout rates.

A recent meta-analysis[17] of the efficacy of second-generation antidepressants (SSRIs, SNRIs bupropion and mirtazapine) showed response rates of 44% for active drug and 35% for placebo, suggesting only modest efficacy (number needed to treat = 11). A similarly small difference in favour of active drug was found for remission rates (33% vs. 26%). There authors reported marked heterogeneity between studies, with superiority over placebo found for fluoxetine in one of three studies, for paroxetine in two studies, for sertraline and for duloxetine but not for escitalopram or venlafaxine. Results for bupropion showed borderline superiority over placebo in terms of response rate but not in terms of remission. Studies lasting 10 weeks or more were associated with greater superiority for active drug over placebo than studies lasting 6–8 weeks, supporting the traditional view that antidepressant response may take longer to emerge in older people[14].

A similar review of single versus dual action antidepressants in older people included head-to-head comparator trials as well as those with a placebo arm, and continuation as well as acute trials[18]. They concluded that overall, dual action agents 'do not appear to confer any additional benefits in efficacy over single action agents (SSRIs)'. Unlike the meta-analysis reviewed above[17], the primary analysis in this study was by class and they did not examine whether there was heterogeneity between individual studies.

One striking feature of these trials is the relatively low overall response and remission rate for active antidepressant medication. Sneed *et al*.[19] have carried out a systematic review comparing reported response rates in placebo-controlled and comparator trials of antidepressants in older people. They identified nine comparator trials and seven placebo-controlled trials published since 1985 that met their entry criteria. Response rates were considerably higher (60%) than in the placebo-controlled trials (46%); the odds of being a responder were 1.82 times higher in the comparator trials. Type of trial (placebo-controlled vs. comparator) accounted for 27% of the variation in responder rate. The authors conclude that expectation is an important contributor to outcome in such trials and that concern about possibly being on placebo may lead to a suppression of the antidepressant response[14].

The side-effects profile of SSRIs includes nausea, diarrhoea, insomnia, headaches, agitation, anxiety and sexual dysfunction. The SSRIs also seem to worsen Parkinsonism. As with other antidepressants[20], there have been case reports of hyponatraemia, hypomania and seizures[7]. An important aspect of their use is their drug–drug interactions, and their inhibitory effects on hepatic cytochrome p450 isoenzymes, the route through which many drugs commonly prescribed for elderly people are metabolized[21]. Paroxetine, norfluoxetine and sertraline have clinically important inhibitory effects (*in vivo*) on cytochrome P2D6, resulting in increased plasma concentrations of co-administered TCAs, such as desipramine, and antipsychotics, such as haloperidol[22]. Sertraline, however, had a modest effect on plasma nortriptyline levels in depressed elderly patients[23]. Fluoxetine increases plasma levels of co-administered carbamazepine; alprazolam and fluvoxamine increase plasma concentration of co-administered TCAs and antipsychotics by inhibiting cytochrome P1A29. An extensive list of drugs metabolized by various p450 isoenzyme types is provided in the reviews by Catterson *et al*.[4] and by Rivard[6].

Despite these potential problems, two recent reviews of (SSRIs) in older people[24,25] have found that they are generally well tolerated but that gastrointestinal (GI) problems including nausea are relatively common. Increased risk of GI bleeding is potentially important because older people are in any case at greater risk of such bleeding. SSRI-induced restlessness, sedation and extra-pyramidal movement disorders may also be particularly disabling in older people. SSRI-induced hyponatraemia is increasingly recognized to be common in older people. Older age, female gender, low body weight and co-administration of diuretics are indicators of increased risk. Inappropriate secretion of antidiuretic hormone (mediated by activation of 5HT2 and 5HT1C serotonergic receptors) is a likely mechanism. Serum sodium should be checked frequently in older patients on SSRIs, particularly in the first few months of treatment. Drug interactions involving the cytochrome P450 enzyme system may be clinically relevant in older people. Patients on anticoagulants in particular need close monitoring. The potential of the various SSRIs to cause significant interactions varies considerably; citalopram, escitalopram and sertraline may carry relatively low risk.

In the light of this it is perhaps surprising that a recent Australian study[26] found that although antidepressant use had increased in all age groups and most markedly in the 65+ age group, older people remained the highest users of tricyclic antidepressants whose side effects are well documented as being particularly hazardous in older people. This may, however, reflect the tendency to reuse a previously effective antidepressant for a recurrent episode of depression, and the still frequent use of tricyclics in low dose as hypnotics and analgesics in an older population.

CONTINUATION AND PROPHYLACTIC TREATMENT

Early studies indicated a poor outcome of late-life depression[27], with high relapse, recurrence and chronicity. This view was based on naturalistic observation without monitoring of compliance, adequate dosage and duration of treatment, including prophylactic treatment, and was therefore challenged[28]. Controlled studies of maintenance antidepressant medication, however, showed a relatively good outcome for late-life depression[29]. The Pittsburgh group[30] reported a three-year follow-up study of maintenance treatment with nortriptyline or placebo with or without interpersonal psychotherapy (IPT) and showed that 80% of patients assigned to nortriptyline, with or without IPT, remained in remission. The Pittsburgh group also identified the elderly patients who remained well after placebo-controlled discontinuation of antidepressant medication for a period of one year. Recovery of good subjective sleep quality by early continuation treatment was useful in identifying which remitted elderly depressed patients remained well with monthly IPT after discontinuation of antidepressant medication[31]. A study of the effect of treatment on the two-year course of late-life depression[32] showed a 74% survival rate without relapse. This good outcome was obtained by the use of full-dose antidepressant medication, frequent follow-up and rigorous treatment of relapse.

The US National Institute of Mental Health consensus statement update[33] concluded that the overall evidence supports the recommendation for at least six months of treatment beyond recovery for those with first onset in late life, and for at least 12 months for those with a recurrent illness[34]. Moreover, prophylactic treatment should be of the same type and dosage as that which was successful in the initial acute phase. The consensus statement also concluded that treatment response and long-term outcome for all the patients is generally similar to that observed in younger adults, but the temporal course may be somewhat slower in the elderly and risk of relapse somewhat greater[33].

The effectiveness of the tricyclic antidepressant nortriptyline in reducing relapse and recurrence in older depressed patients at high risk is well established[35]. This study also indicated that interpersonal psychotherapy had an additional preventative effect. More recently Reynolds *et al*.[36] replicated their findings using the SSRI paroxetine. In this study they did not focus specifically on patients at high risk. They failed to identify any additional benefit from interpersonal psychotherapy. Klysner *et al*.[37] have shown that continued treatment with citalopram is associated with much lower relapse and recurrence than placebo in patients who remitted on citalopram and were then randomized to citalopram or placebo for the next two years. A similar study by Wilson *et al*.[38] failed to show superiority for the SSRI sertraline over placebo over two years, but the dropout rate in their study was extremely high. Gorwood *et al*.[39] examined relapse rates over 24 weeks in older depressed patients who remitted on open-label escitalopram and were then randomized either to continue with escitalopram or to be switched to placebo. Risk of relapse was 4.4 times higher on placebo.

Though co-morbid anxiety does not appear to affect acute response to antidepressants, the secondary analysis of data from a controlled study of paroxetine and interpersonal psychotherapy by Andreescu *et al*.[40] found that co-morbid anxiety was associated with a slower response and a higher recurrence rate.

Overall the results summarized above provide strong evidence that older people who respond to antidepressants are substantially less likely to experience relapse or recurrence if their antidepressant treatment is continued for up to two years.

The use of lithium in continuation and prophylactic treatment of depression in the elderly has also been recommended[29,41,42], with the use of lower doses/plasma levels[34]. Lithium may be a more favourable prophylactic treatment than antidepressants in recurrent depression with melancholia and in depression with psychotic features (delusional depression), which are particularly common among the elderly, with a tendency to respond less well to antidepressants[28,42]. The other advantage of lithium therapy is the evident decreased mortality, whether from suicide or other causes[43]. A one-year prospective, placebo-controlled study of maintenance lithium in conjunction with cognitive behavioural psychotherapy in elderly depressed patients[44] showed that, although cognitive behavioural psychotherapy reduced depression severity during follow-up, lithium therapy was no better than placebo. This appears to be related to poor compliance, a finding that highlights the serious difficulties in undertaking prophylactic studies in elderly depressed patients.

TREATMENT OF BIPOLAR DISORDER

Elderly patients with late presentation or late-onset mania respond well to standard antimanic treatment with neuroleptics, lithium and anticonvulsants[45]. Neuroleptic treatment is best avoided in the elderly because of its known extrapyramidal side effects, except for floridly psychotic, agitated and behaviourally disturbed patients who need rapid control of symptoms. Lithium remains the treatment of choice, followed by valproic acid[45]. The evidence for the efficacy of lithium in late-life mania is based on retrospective and uncontrolled studies; there have been no controlled studies, and there have been no controlled studies of the efficacy of anticonvulsants in late-life mania. It has been suggested that valproate is a safer alternative treatment to lithium than carbamazepine, whether used as single or adjunct treatment, in elderly manic patients[45]. There are no guidelines regarding the optimal plasma concentration of valproate in relation to efficacy[45].

An evidence-based review of the treatment of mania, mixed state and rapid cycling in younger populations[46] concluded that lithium and divalproex sodium are effective in mania, whereas divalproex sodium and carbamazepine are more effective in mixed states. Divalproex sodium is the drug of choice for rapid cycling disorder. With bipolar depression, lithium is recommended as a first-line treatment and the addition of a second mood stabilizer or a TCA would be an appropriate next step[47].

The guidelines for the continuation and prophylactic treatment of bipolar illness in late life are similar to those advocated for younger patients, except for the notion of high recurrence rates necessitating prophylactic treatment, even after a first-onset manic episode. Lithium remains the medication of choice for prophylaxis[42]. An open naturalistic study of lower doses/plasma–lithium levels[42] showed efficacy in the elderly comparable to that in younger patients at plasma–lithium levels as low as 0.4 mmol/l, with fewer side effects and renal and thyroid adverse effects.

TREATMENT-RESISTANT DEPRESSION

Treatment-resistant depression occurs in one-third of elderly depressed patients[48] and can only be ascertained after adequate recognition, compliance with treatment and effective treatment[49]. It has also been related to cognitive impairment, physical and psychiatric co-morbidity, late onset and presence of melancholic and psychotic features[41]. Moreover, elderly patients with anxious depression are less responsive to nortriptyline than are those without significant anxiety symptoms[50].

Although TCAs[15] and MAOIs[51] have shown efficacy, the SSRIs are specifically advocated[41]. Fluvoxamine has shown efficacy (70% good response) in desipramine non-responders[52,53], and patients who were intolerant of fluoxetine completed a trial of sertraline with a response rate of 76%[54]. Venlafaxine also has long-established efficacy in older people with refractory depression[55].

Combination and augmentation strategies have been advocated[49]. Lithium augmentation in TCA non-responders is effective in 20–65% of cases[56–58]. It is, however, associated with cognitive and/or neurological side effects in 50% of patients[56,57,59,60]. Lithium has been successfully added to SSRIs, notwithstanding the risk of neurotoxicity with an SSRI–lithium combination[49]. Advocated augmentation/combination strategies include TCA/tri-iodo-thyronine, SSRI/TCA, SSRI/anticonvulsants and SSRI/oestrogen (ibid.). Elderly patients requiring adjunctive medication to achieve remission may need continuation of adjunctive medication to remain well and to avoid early relapse[61].

Rajji *et al*.[5] emphasize the limited evidence base from controlled-clinical trials on optimal strategies where initial antidepressant

treatment has failed. They note, however, that remission rates of up to 50% have been reported with a 'switch' to the MAOIs phenelzine[62] or selegiline[63], as well as with sequential augmentation strategies. Augmentation with lithium[64] and with the atypical antipsychotic aripiprazole[65] have also recently been reported to result in useful remission rates in treatment-resistant older people. Most of the studies to date have been small and few are placebo controlled. This is clearly an area where more research is needed.

For refractory bipolar disorders, a review[66] concluded that the safest combination of mood stabilizers is valproate plus lithium. This was also shown in a series of elderly patients with lithium-resistant rapid cycling mania[67].

CONCLUSION

Although there have been impressive advances in the pharmacological treatment of mood disorders in general, there has been a relative paucity of controlled studies in the elderly, particularly in maintenance and prophylaxis. Generalization from the results of studies of younger patients may be inappropriate in view of the significant changes associated with normal ageing and concomitant medical illness, which affect the pharmacokinetics and pharmacodynamics of psychotropic drugs.

Nevertheless, there has been a change of culture. The nihilism that had prevailed in the treatment of mood disorders in late life has been replaced by cautious optimism with regard to the results of controlled trials in naturalistic settings, as well as studies in high-risk groups, including patients with multiple medical conditions and subsyndromal states.

A large majority of elderly patients with depression could be treated successfully with antidepressants, particularly the SSRIs, because of their favourable side-effect profiles and their low toxicity in overdose. The SSRIs, however, challenge the clinician with their clinically significant drug–drug interactions. Patients who improve should receive continuation of prophylactic treatment with the same dose. For mania, lithium remains the optimal treatment, with anticonvulsants, particularly divaloproex, providing a second-line treatment. The efficacy and safety of atypical neuroleptics remain to be evaluated in both acute and long-term management of bipolar illness. There is also hope for those with resistant-mood disorders with the design of augmentation/combination strategies, which require further evaluation.

Psychotherapy of Depression and Dysthymia

Philip Wilkinson

Department of Psychiatry, University of Oxford, UK

Recent years have seen a steady but slow increase in the application of psychological treatments to manage depression in late life, both as stand-alone treatments and in combination with pharmacotherapy. This stems in part from the large body of evidence supporting the benefits of certain psychological treatments in the management of depressive illness in younger adults[1] and the need to test the benefits with older patients.

There are a number of reasons why psychological treatments warrant investigation in the older population. First, they may help to address the types of psychosocial difficulties often associated with late-life depression such as bereavement, adjustment to chronic disease and loss of autonomy. Second, they may confer benefits in reducing the recurrence of depression, which is a significant problem in older patients. Third, older patients may express a preference for psychological treatment over pharmacological treatment (although this does not necessarily predict their effectiveness)[2]. Finally, neuroimaging data indicate that psychotherapy and pharmacotherapy may target different primary sites of the corticolimbic pathway and may therefore have synergistic effects in the treatment of depression[3].

It cannot be assumed that psychological treatments for depression are as effective in older people as in younger adults. Older people are more likely to have cerebrovascular lesions which are known to be associated with poorer response to physical treatments[4]. Depression beginning in later life is also associated with greater reductions in processing speed and executive dysfunction[5] which could impede response to psychological treatment. Symptom profiles in depressed older people, and therefore the target symptoms of psychotherapy, also differ from those in younger people, with greater motivational deficit and less affective change[6].

This chapter reviews the different psychological therapies that have been developed, and to some extent evaluated, for use with depressed older people. It summarizes the indications and evidence for therapies and ends with a brief discussion of access to therapies and research priorities.

BEHAVIOUR THERAPY AND COGNITIVE BEHAVIOURAL THERAPIES

Behaviour therapy and its related treatments form the largest group of therapies employed in the management of depression. Although their evaluation in older adults is patchy, they offer a number of approaches to helping the depressed older person.

Behaviour Therapy

According to learning theory, depression results from reduced engagement in positively reinforcing behaviours (pleasurable events) and excessive exposure to negative reinforcement (avoidance and negative events)[7]. Behaviour therapy uses an operant conditioning model to reintroduce positive reinforcement, to reduce the time spent on negative events and to overcome avoidance. This model is presented to the patient as a vicious circle that needs breaking, based on diaries of the patient's activity and negative mood. This is then followed by scheduling of positively reinforcing behaviours and monitoring of the effect on mood. It may often be possible for patients to resume their previous activities. However, older people experiencing physical illness and disability may be unable to resume all of their previous activities and may need help in identifying alternatives.

Behavioural approaches to depression were later elaborated by incorporating the patterns of negative thinking that occur in depression, giving rise to cognitive behaviour therapy.

Cognitive Behaviour Therapy (CBT)

According to the cognitive model of depression[8] an individual's underlying beliefs about him- or herself and the world may confer a vulnerability to depression that is then triggered in the face of specific types of event. Faulty information processing in the form of over-generalized negative thoughts shapes behaviour and maintains depressed mood.

The validity of the cognitive model as an explanation for cases of depression arising in late life has been questioned given the evidence for structural causes such as cerebrovascular disease. Another limitation of a vulnerability–diathesis model is that an older person may appear to have held the same beliefs for decades and endured previous negative events without developing depression. However, it has been observed in older patients that certain personal beliefs can be adaptive and functional throughout earlier life but can predispose to depression in response to specific age-related events, such as retirement[9].

Cognitive behaviour therapy for depression begins with behavioural activation but in contrast with behaviour therapy it includes analysis of the thoughts that underlie inactivity. As the following case example illustrates, negative thoughts are then

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

addressed through direct verbal challenging and testing them out in specific situations (behavioural experiments), supported by written thought diaries.

CBT Case Example: Mrs Jacobs – a woman with physical problems and depressive illness

Mrs Jacobs was a 78-year-old woman referred for therapy by her general practitioner having developed a depressive illness following a stroke. She had been treated with a course of antidepressants, which had brought about a small improvement although she remained significantly depressed with a 'dread of the future'. She described a loss of confidence and poor concentration and had withdrawn from a number of social activities. She had also noticed a deterioration in her memory, finding it difficult to retain and use new information although this did improve at times when her mood picked up. She had three grown-up children who did not live locally.

Mrs Jacobs had enjoyed a career as a teacher until retiring at the age of 63 years. She had coped with a number of stressful events in her past, such as the loss of her husband, without becoming depressed. Her medical history included hypertension, heart disease and arthritis. Her stroke had occurred after her return from holiday, giving rise to permanent weakness of her right leg. Evaluation by a neurologist, including magnetic resonance imaging, had confirmed the presence of cerebrovascular disease. Fearing further strokes, she became anxious that she would not be able to carry on with her interests which included committee work and trips to the theatre. She feared she would be unable to continue living independently and would have to move to a nursing home. Her therapy goals included being able to manage social events and being able to plan realistically for her future.

In session 1 Mrs Jacobs began to recognize the patterns of thoughts and behaviours which were taking place in her depression. She realized that she had become very conscious of the change in her walking which resulted from her weak leg, thinking that other people were noticing it and commenting on it. This added to her anxiety and caused her to avoid social situations or to go to lengths to check that people were not likely to reject her because of it. These observations were included in a simple formulation and this set the scene for a simple diary of these thoughts and behaviours as they occurred at a committee meeting before session 2. She immediately recognized the biased nature of these thoughts, which brought about some improvement in her mood.

In session 2 Mrs Jacobs was helped to notice the link between her mood, energy and activity. At times she was quite tired with her mind 'in a fog' which caused difficulty organizing activities such as catching up on tasks at home. This led to self-critical thoughts. She expected herself to function as she had before her stroke, discounting any achievements she was now able to make. She was also disappointed by the day-to-day fluctuations in her energy. To illustrate this process she kept a diary between sessions. She was given written information about the link between activity and depression and was asked to begin activity scheduling. This caused her some difficulty as she aimed to complete the activity schedule perfectly, bringing to attention the high standards she had always set for herself. The exercise also brought to the therapist's attention the extent to which Mrs Jacobs was struggling with mental tasks because of her cognitive slowing. Mrs Jacobs was encouraged to plan things in advance but to allow some flexibility depending on her physical state and external events. She approached larger commitments by breaking them into smaller stages and using more written records. To support these changes she successfully challenged her self-critical thoughts with responses such as 'the list of jobs will never finish, so why blame myself?', 'is it really important to do it now?'. The beliefs underlying Mrs Jacobs's high standards were examined – for example, the belief that 'I must always do everything to the best of my ability' – and she began to accept that getting older allowed her the opportunity to relax her standards and take some rest.

In session 6, Mrs Jacobs was helped to use thought challenging to deal with her fear of rejection by friends. She found questions such as 'What am I afraid might happen?' and 'Am I exaggerating the importance of events?' particularly useful. She recognized a tendency to predict that people would not want her. If others were ambiguous in their behaviour (such as not initiating conversation) it was taken as evidence that they did not want her around. She tested out her thoughts using simple behavioural experiments such as initiating conversation with people and being ready to challenge unhelpful thoughts as they arose. She found that actually putting this into practice was not always easy so she needed to plan the stages in some detail beforehand then complete her thought records and observations soon afterwards. She was successful in reducing the intensity of her thought that she was being rejected from 80% to 5%.

By session 9, Mrs Jacobs was becoming more flexible in her activities and coping better with personal relationships. She was still feeling anxious and low in the mornings. She had hopeless thoughts and although she could challenge these successfully later in the morning, she had difficulty doing this at the time. She therefore developed a list of strategies to cope with depression in the morning such as keeping a reminder by her bed of the challenges to unhelpful thoughts and activities she could engage in rather lying in bed ruminating.

By session 10 Mrs Jacobs's mood was significantly improved. She still reported mild cognitive deficits such as difficulty naming and slower thinking, related to her cerebrovascular disease. She identified unhelpful thoughts about developing Alzheimer's disease or losing control of her life. With the therapist she also identified a distortion in her thinking that having irreversible problems (such as her cerebrovascular disease) meant she had an unmanageable problem. Understanding the physical basis to some of her problems also helped her to challenge her self-critical thoughts. At times of additional stress, such as admission to hospital, she would become anxious and depressed and her fears for the future would recur, but she managed to use thought challenging to handle this (Table 87.1). This also helped her to review the plans she had made in case of further disability in the future, such as financial planning and adding her name to the list for her preferred nursing home. At the end of treatment, Mrs Jacobs made a therapy

'blueprint' which included a summary of what she had done to achieve her improvement and what she would need to do if her problems recurred (Figure 87.1).

Problem-solving Therapy (PST)

Problem-solving therapy is a brief intervention of six to eight sessions that is usually delivered in primary care; it is designed to help depressed patients to take an active approach to tackling their psychosocial problems. PST can be considered a behavioural intervention in that it tackles the avoidance and reduction in pleasurable activities that occur in depression, and as a cognitive intervention in so far as it addresses the negative perceptions that may interfere with finding practical solutions to problems.

Problem-solving therapy involves the following stages: definition of problems; establishing realistic goals; generating, choosing and implementing solutions; and evaluating outcomes. Use of a therapy manual helps patients to practise these skills and to continue their use after therapy has ended. Clearly, older people often face irreversible obstacles such as bereavement or disability, in which case goal setting is an opportunity to regain some sense of control through tackling the consequences and effects of these problems. For instance, a depressed patient unable to drive after a stroke may identify new ways to travel.

Table 87.1 Mrs Jacobs's thought diary

Situation	*Emotions*	*Unhelpful thoughts*	*Evidence that it's true*	*Evidence that it's not 100% true*	*More balanced thought*	*Feeling now*
Planning admission to hospital	Anxiety 60%	'I shan't be able to manage'	My children are too busy to help	If they're busy, they still haven't forgotten me	'It's OK to seek out help'	Anxiety 5%
	Depressed 80%	'I might have to ask for help'	I'm having to make all the arrangements	My neighbour did offer to help	'This is how I feel when I'm under pressure'	Depressed 10%
		'I'm all alone'	People won't ask how I'm getting on	If they don't ask, it doesn't mean they don't care	'Yes, I'm in charge of my life. It's hard work, but it doesn't mean I'm alone in the world'

Dialectical Behaviour Therapy (DBT)

Dialectical behaviour therapy has been developed to treat younger adults with personality disorder, particularly borderline disorder[12]. Its underlying theory assumes a biological predisposition to increased emotional sensitivity and impaired emotional regulation. It combines individual therapy to tackle self-defeating behaviours, such as self-harm, with group training in emotional regulation and managing interpersonal relationships; these are backed up by telephone coaching from a therapist. Therapy techniques include the use of metaphor and stories (dialectical strategies) and standard cognitive behavioural strategies.

The study of personality and personality disorder in old age is in its infancy and is hampered by a lack of robust longitudinal research[13]. However, there are indications that certain personality traits in older people are associated with recurrent depressive disorder and this has led to the modification of DBT for the treatment of older patients[14]. Self-defeating patterns of behaviour exhibited by older patients and targeted in DBT may include repeated disengagement from treatment.

For a fuller description of DBT with older adults see Cheavens and Lynch[15].

Mindfulness-Based Cognitive Therapy (MBCT)

Mindfulness-based cognitive therapy is used to prevent recurrence of depression. It is derived from both CBT and mindfulness-based stress reduction, an intervention originally developed to reduce distress in patients experiencing chronic pain and illness[16]. Rather than examine the content of thoughts, as in conventional CBT, MBCT teaches patients how to disengage from recurrent patterns of negative thinking by the use of meditation and refocusing on bodily sensations, particularly breathing. Techniques are taught in group classes with the intention that participants will continue to practise meditation and to employ modified techniques in everyday life. As MBCT aims to prevent rumination over insoluble problems, such as ill-health, it has obvious potential in the treatment of older people. Experience suggests that older patients value its educational approach[17].

Efficacy of Cognitive Behavioural Interventions

Despite a significant number of large-scale trials supporting the acute and long-term benefits of CBT in the management of depressive illness in younger adults[1] there have been few large well-powered trials with older participants representative of clinical populations[18]. In one trial[19] 102 adults aged 60 and over with major depressive disorder were treated over three months with CBT alone, the antidepressant desipramine alone, or a combination of the two. The authors concluded that the addition of CBT to desipramine may be of additional benefit in patients with more severe depression. A more recent trial in a UK primary care setting compared CBT with treatment as usual and treatment as usual with talking control[20] in 204 people aged 65 or over with a Geriatric Mental State diagnosis of depression. Based on improvement in Beck Depression Inventory score, CBT was of greater benefit than treatment as usual and talking control.

A Cochrane systematic review of trials of psychological treatments for depression in older adults included five trials comparing therapies from the cognitive behavioural schools with waiting list controls[21]. The cognitive behavioural therapies were found to be significantly more effective than waiting list controls. However, the authors of this review urge caution in generalizing these findings to clinical populations due to the quality of the trials and their clinically unrepresentative patient populations.

Studies of MBCT

The National Institute for Health and Clinical Excellence Depression Guideline[1] recommended MBCT as a maintenance treatment to reduce the likelihood of future relapse for younger adults who have experienced three or more episodes of depression. MBCT may also be more effective than antidepressant medication in reducing overall psychiatric morbidity and improving quality of life[22]. There have been no randomized trials of MBCT with older people, although a descriptive study of 38 older people with recurrent depression showed it to be an acceptable treatment that required minimal modification[23].

IMPACT Trial (Improving Mood, Promoting Access to Collaborative Care Treatment)

In this large multicentre trial in the United States[24], behavioural activation and PST were used as components of a flexible package of treatment for depression alongside patient education, antidepressant treatment and supervision by a depression care manager. Compared with usual primary care treatment (including antidepressants) the collaborative care reduced depressive symptoms and improved rates of remission on the Symptom Check List 90 over two years.

Studies of DBT

There have been two small exploratory randomized controlled trials of DBT in older people. In the first, in which people with major depression received antidepressant medication with or without group skills therapy and telephone coaching, higher rates of remission were found with the combination treatment at six months. The second study was with participants aged 55 and over with major depression and a diagnosis of personality disorder on the Structured Clinical Interview for DSM-IV Personality Disorders and the Inventory of Interpersonal Problems (Personality Disorders) who had not remitted after eight weeks of antidepressant treatment[25]. They were randomized to 24 weeks of either antidepressant medication management alone or medication management plus DBT. Although those receiving the combination achieved remission sooner, there was no difference between groups in overall rates of remission.

INTERPERSONAL PSYCHOTHERAPY (IPT)

Interpersonal psychotherapy is a short-term individual treatment based on the simple principle that whatever its cause, depression inevitably impacts on relationships. It arose from the interpersonal school of psychiatry and under the influence of attachment and life events theories. IPT aims to address one or two interpersonal goals that are identified during a detailed review of the patient's current and recent relationships.

Interpersonal problems are classified into four categories: complicated bereavements, role transitions, interpersonal disputes and interpersonal deficits. With older people the commonest foci are role transition and interpersonal dispute. A role transition may be the loss of a role, such as retirement from work, or the acquisition of a new role such as becoming a carer for a spouse with dementia. A role dispute may occur, for instance, when an older person dealing

with ill-health begins to require the practical and emotional support of an adult son or daughter. There is naturally some overlap between these categories: for instance, a complicated bereavement after the death of a spouse implies a role transition to being a single person[26].

Treatment strategies used in IPT begin with education of the patient on the nature of depression and encouragement to temporarily adopt the sick role. This should help to validate the depression as a legitimate health problem which can be important for older people. In the management of bereavement, patients are encouraged to express their feelings associated with their loss and then to build up new relationships. With role transitions, a period of mourning for the old role is encouraged followed by support in adapting to the new role. In interpersonal disputes possible treatment strategies include improving the patient's style of communication before renegotiating the basis of the relationship or seeking its dissolution.

Interpersonal psychotherapy can be used as a short-term acute phase treatment of depression (usually up to 16 sessions) or as a maintenance treatment with sessions more widely spaced over a period of months. The latter allows for a greater number of therapeutic foci to be addressed, including long-standing patterns of interpersonal behaviour that may contribute to recurrence (interpersonal deficits)[27]. In IPT it is generally not intended that the therapeutic relationship become a focus of therapy although in tackling long-term interpersonal deficits it may provide useful insights.

IPT has also been adapted for use with cognitively impaired older people through involvement of caregivers in the delivery of therapy[28].

For a detailed description of IPT with older adults, see Hinrichsen and Clougherty[26].

IPT Case Example: Mr D – I lost my wife and my life

Mr D, a 66-year-old widower and retired lawyer, was brought to treatment by his family. He acknowledged being quite depressed in the aftermath of his wife's death from breast cancer five months earlier. On questioning, he stated that his depression had really begun when he retired from his job to care for her declining health a year and a half earlier. In fact, Mrs D had been fighting breast cancer on and off for eight years, an onslaught that he had described as having gradually taken over their lives. He was distracted from his work, and what he described as a previously warm and close relationship had suffered. 'But why shouldn't I be depressed?' he asked. 'My life is ruined, over.' He reported agitation, rumination, decreased sleep and appetite, a 15 pound weight loss, and passive suicidal ideation, with a sense that he might be reunited with his wife in death. His Hamilton Rating Scale for Depression score was 27.

Mr D reported one prior episode of depression in his early twenties; he had also abused alcohol many years before but denied current use. He reported mild prostatic hypertrophy but was otherwise in good medical condition. He was adamant that he would not take an antidepressant medication.

Given a choice between a role transition based on retirement and complicated bereavement, both therapist and patient agreed to focus for 12 sessions on the latter. Mr D felt guilty that he had let his wife down, believed that he should have cared for her better, and considered her the love of his life, an irreplaceable loss after some 40 years of marriage. The therapist encouraged him to reminisce about what he missed about Mrs D and their marriage. She also noted that Mr D had not discussed his feelings much with his friends and had not really used the available social supports. Mr D stated that many friends and family members had either moved away or died in recent years, and he was not in any case one to talk about his feelings. He had withdrawn and kept to himself from the time of his wife's funeral. The therapist encouraged him to consider building new skills in this area, inasmuch as social supports could provide him with some comfort in his difficult situation.

As therapy continued, Mr D reported that he had begun to attend synagogue for the first time in years and that his rabbi had provided some solace. At the same time, Mr D began to discuss his ambivalent feelings about is wife – how her illness had distracted him from and ultimately ended his career and how she had annoyed him at times despite his wanting to care for her. Although they had had a wonderful marriage, there had (inevitably, his therapist noted) been some problems. He began to discuss these issues with a level of affect, initially apologizing for his tears but gradually relaxing and accepting his feelings. His Hamilton score decreased to 13, and he began to become more socially active.

In the latter part of the 12-week therapy, Mr D returned to the law, conducting pro bono work for senior citizens. He also became active as a volunteer for a local cancer society, raising funds and – somewhat to his surprise – developing new friends. Mr D saw his cancer work as a tribute to his wife. He also re-engaged with his children and other family members. By the end of treatment, his Hamilton Rating Scale for Depression score had fallen to 7. He was proud to have improved 'by myself' without medication. Given his history, Mr D and his therapist agreed to monthly maintenance IPT to help him preserve his gains.

Efficacy of IPT

There is good evidence for the efficacy of IPT as an acute treatment for depression in younger adults[1] but acute phase trials with older people been fewer and smaller (e.g.[30]). The most significant trials of IPT with older people have been in the maintenance phase of treatment; these are reviewed below.

MTLLD I and MTLLD II trials (Maintenance Therapies for Late Life Depression)

These trials examined the effect of IPT with or without antidepressant treatment in participants who had recovered from an episode of depression using a combination of IPT and antidepressant.

In MTLLD I[31] participants were relatively young outpatients (60 years or over) who had suffered at least two episodes of depression.

In maintenance treatment they received nortriptyline alone, drug placebo alone, IPT alone or a combination of both treatments. The combination produced the lowest recurrence rate on the Hamilton Rating Scale for Depression and was superior to drug placebo, IPT alone and possibly to nortriptyline alone although this comparison did not achieve statistical significance. Participants were followed up at monthly intervals for three years (Figure 87.2). Participants aged 70 and over had the highest rate of recurrence in the first year and a secondary analysis suggested that the greatest benefit of combined pharmacotherapy and psychotherapy in reducing recurrence was in this group.

MTLLD II[32] addressed the prevention of recurrence in older patients (70 years or over) (i.e. those potentially at greater risk of recurrence). Participants in this trial had more medical illness than those in MTLLD I; some had cognitive impairment and may have been developing dementia. Half of the participants were in their first episode of depression. They were randomly assigned to paroxetine alone, placebo alone, monthly IPT alone or a combination of paroxetine and IPT; and follow-up was for two years. In contrast to MTLLDI, combined treatment did not produce lower recurrence rates than antidepressant alone and IPT was no more efficacious than drug placebo (Figure 87.3).

PROSPECT trial (Prevention of Suicide in Primary Care Elderly: Collaborative Trial)

Although this large primary care trial principally studied the reduction in major risk factors for suicide in older people, it gives some indication of the effect on depression of a care management intervention that included IPT[33]. Other components of treatment were antidepressant treatment and support from a depression care manager who also delivered the IPT in both the acute and maintenance phases of treatment. Patients receiving the intervention had a more favourable course of depression and greater rates of remission during a year's follow-up, compared with those receiving usual care.

REMINISCENCE THERAPY AND LIFE REVIEW

Designed specifically for older adults, reminiscence therapy is usually offered in groups in which participants are encouraged to discuss their earlier life experiences with the help of prompts such as photographs, music and everyday objects. Life review, by contrast, is usually an individual therapy offering a more systematic review of the patient's own life experiences.

Efficacy of Reminiscence and Life Review

A number of small, short-term trials have shown positive effect sizes for reminiscence as a treatment for depression, particularly in community-dwelling people; however, a large randomized controlled trial is lacking[34]. In one study, reminiscence and life review appeared less efficacious than problem-solving therapy[35].

USING PSYCHOLOGICAL TREATMENTS IN THE PRIMARY PREVENTION OF DEPRESSION

It is known that the factors that put older people at risk of developing major depression include chronic illness, functional impairment and low-level symptoms of anxiety and depression. For this reason psychological interventions have been developed for those at risk of depression because of a medical disorder or bereavement (selective prevention) or because of having subsyndromal symptoms (indicated interventions). An example of a selective intervention is PST to prevent depression in older people with age-related macular degeneration as evaluated by Rovner *et al*. in 206 people attending an ophthalmology clinic[36]. This study demonstrated a significant difference in depression levels between intervention and control groups at three months but this was not maintained at six months.

For a summary of prevention trials and a discussion of study design see the review by Cole[37].

PSYCHOLOGICAL TREATMENT OF DYSTHYMIA

Dysthymia indicates a long-standing state of milder depression, especially low mood and is sometimes is accompanied by episodes of major depression. There has been little specific evaluation of psychological treatments for dysthymia, especially with older people, although there is some guidance as to how treatments can be adapted. It is suggested that both CBT and IPT for dysthymia need to take account of the strained relationships and long-term lack of achievement that can accompany it and in IPT the therapeutic focus may need to be the role transition from ill-health to health[29]. It is likely that therapy will take place over a more sustained period with regular maintenance sessions.

OLDER PEOPLE'S ACCESS TO PSYCHOLOGICAL TREATMENTS AND THE NEED FOR FURTHER EVALUATION

Developments in the use of psychological therapies with depressed older people appear not to have significantly influenced provision. In the United States, use of psychotherapy remains uncommon among depressed older people[38] and in the United Kingdom availability has been patchy[39]. The Improving Access to Psychological Therapies programme in the UK[40] has tried to improve uptake through the implementation of a stepped care approach starting with low level interventions such as behavioural activation. Although a key aim of the programme has been to enable working adults to re-enter the workforce it was also intended to improve access for older people. Despite this, older adults have been under-represented in referrals made by general practitioners. Older people appear inclined to take up the offer of psychotherapy, particularly if it presented in an educational format[41].

Availability of therapies may be limited by health care providers. In the United States, for example, Medicare providers may limit the number of therapy sessions or restrict them to certain groups of patients[42]. Therapies that are more straightforward, such as PST, and that can be delivered by non-mental health workers alongside treatment of physical disorders may have more to offer and be more appealing to funders as may brief therapies designed to be delivered in group format[43]. However, before a strong case can be made for an expansion in psychological treatment provision for depressed older people further evaluation of interventions is required. Although the effect sizes in trials with older adults appear to match those with younger people, there remains a paucity of large, robust trials with older adults representative of clinical populations[21,44]. Trials of care management interventions in primary care have been encouraging but these do not measure the specific effects of their psychological treatment components. Indicators of likely response to psychological therapies would help guide decision making and use of resources[45].

Acute Management of Late-Life Depression*

V. Gardner and D.C. Steffens

Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, NC, USA

The acute management of late-life depression may require hospitalization, both for accurate diagnosis and for effective treatment. Ambulatory management is frequently favoured because of rising hospital costs in a managed care environment. However, the elderly present special challenges that may require that diagnosis and/or treatment be undertaken in a hospital setting. The hospital provides an environment for the monitoring of symptoms for accurate diagnosis and proper personnel for regular and accurate treatment administration. Several factors may interfere with both accurate diagnosis and effective treatment on an ambulatory basis[1], including underlying chronic medical illness, pain, neurodegenerative changes, dementia, adverse life events, inadequate family support, secret self-medication, substance abuse, bereavement, interpersonal conflicts and social isolation of the elderly patient.

Actually, the elderly patient who is cognitively intact may be reliably managed on an ambulatory basis and can be instructed about medication side effects. Similarly, the more impaired elderly patient who has adequate social support for observation and medication management may only need the community support of a visiting psychiatric nurse, assuming one is available. Varying levels of care are also implemented in the hospital environment. Patients may have the usual care of routine monitoring or may have more intense one-to-one monitoring if they are an imminent risk to themselves or others.

As a general rule, the more the physical and psychiatric impairments and the fewer the psychosocial resources, the greater the need to hospitalize for accurate diagnosis and effective treatment. When deciding safe and effective management, the following factors favour hospitalization: poor or unstable physical health, high suicide risk, impaired judgement and reality testing, likelihood of poor compliance, impaired cognitive functioning, lack of social support, and severe anorexia and weight loss.

CO-MORBIDITY OF PHYSICAL ILLNESS: THE INTERFACE OF PRIMARY CARE AND PSYCHIATRY

Accurate diagnosis is a prerequisite for effective treatment. Elderly patients with depression present to their primary care physicians and psychiatrists in a complex manner, and signs and symptoms of physical illness and depression overlap. Even the normal effects of ageing may cause diagnostic difficulties and restrict treatment options. Many primary care physicians diagnose and treat late-life depression without referral. However, those patients who fail two or three trials with antidepressants, usually selective serotonin reuptake inhibitors (SSRIs) or newer agents, are commonly referred to a psychiatrist for further management. These patients represent a treatment challenge and may require more complex medication regimens. Hospitalization may be necessary to enable close monitoring and minimise risk of self-neglect, suicidality and treatment side effects. Primary care physicians also refer for the following reasons: suicidality, co-morbidity with substance abuse, dementia, anxiety disorder, presence of psychosis (delusions, hallucinations), catatonia, bipolar disorder and inability to tolerate antidepressant treatment[2,3].

Depression is often co-morbid with other physical diseases. Approximately 80% of older adults suffer from at least one chronic health problem[4]. The prevalence of co-morbid depression may be up to 30% in stroke patients, 18% in myocardial infarction patients, 51% in patients with hip fracture and 50% in patients with chronic pain[1]. Existence of an undiagnosed and untreated depression with these illnesses leads to higher disability[5]. The diagnosis of depression in the context of established physical illnesses may be challenging, and the hospital environment provides the necessary monitoring and support staff when complicated medication changes are required. For example, a patient with cardiovascular disease may present with decreased energy and apathy. Determining whether this is caused by a compromised cardiac status, a medication side effect, or is actually a symptom of depression may be difficult without hospitalization, close monitoring and various medication trials.

Formerly, hospitalization was favoured for the initiation of tricyclic antidepressant therapy in elderly patients with unstable cardiac disease. First-line treatment with SSRIs has made this less often necessary, though older people are also vulnerable to adverse effects of SSRIs such as hyponatraemia.

Co-morbid neurological illness is also common in geriatric depression. Patients with depressive symptoms following a cerebrovascular accident also present a diagnostic challenge. There may be communication difficulties or other neurological abnormalities. Depression may be diagnosed only by the report of the nursing staff and family, who observe apathy, irritability, tearfulness and weight loss[7]. Patients with Parkinson's disease may develop an affective illness or psychosis, which may be secondary to treatment with L-dopa or dopaminiergic agonists. Hospitalization may be required for medication changes if outpatient support is inadequate.

Severe anorexia, weight loss and refusal to eat are indications for hospitalization for safe and effective treatment[1,8]. Poor oral intake commonly accompanies severe depression, but it may also result from a variety of medical conditions. For example, individuals with active rheumatoid arthritis may experience insomnia, fatigue and poor appetite equally from their physical illness or an associated depression[9].

SUICIDE RISK AND THE DECISION TO HOSPITALIZE

Suicidality is the most common reason for psychiatric hospitalization. The goals for inpatient treatment are: (i) the preservation of life and safety; (ii) the elimination of suicidal intent and ideation and treatment of underlying disorders; and (iii) the improvement of intrapsychic capabilities, personal factors and psychosocial circumstances to facilitate coping after discharge and decreasing risk of the return of suicidality. However, implementation of these treatment plans is predicted on the initial detection of suicidality.

Careful assessment of suicide risk in depressed older adults is thus vital. The elderly are less likely to have made a prior suicide attempt, but they consistently demonstrate a higher rate of completed suicides[10]. The ratio of attempted to completed suicides decreases with age from 200:1 in young adulthood to 4:1 in the elderly[11]. The higher rate is due primarily to the increased frequency of deaths among older, white males. In 1992, people 65 and older accounted for 13% of the population but almost 20% of suicides. Even though the frequency of suicide has increased among older persons in the United States, the prevalence is not as high as that of other industrialized societies[12].

Recognition of variables such as gender and race may influence management decisions. Risk factors for suicide in late life include increased age, with the highest prevalence of suicide of persons older than 85[10]. Also, being male, white, single, separated or divorced, or widowed are risk factors for suicide. Other risk factors implicated in late-life suicide include: a positive psychiatric history (especially depression and alcohol abuse and dependence); physical illness and functional disability (especially diseases of the central nervous system, malignancies, cardiopulmonary conditions, and urogenital diseases in men); previous suicide attempts; psychological factors (i.e. hopelessness); social factors (stressful life events, e.g. bereavement); and biological susceptibility (dysregulation of the hypothalamic–pituitary–adrenal axis or the serotonin system).

Most older people who commit suicide have seen a primary care provider within 30 days of death[11]. This observation stresses the need for collaborative efforts with primary care physicians and the need to make careful assessment based on risk factors.

A number of assessment guidelines have been developed to aid in the evaluation of potentially suicidal patients. A four-item screen for identification of suicidal ideation among general medical patients was developed by Cooper-Patrick *et al.*[12]:

1. Have you ever felt that life is not worth living?
2. Have you ever thought of hurting or harming yourself?
3. Have you considered specific methods for harming yourself?
4. Have you ever made a suicide attempt?

This fourfold layered approach to assessment is useful in obtaining the necessary data without disrupting the therapeutic relationship. If the answer to the first or second question is negative, then the enquiries can cease and the older person may be considered at low risk for suicide[10]. This approach has advantages over other assessment tools, which usually suggest one question to be asked to assess suicidal risk.

DELUSIONS AND LATE-LIFE DEPRESSION

Accurate diagnosis and effective treatment of depressed elderly patients with delusions can be hindered by their impairment of reality testing. Their sometimes well-organized and complex delusions may make them distrust medicine and the physician who prescribes it. This disorder is less frequent in the community and more prevalent in the hospital setting[13,14]. Accurate diagnosis is necessary, as some studies have suggested that the depression is more severe[14,15] and it has been associated with suicide[13]. Varying reports also demonstrate decreased cognitive functioning and social functioning among patients with delusional depression[16]. These patients are best treated in the hospital. They cannot be relied upon to take accurate doses of medications. Effective pharmacologic treatment for delusional depression may require combination treatment with antipsychotic medication and antidepressants[15]. ECT remains an effective and relatively safe treatment for the treatment of delusional depression[17–19] and can be performed on an outpatient basis only with adequate social support.

COGNITIVE DYSFUNCTION AND LATE-LIFE DEPRESSION

A full discussion of how depression is distinguished from dementia is given elsewhere in this book. To summarize, diagnosis is difficult because several symptoms of depression and dementia overlap, such as a flattened affect, psychomotor retardation and presence, at times, of delusions[20]. Delusions are reported to occur in up to 40%[13] of Alzheimer's disease patients, although they are described as transient and less organized than in delusional depression[13]. Major depression occurs in over 20% of patients with Alzheimer's disease and vascular dementia[4,21]. This significant co-morbidity may lead to profound disability[22].

The diagnosis of depression in dementia usually requires the input of family members or nursing personnel[23,24]. The patient with cognitive dysfunction and impaired reality testing cannot reliably report symptoms, take medication accurately, or reliably report side effects.

Dementia with depression and behavioural disturbance is frequently too complex to treat on an outpatient basis. These patients may even require involuntary commitment. Aggression may be verbal or physical. Aggression and agitation in dementia may be as high as 50% in the outpatient population[25,26]. The hospital environment is the only setting with constant monitoring to make an accurate diagnosis, contain behaviour and monitor medication.

The reversible cognitive impairment that may accompany depression also increases disability[27]. With treatment, the cognitive impairment usually improves. However, these patients are at higher risk of developing an irreversible dementia in the future[28].

Bereavement

Robert J. Kastenbaum

Arizona State University at Tempe, Tempe, USA

I have lived longer than the reach of my wildest dreams. Every day is a bonus!
My body's done its job. I've done mine. So! When it's time to go, it's time to go!

Self-reflections of this kind are more common among long-lived people than those who are still making their way towards an as yet unrevealed future. Death is less theoretical, and loss a prominent feature of the lifescape. Advanced age and bereavement are normative circumstances, not psychiatric syndromes. Daily life can present a variety of concerns, such as remembering which medication to take when, fear of falling on icy pavements, and worry about paying bills and continuing to live independently. Bereavement introduces additional concerns. 'Who can I share my day with?' 'Who will do the driving/cooking?' 'Where do I go from here?' These are human rather than geriatric problems.

The psychiatry of bereavement in old age does not assume pathology or need for professional intervention, nor does it assume that all elders respond in the same way. Major research projects find a 'remarkable heterogeneity in older adults' adjustments to loss'[1]. Resilient coping is more common than prolonged distress and dysfunction. Hastily prescribing psychotropic medication for a 'geriatric patient' can become part of the problem, rather than the solution. Instead, we ask, 'Who is this person?' 'What was the nature of this unique relationship that has been ended by death?' 'What does this loss mean to the bereaved person?' – and 'What coping skills and resources can be called upon to make it through?'

A perspective on bereavement in old age can be developed by following the basic sequence of events. We then identify challenges for bereaved elders and those who would offer services to them.

THE PRE-BEREAVEMENT SITUATION

Consider first the situation prior to a bereavement in old age.

1. What was the nature and status of the relationship at this time?

This question should be answered structurally and substantively, e.g. 'He was her older brother; she relied on him for advice and support more than on any other person, including her husband', or 'She was his second wife; he had expected her to look after him – actually, to wait on him hand and foot! – and suddenly he had to be the caring person.' It is useful to explore affective and pragmatic dimensions of the relationship. Was the survivor or the deceased heavily dependent on the other person? Had the relationship been in serious trouble? If so, was this characterized by silent co-existence or stormy disputes? Did the deceased provide most of the couple's link to society? Had the survivor organized his or her life around taking care of the deceased?

An elderly person's response to the death of an adult child or grandchild is too often underestimated[2]. There can be a deep interiorization of grief after the first shock of the loss, followed by an intensified life review. Researchers have documented a 'double pain': their own loss of a grandchild and their anguish over their adult children's grief[3]. There is also often a *disenfranchised grief* situation[4]. Grandparents can be subject to interpersonal signals that they are not fully entitled to mourn the loss. The extent to which grandparents might become isolated in their grief is influenced by their pre-bereavement status in the family. Counselling interventions could include resolving issues that generated intra-family tension prior to the loss. Instead of labelling the problem as 'depression' in the elder, one might instead discover a dysfunctional family pattern that is affecting all the members.

2. How was the prospect of bereavement integrated into the life scenario?

Bereavement in later life most often involves the loss of a sibling or spouse. It is not unusual for elderly people to have floating expectations regarding the loss of people they have known for much of their lives. These cohort peers are at significant risk for death because of their advancing age and accumulated vulnerabilities. Therefore, it will be a sad but not surprising day when their lives come to an end. On the other hand, they have always been around, so it is easy to assume that they will continue to go on and on. A recently bereaved elder might alternate between the more logical and the more habituated-wishful view. Psychologically, the death has been both anticipated and not anticipated.

Anticipatory grief is often a more complex response than usually assumed. Anticipatory grief is similar in many respects to the grief that is experienced after a death[4]. There are affective, cognitive and somatic components, e.g. sadness, obsession, exhaustion etc. It has often been suggested that anticipatory grief helps the survivor to cope with the loss – paid for in advance. Early studies suggested that sudden death has a much more disturbing impact than expected

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

death[5]. More recent studies have taken more variables into account and suggest that anticipatory grief does not always cushion the survivor's stress when the loss does occur[1]. Potential caregivers would do well, then, to observe the particulars of the situation carefully, rather than assume that expectation is necessarily ameliorative. (Many elders have told me how they still feel helpless and miserable because they could not do anything to palliate the suffering prior to an expected death.)

Not all deaths are clearly expectable. Fatal accidents (especially falls and motor vehicle) are far more common among people 65 and older than in any other age group. Nevertheless, there is a greater probability the death will have been expectable, if not necessarily expected. Not only does an increasing proportion of deaths occur in old age, but modern health care has lengthened the interval between development of a life-threatening condition and the day of death. The four leading causes of death for elderly people in the USA (heart disease, malignant neoplasms, cerebrovascular disease and respiratory conditions) all involve a long period of living with progressive life-threatening conditions and, therefore, opportunity for both prolonged stress and adaptation to the prospect of death for the patient and significant others.

Physicians and other caregivers have the opportunity to strengthen the survivor's ability to cope with grief by sensitive response to the situation as it exists prior to death. Offering accurate information, suggesting other options and improving the lines of communication within the family are among the ways in which one can help to shape the anticipatory grief period into a source of strength rather than intensified anxiety. The age differential between most caregivers and the elderly bereaved people they are trying to help sometimes interferes with communications, e.g. when elders are patronized and their ability to cope with bad news is underestimated. There is also an underappreciated connection between quality of terminal care and grief recovery. A hospice physician reports that, 'The pain relief we achieve for an old man in his last weeks of life helps his wife to be more of her normal self when he really needs her – and a widow with fewer regrets and nightmares later.'

3. What was the survivor's own health status prior to the bereavement?

This is a particularly useful question to ask with respect to the older bereaved person[6]. The spouse was most frequently the principal family caregiver in the 40 hospices studied by Mor *et al*.[7] About two thirds of the spouses were above the age of 55 and it was not unusual for the caregivers to be over 75. Elderly caregivers seldom developed new physical problems over the course of the spouse's final illness, but they tended to ignore their own existing conditions. During the first months of bereavement, the survivor's health was sometimes impaired by exacerbation of previous illnesses and impairments. It would be helpful, then, to encourage the spouse and other elderly family members and friends to look after their own health during the pre-bereavement period, and to see that health status is carefully assessed afterward. Symptoms that might appear to be part of an anxious depression syndrome could be related to physical health problems that have not received the attention they deserved.

4. Who else was there and what else was happening?

Strained interpersonal relationships and unanswered questions sometimes increase stress on patient, family and staff. It might be useful to assess the prevailing attitudinal climate. Some bereaved elders report that they felt unwelcome by staff members during their bedside visits. 'I never had a chance to really *be* with Herman. The nurses thought they owned him.' Others said they were told different things by different people. 'I can understand things if I'm told right. I worry more when I'm not sure what to worry about.' By contrast, some bereaved elders drew comfort and strength from the bedside scene. 'The people from the church were over all the time. They really cared. We were so far from the rest of the family, but they were just like family to us.' 'Miriam seemed so at peace with herself. She whispered to me once, "This is a great place to die. They're all so nice".'

A consultant can make a positive difference by identifying interpersonal issues in the end of life period and encouraging humane and effective approaches.

AT THE TIME OF DEATH

Learning what happened around the time of death can help us understand the bereaved elder's state of mind. Consider, for example, the difference between death at home and in a hospital setting. A terminally ill woman was being looked after at home by her elderly mother, with support from a local hospice service. The mother had accepted her daughter's wish to be allowed to die at home without intubation and other futile procedures. But when the daughter appeared to be actively dying, the mother panicked and called not the hospice but a visiting nurse service. Now, as a survivor, the old woman is haunted by memories of her suctioned, intubated and drugged daughter accusing her with her eyes[8]. In a more frequent scenario, an elderly person will call for assistance from paramedics when his/her spouse appears to have died. But when the paramedic team arrives, the caller may have second thoughts about seeing the spouse's body subjected to resuscitation procedures. Some bereaved elderly persons remain troubled by unanswered questions about whether they did the right thing at the right time.

Knowing only that the death took place in a hospital does not tell us whether supportive nurses encouraged a woman to be with her husband right through to the end and to have time with him afterward – or whether she was made to feel unwelcome and hustled away. Perhaps, again, she had not been notified until some time after the death. The particularities of the final scene can provide either an acceptable conclusion to the story of a marriage or friendship, or torment the survivor with resentment, self-doubt and other disturbing thoughts.

The psychiatrist often has the opportunity to increase the sensitivity of physicians, nurses and caregivers in their communication patterns around the time of death. Survivors may hold on to a word or gesture, either as a cherished or an infuriating/depressing memory. Often one can be helpful simply by validating the survivor-to-be's feelings and offering the opportunity to clarify his/her own thoughts by active listening. The generational differences between bereaved person and psychiatrist can be a source of misunderstanding. An aged widow, for example, might keep feelings bottled up in accordance with the implicit rules that characterized her generation. Patience and encouragement could help her to express and cope with her feelings. It happens the other way, too: caregivers whose own tradition is marked by subdued behaviour and restraint of emotions may not be prepared for families in which intense expressions of grief are expected, even required.

EARLY PHASES OF BEREAVEMENT

The idea that there are fixed 'stages' of either dying or grief has attracted more believers than it deserves. One can select and force

observations to fit stage theories, but to what purpose? Individual responses to grief deviate markedly from the models: this is even more common in old age, where uniqueness has been deeply engraved and polished to a high gloss.

It does make sense, though, to differentiate between responses during earlier and later periods subsequent to bereavement. Indicators of a potentially intense, disabling and protracted reaction often appear within a short time. In their classic study, Parkes and Weiss[9] found that those who had the most difficult time coping with the spouse's death tended to smoke and drink more heavily, use tranquillizers and express depressive mood. Other investigators have also found that response to loss within the first few months provides a fairly reliable forecast of long term adjustment. The obvious lesson here is that early-appearing indicators, such as loss of appetite, withdrawal from friends and activities, sleep disturbances and escape into alcohol and drugs (including the hoarding of prescription or over-the-counter elixirs) should be taken seriously. Time alone will not necessarily prove the healer.

Dependency needs often come to the fore when the survivor is experiencing significant difficulties in coping. Counsellors and therapists can be effective in helping survivors to rekindle their sense of competency and autonomy. This is likely to be a step-by-step progression, in which the therapist may have to play the roles of protector and mentor for some time. The advanced age of the bereaved person does not necessarily stand in the way of therapeutic success. Many people bring positive coping skills and experience into their later years of life, and some continue to participate in mutually rewarding social support networks.

It is not unusual for an elderly person to seem relatively unresponsive to a death. In some situations this is the observer's failure to notice subtle but significant changes. But the lack of a strong overt response is sometimes associated with bereavement overload[10]. Re-activated grief from previous losses can command the person's attention so that there is not enough emotional energy available to respond fully to the most recent death. Survivors of the Holocaust and other disasters have often been burdened in this way.

An upsurge in fear of personal death is also not unusual, especially when it is a sibling who has died[11]. A death that hits that closely to the survivor's own situation can lead to a dysfunctional pattern in which depression and anxiety vie for dominance. Here again, therapists have found it useful to bolster the individual's sense of competence and autonomy, as well as to encourage sharing of the concern.

Abundant if somewhat circumstantial research evidence supports the proposition that enhancing self-esteem can be a powerful hedge against mortal terror[12,13].

LATER PHASES OF BEREAVEMENT

Many senior adults have proven highly resilient after experiencing bereavement. Studies do not invariably find that widows sit around weeping and feeling helpless. The gender dimension is important here. Women outnumber men in the upper age echelons and often show themselves more skilful in providing – and receiving – social support. By contrast, the bereaved older man runs more risk of becoming isolated. In some environments, such as the retirement community with its high density of older women, the widower may be valued and looked after. Nevertheless, there is a major problem of hidden grief among older men, a problem that often persists for years after the loss. Quiet, keeping to himself, expressing little obvious emotion, the older bereaved man is more likely to be suffering intensely than his female peer, with her greater facility in self-expression and more sensitive support network[1]. Psychiatrists and other caregivers might be well advised to give more attention to the possibility of bereavement – even a remote bereavement – as the underlying factor in a variety of behavioural and somatic problems experienced by older men. Unfortunately, some of the most traumatic bereavements leave the elderly survivor with the most limited social support. This is especially the case with suicide. The high rate of suicide among elderly white men often leaves their spouses and siblings alone with their grief.

A FEW SPECIAL CONSIDERATIONS

First, grief counselling is proving effective for many adults, including those of advanced age, who had been experiencing significant adjustment problems. A false alarm received widespread attention before being revealed as such. A 'finding' that grief counselling is not only ineffective but sometimes harmful was itself found to be without empirical and scholarly credibility[14]. Grief counselling remains a viable option for bereaved people whose personal and interpersonal resources have been temporarily overwhelmed.

Second, bereavement is a status marker in spousal death. The survivor, no longer a husband or wife, tends to be treated in a different way, sometimes as 'the odd one out.' Counsellors can be helpful in supporting the survivor's transition to meaningful new roles, and the restoration of self-confidence.

Third, the 'little deaths' that often accompany the later years of life can both intensify and anticipate grief reactions. The old man may have been mourning the loss of his mobility even before his wife died; the older woman who was relieved of her starring role as a church soloist may have felt abandoned and rejected long before her husband's death.

Fourth, the death of animal companions can lead to authentic grief reactions[15]. The grief syndrome may be similar to what is experienced upon the death of a human companion, although the intensity is less likely to endure as long. Rage joins with grief when an elderly person is placed in a nursing home and then learns that his/her animal companion has been taken to the pound and destroyed.

Fifth, the profile of the senior adult population and the conditions of their lives are continuing to change. Care providers have the challenge of keeping up with these transformations instead of relying on practices and assumptions that might be outdated. Some examples of relevant population trends are:

- More elders are receptive to counselling and becoming acquainted with the internet. Each new generation of elders is bringing enhanced technological background and receptivity to mental health options.
- The burden of Alzheimer's disease is being experienced by an increasing number of elderly family caregivers both during the course of the illness and in the mixed relief and sorrow that occurs in bereavement[16,17]. The increasing scale of caregiver stress and vulnerability presents a challenge that has not yet been fully addressed.
- Population experts see the USA as rapidly becoming 'a majority of minorities'. Familiar ways of life and death have centred on a white Christian majority. Increasing ethnic and racial diversity is bringing a new mix of attitudes and expectations, including care of the dying and mourning and memorialization practices. There are

often attitude divisions within the same family system as tradition contends with response to external influences. Care providers will have their sensitivities tested.

- Life course coherence and continuity were once bolstered by long-time residence in a relatively stable place and by other supports for familiarity, belonging and predictability. Fewer of today's elders are dying from the worlds they knew and which knew them well[18]. The sense of meaning, coherence, and completion is becoming more difficult to achieve both as life nears its end and as the bereaved try to come to terms with their loss. It remains to be seen whether or not mental health specialists will expand their range to include such ongoing changes in the life course.

In a sense, there are no 'little griefs', and there may be no 'getting over' the greatest losses we experience in our lives. But most elderly adults have learned to live with disappointments, limitations and suffering. When bereavement comes, as a rule they do not need drugs, hospitalization and the whole rigmarole of the health care system. To be offered companionship and to see in that companion's eyes that one is still valued and needed is often all that is required for the survivor to get on with life.

Suicidal Behaviour

Brian Draper

School of Psychiatry, University of NSW, Sydney, Australia

Despite an increase in research knowledge about suicidal behaviour in old age, the translation into community understanding and clinical practice still lags. One common misunderstanding is about the rationality of suicide associated with age-related suffering[1]. While much old age suicidal behaviour occurs in this context, that does not mean it is rational. To better understand suicidal behaviour in late life, it is also important to look at the vulnerability factors from early and mid life. This chapter will examine suicidal behaviour from a life cycle perspective and consider a framework for prevention.

Although suicide rates worldwide are highest on average in persons aged over 75 years, being approximately three times higher than in persons under 25 years of age, the pattern is variable, with about one third of countries that report mortality data to the World Health Organization having higher rates in young adults than in older persons[2]. Furthermore, over the past 30 years many countries have reported a decline in suicide rates in older people alongside an increase in suicide rates in youth and young adults[2]. The reasons for this reduction are unclear but may include improved physical health in middle age and old age, better community services for the disabled to enhance independence, greater financial security in later life, marriage and the prescription of antidepressants[1,3].

In contrast, non-fatal suicidal behaviour declines with age in most countries, with the ratio of attempted to completed suicide in old age being estimated to be between 2:1 and 4:1 as compared with 100:1 to 200:1 in young persons[2]. Attempted suicide in old age closely resembles suicide, with high levels of lethal intent, less impulsivity and clinical features that are similar to those found in completed suicide[4,5]. Thus suicidal behaviour in the elderly is more likely to have a fatal outcome. However, there is a recently observed trend for the 'young old' aged 65–75 years to have higher rates of less lethal and more impulsive attempts, a phenomenon described as 'elderly adolescentism'[2]. Rates of indirect self-destructive behaviour in residential care are high, with one study reporting a weekly prevalence of 61% although the extent to which the behaviour could be regarded as intentional or part of a spectrum of suicidal behaviour is unclear[6]. Suicidal ideation in old age has prevalence rates reported between 2.3% and 15.9% in the previous month and lower rates have been reported in individuals aged over 75 years compared with those 'under 55 years of age'[2].

RISK FACTORS FOR SUICIDAL BEHAVIOUR

Risk factors in late life are similar to younger age groups and include demographic characteristics, psychopathology, personality traits, traumatic life events, physical ill health and disability, previous suicidal behaviour, genetic factors and access to lethal means[2]. However, over the age range, factors have different levels of influence, with one psychological autopsy study finding major depression was more likely in suicides aged over 55 years while substance abuse was more likely in suicides aged 21–54 years[7]. Risk factors that are more overtly important in suicidal behaviour in younger people may still convey vulnerability in late life. In a life cycle approach to understanding the development of risk for late life suicidal behaviour, it is important to recognize that some pathways begin early in life. It is often the interaction of distal risk factors with proximal factors that provides the lethal mix.

Demographic Factors

Across the life span, males have approximately a four times higher risk of suicide than females and with advancing age the male to female ratio increases[1]. Females are at higher risk of non-fatal suicidal behaviour, with rates about 1.5 times higher than males, but the rates tend to converge with advancing age[6]. There is some evidence that suicidal behaviour is more common in those who are divorced or widowed[2,4].

There is heterogeneity of suicide rates between countries and ethnicity appears to be a factor, with different suicide rates of ethnic groups within multicultural societies[2]. For example, in Australia suicide rates of older migrants are closely related to suicide rates in their country of origin[8]. Other cross-national research has found elderly suicide rates to be associated with population growth, the elderly dependency ratio and the proportion of elderly in the population[9]. There is also regional variation within countries, with higher rates reported in rural areas of some countries such as Australia[10]. In the United States, cross-state variation is related to macro-social indicators of social integration and aspects of state-level policies[11]. Low socioeconomic status has been found as a risk factor worldwide[1].

Early Life Factors

Genetic factors contribute to suicide risk by mediating transmission of impulsive aggression or neuroticism and neurocognitive deficits[12]. While there has been little research in late life, one study has suggested that an interaction between genetic factors and the physiological effects of ageing might have an important role in violent suicides[13]. Genetic factors also work indirectly by increasing the risk of mood disorders and substance abuse[12].

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Childhood adversity, which includes abuse and parental neglect through death, separation and inadequate care, is a well-established risk factor for suicidal behaviour, depression and substance abuse in younger adults[12,14]. There is increasing evidence that childhood adversity influences late life suicidal behaviour and mental disorders too. Higher rates of childhood adversity were found in older persons who attempted suicide compared with controls[15]; childhood physical and sexual abuse was significantly more frequently reported by older persons with a history of suicidal behaviour, mood disorders and alcohol abuse in a large general practice survey[16]; and the risk of attempted suicide and suicide is higher in older Holocaust survivors[1].

Childhood adversity and genetic factors also affect personality development. A number of personality traits have been linked to suicidal behaviour in late life, including inflexibility, anxious, obsessional and 'low openness to experience' (individuals that are comfortable with the familiar and have a constricted range of interests) traits[1,17]. In essence these traits describe an older individual who has difficulty coping with the challenges related to ageing, including failing health, loss of confidants and demanding life events.

Adulthood Factors

It would seem self-evident that the lifestyle followed by an individual as an adult, including their interpersonal relationships and employment, will have some bearing on their health and well-being in late life. For example, involuntary job loss near retirement age has been found to lead to enduring depressive symptoms in individuals with low finances[18].

The links to late life suicidal behaviour are indirect and largely mediated through the impact mid-life lifestyle factors have upon the development of late life risk factors such as physical health and depression. There is increasing evidence that mid-life vascular risk factors such as hypertension, smoking, diabetes and metabolic syndrome, which are associated with lifestyle factors such as diet and exercise, may lead to late life depression, cognitive impairment, and cerebrovascular and cardiovascular disorders[19,20]. Further, a case-control of suicides over age 50 years found that cerebrovascular risk factor scores were significantly higher in suicide cases[21].

Late Life Factors

Psychopathology

Up to 97% of older persons with serious suicidal behaviour have a mental disorder[1,4,5,22]. A review of controlled psychological autopsy studies found that the presence of any Axis I disorder was associated with an elevated risk of suicide in older persons with significant odds ratios ranging from 27.4 to 113.1[22]. Depression is the major independent risk factor across cultures and although the type of depression varies, major depression is the strongest predictor of suicidal behaviour in late life, accounting for about 50% of cases[1,4,5,7,22]. Although many cases are recurrent episodes, first-episode major depression is prominent too[1,4,22]. Other types of depression including dysthymia, minor depression and subsyndromal depression are also important and may have a particular role in older persons with co-morbid chronic physical ill health and disability[1,4]. In the context of recovery from a depressive episode, unremitting hopelessness can increase suicide risk[23].

Other mental disorders are less commonly found in late life suicidal behaviour, though co-morbid disorders are common[1,4,5,22]. Late-life psychoses, including schizophrenia and bipolar disorder, account for less than 10% of attempted and completed suicides[1,4,5,22]. The role of anxiety disorders is unclear, with some studies finding an increased risk though it seems usually in the context of mixed anxiety/depressive states[1,22]. Alcohol abuse, though less frequently implicated in old age compared to younger suicides, remains a significant factor especially with co-morbid depression[1,4,5]. Personality disorders are less common in suicidal behaviour in late life compared with younger cohorts, being present in 2.5–7% of older suicide attempters[1,5].

Until recently, dementia has not been regarded as a risk factor for suicide. A nationwide longitudinal study from Denmark using register data reported that hospital-diagnosed dementia was associated with an elevated risk of suicide particularly in those aged 50–69 years, where the relative risk was 8.5 in men and 10.8 in women. The risk was higher in the first three months after diagnosis, particularly in men. Controlling for mood disorders reduced but did not eliminate the increased risk. The risk was higher in Alzheimer's disease than in vascular dementia[24]. In some, frontal lobe impairments may lead to impulsive, poorly planned attempts. It is unclear whether insight into the dementing process is a factor that increases the risk of suicidality[1,4].

Previous suicidal behaviour

Compared with younger age groups, a history of suicidal behaviour is less frequent in older persons with suicidal behaviour but follow-up studies of older suicide attempters have found high rates of repetition[1,25]. In the WHO/EURO multicentre study of suicidal behaviour, 13% of older people admitted to hospital after a suicide attempt died by suicide within 12 months and 11% made further attempts[25]. Survivors of suicidal behaviour in old age remain a high risk group and require close monitoring. Observational studies suggest that older suicide attempters are likely to receive specialist mental health management, particularly if they have a diagnosed mood disorder, but treatment studies are lacking[5].

Physical health and disability

While physical ill health is a contributory factor in most cases of late life suicidal behaviour, its precise role is unclear[1]. Some studies have found an independent effect of physical illness that is increased when there are multiple illnesses, while others have found little evidence of a physical illness effect[1,26]. There is a lack of consistency regarding specific illnesses that might increase suicide risk, but chronic pain, breathlessness and functional impairment are frequently reported features[1,26]. These may result in dependence on carers, loss of dignity and the fear of institutionalization that may contribute to demoralization, depression and suicidality. A threshold phenomenon may exist whereby the physically ill may become suicidal with milder degrees of depression[4], or, put another way, physical illnesses may amplify suicide risk in those with premorbid vulnerability[27]. Depression, pain and insomnia have the capacity to temporarily affect judgement by subtly distorting the patient's perceptions in a manner that may convince family, friends and doctor of the 'rationality' of suicide, especially in those with terminal illness, which is present in about 5–10% of older persons with suicidal behaviour. Yet the wish to die usually resolves once these symptoms are treated. Psychological reactions occur, with some people feeling overwhelmed by the knowledge of a serious illness and others convincing themselves that they have cancer, often ignoring reassurances

by their doctor[28]. Some physical illnesses, including cancers, thyroid disorders and cerebrovascular disease, can cause severe depression and these might not be detected until after a suicide attempt[4].

Psychosocial factors

In general, disruption of social ties increases suicide risk in old age independent of the presence of mental disorders[22]. As in other age groups, family discord is perhaps the most powerful psychosocial factor[1,22,27]. In many cases the problems are chronic and there is some evidence that males are more vulnerable[1]. It is likely that chronic family discord interacts with physical health issues in situations that include those who are disabled and feel a burden on others, and in caregivers who become severely stressed in caring for a disabled partner, where there is an increased risk of murder/suicide[1]. A range of other life events, particularly those involving loss, including recent bereavement, and financial problems have been implicated in late life suicidal behaviour[1,4,5,27].

Living alone has consistently been identified as a factor and this is often regarded as a proxy for loneliness, social isolation and inadequate social support[1,4,5,22]. Accommodation issues, including fear of nursing home placement and dissatisfaction with living arrangements, are also reported[1,4]. It is unclear whether the suicide rate in nursing homes is different to the general population but the main risk factors of depression and physical disability are the same[1]. Indirect self-destructive behaviour, including refusal to eat, drink or take medications, is common in nursing home residents and while most cases appear to be associated with severe dementia rather than depression with suicidal intent[6], there are likely to be some suicidal individuals.

Biological factors

As with the previously mentioned genetic factors, two other biological factors associated with suicide have not been well studied in late life. Serotonergic neurotransmitter abnormalities have been found to be associated with suicidal behaviour across the age range with low levels of 5-hydroxyindoleactic acid in cerebrospinal fluid[29]. Non-suppression of the dexamethasone suppression test, which is a measure of the hypothalamic–pituitary axis activity in mood disorders, is also predictive of suicide[29].

Other late life biological factors include cerebrovascular disease and Alzheimer's disease. The risks of suicide and suicidal ideation have been reported as higher in Alzheimer's disease than in vascular dementia but studies of Alzheimer's disease neuropathological changes in late life suicide are inconsistent[1]. Interestingly, older subjects with major depression who were apolipoprotein E $\varepsilon 4$ (*APOE4*) carriers had an increased suicide attempt history than depressed subjects who were not *APOE4* carriers[30].

Risk factors are unlikely to act independently in most cases but at present our understanding of how identified risk factors interact to determine risk in an individual is limited[1,22]. The motivations that appear to drive the final suicidal act are quite varied and reflect this multiplicity of pathways[28]. In addition, whether an individual has access to a lethal means that is acceptable to them plays a critical role, and this latter factor varies between cultures[1].

STRATEGIES FOR SUICIDE PREVENTION IN LATE LIFE

While an understanding of factors that are associated with suicidal behaviour provides a platform upon which to build prevention strategies, there is very little known about protective factors. There is weak evidence that spirituality and good quality of life may be protective but more research is required[1].

A public health approach to suicide prevention considers three levels of interventions. Universal strategies implement broadly directed initiatives to prevent suicidal behaviour and related morbidity through reducing risk and enhancing protective factors at a population level. Selective strategies target 'high risk' (at a population level) asymptomatic or presymptomatic older persons with distal risk factors for suicide. Indicated strategies focus on individuals with detectable symptoms and/or other proximal risk factors for suicide[1].

Universal Prevention

These strategies should concentrate upon improvement of quality of life and prevention of depression in late life in the general population. A whole of life approach to ageing that addresses key issues such as reduction of childhood adversity, provision of basic health care, reduction of poverty, and promotion of a healthy lifestyle, including diet, exercise, and reduction of substance abuse and smoking is required. The relationship between vascular disease and late-life depression is an obvious focus of health education programmes over the life span. As such, suicide prevention would not be the main focus of the strategy but rather it would be one of the potential outcomes.

Benefits accrue for persons of all ages so programmes that focus on late life issues such as ageism, normal ageing, healthy lifestyle in late life, and stigma of late-life mental disorder are important. It is important to realize that there is still a perception that it is 'normal' for older people to be depressed and that 'nothing can be done' about it, even though the available evidence contradicts this. These negative attitudes can set the tone of society.

Psychosocial strategies that might improve well-being and reduce depression in late life could focus upon encouragement of social interaction through attendance at clubs, connection with family, participation in casual work, becoming a volunteer, and engagement in pleasurable activities such as physical exercise, music, dance, education, travel and sport. For many older people lack of transport thwarts efforts to accomplish these goals so an improved senior's transport strategy would be beneficial. An important study of a community-based programme that targeted the elderly in the rural town of Yuri in Japan involved population strategies including psychoeducation, group activities and self-assessment of depression over an eight-year period. It proved to be effective in reducing the risk of suicide in females but not males[31].

Selective Prevention

The aim of selective prevention is to prevent suicidal behaviour and related morbidity by addressing the specific characteristics that confer high risk. Older persons with a history of depression and/or suicidal behaviour, chronic pain sufferers, and disabled older persons who live alone or with few social supports are some examples.

Education is an important strategy. Asymptomatic older persons with a history of major affective disorder should be educated about warning signs of depression to enable early intervention. Programmes that aim to minimize the effects of disability upon older people by providing services that enhance independent function are of critical importance. This has been the general direction taken in many countries where aged care service delivery has increasingly focused upon maintaining older disabled persons at home. A programme established in the Veneto region of Italy used Tele-Help,

a portable device that lets users send alarm signals activating a pre-established network of help and assistance, and Tele-Check, where trained staff members contact each client at least twice a week to offer emotional support and monitor the client's condition through a short, informal interview. At ten-year evaluation, a significantly lower than expected number of suicidal deaths was observed in the users compared to the general population[32]. Another approach is to focus upon the prevention of depression in the elderly with chronic physical co-morbidity. A six-session problem-solving therapy intervention in older patients with age-related macular degeneration led to a 50% reduction of new episodes of major and minor depression at two months after completion of the treatment although the effect had disappeared by six months[33].

The promotion of community groups and religious organizations to contact and support isolated older people should be encouraged. Potential target groups include rural elders, older migrants and carers. Older men are particularly vulnerable to depression and suicide in the year after divorce or death of their spouse and so could be specifically targeted for counselling in primary health care.

Indicated Prevention

The aim of indicated prevention is to identify and treat older persons with detectable symptoms and/or other proximal risk factors for suicide. Recognition of depression and suicide risk by gatekeepers (e.g. general practitioners, clergy, nurses, home care workers, police, ambulance officers, social workers) is an important component. GPs and other physicians have difficulties in the identification, assessment and management of depression and suicide risk in old age. This is accentuated with co-morbid physical illness where there are low levels of recognition, diagnosis and treatment of depression[34].

Studies from around the developed world consistently find that the majority of older suicide victims have been in contact with health professionals, particularly GPs, in the months before death[1]. While communication of suicidal ideation occurs in up to 45% of mental health contacts, it is less likely to occur in GP contacts and with older persons[1]. There is little known about contacts with nurses and other allied health professionals in the context of hospital and community treatment of physical ailments. Hence it is unclear how often health professional contacts in the weeks before suicide represent an opportunity for suicide prevention.

Despite this uncertainty, education of 'at risk' older people and their carers, gatekeepers and health professionals involved in their care is the key. The education needs to be linked to an intervention to improve its effectiveness, with strategies that include the removal of barriers to care, depression screening, and the use of treatment guidelines. A community-based 10-year suicide prevention programme for older people in the Japanese rural town of Joboji with strategies including screening for depression, follow-up with mental health care or psychiatric treatment, and health education on depression found that the relative risks estimated by the age-adjusted odds ratios for both males and females were reduced to almost 25% more than a regional historical trend, with a better response to education for females than for males[35].

One important component of health professional education is the assessment of suicide risk and management of older people at high risk. Even when depression is suspected, the assessment of suicide risk is often missed in older patients. A GP survey using case vignettes of older people with depression found high levels of depression recognition but only 2.4% spontaneously indicated that they would ask about suicidal ideation, which increased to 77% with prompting. The rest either indicated that they thought the patient would communicate suicidal thoughts themselves or that they feared that they might induce suicide by asking directly[36]. Assessment of suicide risk requires the health professional to be attentive, calm and non-threatening; to give the patient space and time to vent; to work in collaboration with the patient; and to use the word suicide without flinching. The use of open-ended questions followed up by specific questions about the nature, timing and context of suicidal thoughts is recommended. The only effective means of identifying those at risk is direct questioning[37]. Deterrents to suicidal behaviour, including religion and fear of upsetting family or friends, need to be determined. Collateral information from family and friends should be obtained as often the family member is aware of suicide risk but will not inform the health professional unless specifically asked[38]. The American Psychiatric Association's 'Practice Guideline for the Assessment and Treatment of Patients with Suicidal Behaviors' states that family and friends can be contacted without the patient's consent if suicidality is suspected[39].

All depressed older persons should be assessed for suicide risk but how often this should be repeated during the course of the illness is unclear. If enquiries about suicide risk are repeated too often therapeutic rapport might be undermined. Many older depressed patients were assessed by GPs to be improving in the weeks before suicide and so suicide risk assessment was not considered[38]. Improvement in depression can be deceptive in terms of suicide risk[1].

In the absence of clinical depression there are some other situations in the context of the older person's life circumstances that might warrant a suicide risk assessment. Persons with late-life psychosis with distressing persecutory symptoms are one example. As noted earlier, suicide risk is increased in older people with obsessional, anxious and low 'openness to experience' personality traits. Such individuals may have a restricted capacity to adapt to change and the various challenges associated with ageing. Recent life stressors, including the diagnosis of cancer or other serious disorders such as Alzheimer's disease or the death of a spouse or a close friend, may be overwhelming. Chronic stressors such as pain, loneliness, complicated grief or severe disability, especially in the absence of adequate social support, are all circumstances that might lead to a suicide attempt in the vulnerable person, especially if there has been a history of previous suicide attempts and in the presence of substance abuse. There are some types of behaviour that might alert the clinician to suicidal preoccupation. These include the giving away of possessions, changing of will, stockpiling of pills and passive indirect self-destructive behaviour such as refusal to eat and medication non-compliance. However, pervasive hopelessness was the most frequently reported observation in one study of the last health professional contact with suicide victims[38].

High-risk management guidelines for older suicidal patients in primary care settings were developed for the Prevention of Suicide in Primary Care Elderly: Collaborative Trial (PROSPECT)[37]. The intensity of the suicidal ideation, clarity of plans and access to means should determine the location of care. Hospitalization is often indicated, particularly when there is severe depression with features of psychosis, agitation, hopelessness, refusal to eat, poor insight, ruminating insomnia or where there is co-morbid substance abuse. Impulsivity, especially in association with impairments of executive function, is another feature that might require short-term hospitalization. Other factors to consider include the lack of social supports, and presence of concurrent medical issues and associated functional impairment that impact upon safe outpatient treatment, a history of

poor compliance with treatment, or where the older person appears to have 'given up'[1].

Outcomes of hospitalization related to suicidal behaviour have not been specifically studied. The resolution of suicidal ideation before discharge is paramount and the clinician needs to be aware that the intensity of suicidal thoughts can fluctuate from day to day in the context of major depression[40]. Integration of hospital and post-discharge community care improves the outcomes of older depressed patients through strategies that include having the community nurse get to know the patient before discharge, a pre-discharge home visit to check on functional needs and remove any guns or stockpiled medications, continuity of medical care post-discharge, and members of the multidisciplinary inpatient team having a transitional role to help the older patient and the family settle in at home[1].

Optimal management of the older suicidal patient requires the development of a therapeutic alliance that is often best achieved by ensuring that alleviation of the patient's suffering, whether it be physical, psychological or spiritual, is central to the care being provided. Important components of community treatment include an individualized case management approach with ongoing care (at least weekly until suicidal risk has settled), medication monitoring, and psychoeducation of the patient and carer. Explicit written instructions to the older patient and family about what to do if suicidal thoughts recur and the provision of an emergency contact are required. Avoidance of alcohol and illicit drugs should be stressed[37].

It is beyond the scope of this chapter to discuss treatment of depression in detail but it is essential that effective treatment be provided that not only obtains a response but also achieves remission. The available evidence suggests that electroconvulsive therapy is the most effective treatment for severe depression in late life, particularly when there are psychotic features or with high acute suicide risk. Antidepressant medication remains the cornerstone of effective treatment for major depression even with co-morbid chronic physical illness where effectiveness is reduced and should be maintained for at least two years to prevent relapse. Psychosocial treatments, including the various types of psychotherapy, activity programmes, exercise and supportive therapies, are crucial[34].

Improving the effectiveness of the treatment of depression in primary care can be achieved through collaborations between primary care health professionals and mental health professionals. The collaboration should involve a significant educational and supervisory approach by the mental health professional. An example is provided by the multi-centre PROSPECT study, where a depression health specialist was assigned to assist the primary care physician with guideline management based on an algorithm that included the selective serotonin re-uptake inhibitor (SSRI) antidepressant citalopram and/or interpersonal psychotherapy. Rates of suicidal ideation declined faster in the intervention patients compared with usual care after four months of treatment[41].

There is debate about whether antidepressants reduce the risk of suicide, with naturalistic studies suggesting that the higher rates of antidepressant prescription since the introduction of the SSRIs have been associated with lower suicide rates[1]. Concerns have been raised that SSRIs might increase the risk of suicide in the elderly, particularly violent suicide, in the first month of treatment but the absolute risk is low and probably outweighed by the benefits of treatment[42]. There is stronger evidence that lithium prophylaxis has specific anti-suicide effects apart from its prophylactic efficacy in affective disorders but there are no studies that have specifically examined whether this occurs in old age[1].

CONCLUSION

A life cycle approach is required to obtain a better understanding of suicidal behaviour in late life because the causes are complex and involve factors that arise from the entire lifespan. No single prevention strategy is likely to be successful. A multifaceted, multilayered approach to suicide prevention in old age is required.

The Assessment of Depressive Syndromes

Adriana P. Hermida and William M. McDonald

Emory University School of Medicine, Atlanta, USA

Among community dwelling older adults, the prevalence of major depression ranges between 1% and 4% with a higher proportion of women meeting criteria for depression with no significant racial or ethnic differences[1]. Although the prevalence of individuals with major depressive disorder may not be as high as for younger subjects[2], high levels of *depressive symptoms* are relatively common in the elderly living in the community, and the number of elders with depression syndromes increases in patients with chronic medical illnesses[1,3,4]. The number of medically ill elders diagnosed with depressive syndromes in long-term care facilities is estimated at 10–15% with up to 35% experiencing significant depressive symptoms[5–7].

The diagnosis of depression in the elderly requires a multidimensional approach and should be undertaken with a clear understanding of the normal ageing process and the psychosocial factors that are unique to the elderly. These aspects of ageing are discussed in Chapter 18. Depression and depressive disorders are often misunderstood by physicians caring for the elderly as well as by the lay public, including family members and, often, the elderly patient. 'Ageism' is the term used to describe the discrimination against people because of their age and nowhere is this more apparent than in the diagnosis and treatment of depressed elders, particularly those with co-morbid medical illnesses. The oft-repeated phrases epitomize this way of thinking 'Why wouldn't they be depressed ... they are old?' and 'Of course they are depressed – they live in a nursing home and have cancer'. Underlying this viewpoint is the notion that treating the depressed elderly is futile and a waste of valuable health care resources. Among other factors ageism has been shown to be an important component in the decision as to whether to start drug therapy in elderly patients[8].

A more rational view is to consider the costs of the treatment of depression in comparison with potential treatment benefits, including the cost savings to society of an individual remaining functionally independent in a community setting[9]. In this light the treatment of depression in the elderly has the potential for providing both benefits to the individual and health care savings. Depressive symptoms can lead to accelerated cognitive decline, physical impairment and increased health care costs[10]. Increased service utilization and social morbidity are common in patients with depressive symptoms even when these symptoms are not severe enough to fulfil the criteria for a major psychiatric disorder[11]. Concomitant depression can limit compliance with medical treatments and worsen the cognitive decline associated with dementia. Further, depression can adversely affect the clinical course of other medical illnesses and increase morbidity and mortality[12,13], and the elderly have the highest suicide rate of any age group[14]. The social and economic consequences of this disorder in the elderly are severe.

Yet the diagnosis and treatment of elderly depressive disorders can be difficult. The elderly are often subject to more adverse side effects from pharmacotherapy, and the diagnosis of depression is complicated by the overlapping symptoms of depression, concomitant medical illnesses and normal ageing[15]. In fact, the elderly often present with more subtle forms of depression (e.g. minor or subsyndromal depressive disorders) that can be difficult to diagnose, yet cause significant disability and make the decision to treat more difficult. Some have argued that elderly depressives should have specific age-appropriate criteria that include these subsyndromal symptoms since the elderly are not easily classified by traditional psychiatric nomenclature[16].

This chapter will review the multiple depressive syndromes in depression and provide guidance on making the correct diagnosis of depression in elderly patients, particularly those with concomitant medical illness. The diagnosis and clinical significance of subsyndromal depressive syndromes will also be outlined in detail. Finally, the appropriate method for taking a history and the basic laboratory tests needed to eliminate common medical conditions that mimic depression as well as the medications that may cause depressive symptoms will also be reviewed.

THE SYNDROME OF LATE-LIFE DEPRESSION

To accurately assess the depressed older adult, the clinician must consider the range of depressive disorders from the more severe major depression to the subsyndromal depressive disorders. Depressive disorders include the mood disorders outlined in the Diagnostic and Statistical Manual of Mental Disorders Version IV (DSM-IV): major depressive disorder, dysthymic disorder, mood disorder due to a general medical condition, substance-induced mood disorder, bipolar disorder, mood disorder not otherwise specified (which include the minor and subsyndromal depression) and adjustment disorder.

Major depression is distinguished from the other mood disorders by the severity and persistence of symptoms, which by definition have lasted for at least two weeks and are associated with significant impairment in an individual's social, occupational or other

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

important areas of functioning. Symptoms of major depression comprise depressed mood and/or anhedonia and associated neurovegetative and cognitive symptoms, including significant weight loss/weight gain or decreased/increased appetite, insomnia or hypersomnia, psychomotor agitation or retardation, diminished ability to think or concentrate, feelings of worthlessness or excessive inappropriate guilt, and recurrent thoughts of death or suicide.

Specifiers describing the quality of the current episode include melancholic, atypical and catatonic features. *Melancholic* features consist of lack of mood reactivity to pleasurable stimuli, diurnal variation in mood (i.e. depression worse in the morning), early morning awakening, psychomotor retardation or agitation, significant weight loss or anorexia and excessive or inappropriate guilt. A melancholic depression may be associated with specific neuroanatomic changes[17], and may affect response to antidepressants[18–21], electroconvulsive therapy (ECT)[22,23] and psychotherapy[24,25]. *Atypical* features include mood reactivity, increased appetite or weight gain, hypersomnia, leaden paralysis and extreme sensitivity to interpersonal rejection. Atypical depression in the elderly has been shown to respond preferentially to monoamine oxidase inhibitors (MAOIs) although the MAOIs may be more difficult to use in this population[15,26]. The specifier *catatonic features* is appropriate when the clinical picture is characterized by marked psychomotor disturbances that involve motoric immobility, excessive motor activity, extreme negativism, mutism, peculiarities of voluntary movements, echolalia and echopraxia. Motoric immobility can be manifested by cataplexy or stupor. Catatonic states have been found to occur in 5–9% of psychiatric inpatients. Among inpatients, 25–50% of catatonic states occur in association with mood disorders, 10–15% in association with schizophrenia, and the remainder in association with other mental disorders and a wide variety of medical conditions[27].

An additional specifier of major depression in the DSM-IV criteria is a *seasonal pattern*, which is associated with the onset and remission of major depressive episodes at characteristic times of the year. This pattern of onset and remission of episodes must have occurred during the past two years.

In the DSM-IV, depression is subtyped according to whether the mood disturbance is associated with psychotic symptoms. Psychotic symptoms in major depression are more likely to be mood-congruent (i.e. delusions or hallucinations of a depressive nature). Psychotic depression may be more common in late life. Many elderly patients with psychosis develop delusions of poverty, somatic delusions or persecutory ideations[28,29]. Hallucinations of derogatory voices are rare. Known precipitants of psychotic symptoms in the elderly include personal trauma, physical illness and certain medications such as corticosteroids and anti-parkinsonian medications.

Subsyndromal depressions (SSDs) include minor depression, dysthymia and syndromal depression that does not meet the criteria for major depression. SSDs are characterized by depressive symptoms that do not meet full criteria for a major depression but are associated with depressed mood and significant disability[30]. SSD is common and associated with significant impairment in a number of areas of social and occupational functioning and an increased risk of developing syndromal major depression[31,32]. Minor depression is a mood disorder that does not meet full criteria for major depressive disorder but which is associated with at least two depressive symptoms that are sustained for a period of two weeks (although not necessarily every day) without the degree of impairment in major depression. Technically a patient with minor depression would be coded as 'Depression, not otherwise specified' or NOS since minor depression is a research diagnosis. Research, much of it in primary care clinics, supports the validity of minor depression as a distinct clinical entity[31]. Dysthymic disorder (dysthymia) is defined as a chronic low-grade depression, which lasts for at least two years. Personality styles and the individual's ability to cope with changing life situations may predispose the individual to develop a dysthymic disorder (see Chapter 104) and older adults with changing roles and life conditions may be particularly prone to dysthymia. Additionally, dysthymic disorder may develop secondary to a medical disorder, anxiety disorder or somatization disorder. Dysthymia preceding a major depressive episode has been shown to predict a poor outcome to treatment[33]. Phenomenologically, SSD is the 'grey' zone between syndromal major depression and depressive symptoms. In geriatric psychiatry, depression is often defined as a spectrum rather than a dichotomy. There is increasing evidence that elderly subjects meeting the criteria for SSD have levels of cognitive and functional impairment intermediate between elders who are not depressed and those with major depression[34]. Nevertheless, patients with SSD demonstrate significant disability, are more likely to have persistent depressive symptoms which worsen over a year, be at a higher risk of developing major depression, and benefit from somatic treatments and psychotherapy[25,35]. Clearly, future research is needed to clarify the prevalence and treatment response of SSD in order to target appropriate treatments.

Substance-induced mood disorder is a prominent and persistent disturbance in mood that is judged to be due to the direct physiological effects of a substance such as excessive alcohol use. Alcohol abuse in older adults is common and may go for years misdiagnosed[36]. The elderly are particularly prone to substance-induced mood disorders because of chronic and often excessive use of over-the-counter medications mixed with prescription medications[37,38]. Increasingly the elderly are using herbal medications and often the effects of herbal medications are unknown, particularly in combination with other drugs[39].

The diagnosis of adjustment disorder with depressed mood is appropriate for an elderly patient adjusting to severe changes in lifestyle and the loss of loved ones. In the DSM-IV, the patient is not classified with an adjustment disorder unless his/her reaction is considered maladaptive and the level of impairment is significantly severe, and greater than what would be normally expected. Whether the elderly subject's reaction to these stressors is classified as a disorder is a clinical judgement. Several common life events that may prove to be stressors in the elderly include retirement, financial problems, living in high crime areas, physical illness, the death of a spouse and moving to an institutional setting. Yet older adults also may also be protected from stress as those who survive into old age are more likely to have relatively more socioeconomic security and the benefit of the wisdom that can come with older age[40]. Regardless, the clinician should observe the patient diagnosed with adjustment disorder longitudinally for the development of symptoms of a major depression if the individual's reaction to stress is persistent or severe.

The symptom profile of older patients with depression has also been described as qualitatively distinct from that of younger adults. Depressed elderly patients are more likely to show cognitive changes, somatic symptoms, fatigue and loss of interest as opposed to depressed mood and guilt[41,42]. Other researchers emphasize that these differing presentations are the result of accompanying cognitive changes with ageing and co-morbid medical illness, which are more likely to occur in older depressed patients, and that depressed elderly patients without concomitant medical illnesses have presentations similar to younger subjects[43]. Support for this latter view has been

provided by Blazer and his colleagues[44], who compared depressive symptoms in a group of middle-aged (35–50-year-old) and older (60-year-old) inpatients with melancholic depression. The symptom profiles of these patients were markedly similar to the elderly, differing only in their more frequent reporting of weight loss and less frequent suicidal thoughts. Finally, Blazer discusses some of the misconceptions of depression in the elderly, pointing out that, as discussed above, symptomatically there is little difference when compared to adult early-onset depression.

CO-MORBID MEDICAL DISEASE

A variety of medical illnesses are associated with depressive symptoms. Mood disorder due to a general medical condition is a persistent disturbance in mood due to the direct physiological effect of a general medical condition. In the geriatric population the differentiation between mood disorder due to a general medical condition and depression as a psychological reaction to the disability due to the medical illness is challenging.

There are basically two different approaches to defining depression in medically ill patients. The *inclusive approach* counts a symptom if it is present without considering whether it is due to the underlying medical condition. Using the inclusive approach, a patient with Parkinson's disease and insomnia would be counted as having insomnia as a depressive symptom if they stated that they could not fall asleep for two hours regardless of whether they said the insomnia was due to dyskinesias or guilty ruminations. The *aetiological approach* counts a symptom towards a diagnosis of depression only if the rater determines that it is not due to the underlying medical disorder. In the example given above the clinician would try to determine if the insomnia was due to depression or dyskinesias. Clearly this distinction can be difficult, particularly because patients, their families and clinicians tend to discount many depressive symptoms because they are felt to be a symptom of the medical illness.

However, the research in this area would support the use of the inclusive approach as more reliable in diagnosing depression in patients with co-morbid medical illnesses[45] and medical conditions such as post-stroke depression[46]. The inclusive approach is more objective, whereas the aetiological approach is subject to the judgement of the clinician and is inherently less reliable. The danger in using the inclusive approach is a loss of specificity and an over-diagnosis of depression. However, the real danger in evaluating medically ill patients with depression is a loss of sensitivity and missing patients who could potentially benefit from somatic treatments. As described below, co-morbid medical illnesses can have a significant detrimental effect on long-term outcomes and mortality. The available treatments for depression are increasingly better tolerated by the elderly and the risk/benefit ratio favours a modest overtreatment of depressive syndromes in the elderly.

Certain endocrine and vitamin deficiencies, medications and medical conditions are associated with depressive symptoms. Discontinuing the offending medication, and/or correcting the endocrine or vitamin deficiency should be done prior to starting an antidepressant[47]. Other medical conditions, such as Parkinson's disease, multiple sclerosis, pancreatic cancer and stroke, are associated with high rates of co-morbid depression and the depressive episode should be treated while managing the co-morbid medical condition. Again, the clinician should not try to determine if the depression is due to the disability of the medical condition but should treat the depression if the patient meets criteria for the disorder.

Parkinson's disease is illustrative of a neurological condition associated with high rates of depression, overlapping symptoms of depression, and the importance of recognizing and treating co-morbid depression in patients with medical disorders. Co-morbid depression occurs in about 20–30% of patients with Parkinson's disease[48,49]. There is considerable overlap of the symptoms of Parkinson's disease and depression, including flat affect, bradykinesia, fatigue, agitation (in the form of psychomotor agitation or dyskinesias), insomnia and cognitive problems. Yet depression in patients with Parkinson's disease can be accurately diagnosed using the inclusive approach and many depression psychiatric rating scales[50]. Co-morbid depression is not simply a reaction to the medical illness and disability[51]; there is evidence of the underlying neuroanatomic degeneration secondary to Parkinson's disease as a cause of depressive syndromes in Parkinson's disease[52], and the treatment of depression can lead to an improvement in the overall quality of life[53]. The identification and treatment of Parkinson's disease with co-morbid depression is therefore important.

Cerebrovascular disease has been shown to be associated with the development of mood symptoms. Depression is a risk factor for stroke[54] and approximately half of post-stroke depressions will meet criteria for major depression, and the other half will have minor depression[55]. Robinson pioneered the early work in understanding the relationship between lesion location (i.e. subcortical in the left anterior pole) as crucial to the development of depression[56–58] and independent of the amount of physical disability caused by the stroke[59]. Post-stroke depression is associated with a longer recovery time[60] and increased mortality[61], and the treatment of post-stroke depression is associated with improved recovery in activities of daily living, cognition and decreased mortality[62].

Controversy still exists whether a left-sided stroke presents with more depressive and catastrophic responses than right-sided insults, which have been described as lesions with emotional neglect, indifference and even euphoric responses[58,63]. Hama *et al*.[64] found that the severity of affective depression was associated with left frontal lobe damage whereas apathetic depression was mostly related to basal ganglia damage. However, Robinson's relationship of anatomic lesions to psychiatric symptoms laid the groundwork for understanding the interrelationship of depression and medical disease. The body of evidence in stroke with co-morbid depression also supports the importance of the detection and treatment of depressive syndromes in the long-term course of patients with cerebrovascular disease.

The relationship between dementia and depression is complicated. Over 50% of patients with dementing illnesses such as Alzheimer's disease may also have depressive symptoms, with 20% meeting criteria for a major depressive episode[65]. Depressive symptoms may also precede cognitive decline in community elders[66], and a significant number of individuals with depression and reversible cognitive deficits eventually progress to syndromic dementia[67,68]. The biological markers of Alzheimer's disease are found in patients with major depression, including the genotype apolipoprotein E $\varepsilon 3/\varepsilon 4$ (*APOE4*)[69], which has been linked to Alzheimer's disease. Additionally, depressed patients with the *APOE4* genotype have more hippocampal shape abnormalities than depressed patients without *APOE4*[70], and individuals with late-onset depression and mild cognitive deficits have significant brain amyloid load in a pattern similar to the pattern found in Alzheimer's disease[71].

Diagnosing depression and initiating appropriate treatment in patients with co-morbid medical disorders is therefore important in long-term outcomes and may have a significant effect on the course of the illness. The diagnosis should be made using the DSM criteria

and generally the clinician should not attempt to distinguish if the symptoms are due to depression or to the medical illness (i.e. an 'inclusive' approach).

TAKING A HISTORY FROM THE DEPRESSED OLDER ADULT AND FAMILY

The key elements in the patient's history include evidence of a previous psychiatric illness, especially a major depressive or manic episode, particularly if that episode responded to somatic therapy (e.g. lithium, antidepressants or electroconvulsive therapies). Obtaining pharmacy and other medical records regarding the symptoms, dose and the duration of medication trials can further aid in the assessment of depressed individuals. Major depression is a recurrent illness, with about half of the patients experiencing two or more episodes in their lifetime.

In general the clinician evaluating the depressed older adult should include a knowledgeable informant. Depressed elders tend to discount their depressive symptoms[72] and the DSM criteria have been shown to be reliable in elderly patients with primary depression as well as depression secondary to co-morbid medical conditions such as stroke[62] and Parkinson's disease[50].

In order to distinguish dementia from depression, researchers have relied upon the findings in the family and individual histories, mental status and laboratory examinations[73]. Determining the time of onset of the depressive symptoms and the number of episodes may also be useful, since most dementias are slowly developing, with early evidence of cognitive decline (e.g. the inability to balance a chequebook) being present months to years before the typical form of the disease becomes apparent. In contrast, the course of depressive illness may seem more abrupt. In fact Driscoll *et al*.[74] found that late-onset, recurrent depression takes longer to respond to treatment than late-onset single-episode depression and is more strongly associated with cognitive and functional impairment.

An accurate family history may also provide valuable diagnostic information, since dementing illnesses (e.g. Huntington's chorea and Alzheimer's disease, particularly the early-onset form) and major depression (especially the early-onset form) have both been demonstrated to have a genetic diathesis. The family history should also include questions about neurological and medical disease, alcohol/drug abuse, anxiety, suicide and psychosis, since these conditions are often associated with concomitant depression.

THE MENTAL STATUS EXAMINATION

The mental status examination and standardized depression rating scales may also aid in determining whether the patient has depression, dementia or (as is often the case) both[75]. The depressed patient approaches the mental status examination with the same lack of interest that is also apparent in other areas of his/her life. The depressed patient may attempt to prematurely terminate the interview or consistently refuse to try to answer questions. On the other hand, the demented patient may be quite concerned about his/her declining cognitive skills and, at the same time, make attempts to cover his/her deficits with confabulation. He/she may use notes and other reminders to keep up with facts and uncovering his/her deficits might be quite distressing. This is in marked contrast to the apathetic attitude of the depressed patient[41]. The depressed inpatient is also more likely to be able to find his/her way around the ward and to keep track of the ward routine and personnel. In contrast, the demented patient will forget meal times and confuse familiar faces. This confusion may often get worse as evening approaches and is incorporated in the well-known clinical syndrome of 'sundowning'.

Apathy can be difficult to distinguish from depression. Apathy is essentially the loss of interest without a loss of pleasure but can be misdiagnosed as depression since it is frequently associated with many of the same symptoms (e.g. disinterest, withdrawal, flat affect). Apathy is associated with dementia and other medical conditions that occur with depression, including stroke[76] and Parkinson's disease[77].

The mental status examination of patients with physical illnesses may show primarily problems with concentration and attention. In more severe cases, evidence of delirium may be present. Delirium is diagnosed when the level of consciousness becomes impaired. In this condition, disorientation and memory impairment may be present along with illusions (which are misinterpretations of environmental stimuli), hallucinations and disturbances in psychomotor activity and the sleep–wake cycle. As opposed to dementia, these symptoms usually evolve over hours and days rather than months and may show a waxing and waning course along with autonomic instability.

A common clinical dilemma occurs in patients who are known to be demented, but in whom the clinician seeks to make an accurate diagnosis of depression. In these patients, the clinician may need to assign more importance to neurovegetative signs, such as weight loss and insomnia, although these same symptoms may occur in non-depressed demented patients if they are too disorganized to prepare a meal or have night-time confusion. Some researchers have pointed to the presence of cognitive symptoms of depression (i.e. depressed mood, anxiety, helplessness, hopelessness and worthlessness) as being more prominent in demented patients, whereas neurovegetative signs are notably absent[78].

Monitoring the patient over time, observing for some overall consistent pattern of depressed mood and affect, is also helpful. Although there is little or no data to support empirical trials of antidepressants, given the relatively low side-effect profile of the newer antidepressants[79,80] (SSRIs; see Chapter 86), many clinicians will often attempt a trial of an antidepressant in these difficult situations in hopes the treatment may improve cognition and function. Methylphenidate has been used to treat depressive symptoms such as fatigue, apathy, lack of energy and decreased concentration in depressed medically ill older adults. Despite the long history of its use due to rapid effect, there is little definitive evidence to support this. A few trials have been conducted. Small sampled double-blind trials suggest that methylphenidate is generally well tolerated and modestly efficacious in medically burdened patients[81]. Caution is advised regarding the possible exacerbation of anxiety, psychosis, arrhythmia and potential interaction with warfarin.

PSYCHOLOGICAL TESTS

Neuropsychological assessment is a useful tool to determine the level of cognitive functioning of a patient at a certain point in time but cannot be used to accurately differentiate depression from dementia, especially during the acute episode of depression. Patients suffering from depression have impairments in visuo-spatial ability, memory, psychomotor slowing, speed of information processing and executive functioning, with the executive deficits being particularly related to late age at onset of first lifetime depressive episode[82]. The demented patient will demonstrate a more global decline, with relatively lower scores on aspects of the testing requiring adaptability and processing

of information (e.g. performance IQ) as opposed to rote skills and long-term memory tasks (e.g. verbal IQ). Even though a neuropsychological assessment often does not yield a definitive diagnosis, there are some characteristics in patient behaviour that are important to consider when evaluating an older cognitively impaired patient for depression. The depressed patient will more likely show results that are inconsistent over time and are effort-dependent.

Several other factors in depression have been related to worse performance in cognitive testing, including severe depressive symptoms, severe anxiety, the presence of vegetative symptoms and psychotic symptoms. A recent study by Bhalla *et al.*[83] examined cognitive diagnosis among subjects 65 and older before and after depression treatment response. They found that 48% of remitted depressed subjects had persistent cognitive impairment after effective treatment of depressive symptoms. The same group found that very few depressed individuals went from cognitively impaired to cognitively normal over one year follow-up[84]. It is not clear if depression represents a risk factor for or occurs in the prodromal stage of dementia[83,85], but some studies have reported that late-life depression may be associated with subsequent mild cognitive impairment and dementia including Alzheimer's disease and vascular dementia[86].

Standardized depression scales may yield false positive results in demented patients, particularly if they are heavily weighted for cognitive symptoms such as attention and concentration, which overlap with symptoms of depression. Depression scales that have been specifically designed to grade levels of depression in patients known to be demented include the Cornell Scale for Depression and Dementia (CSDD), the Geriatric Depression Scale (GDS), the Beck Depression Inventory (BDI) and the Montgomery–Asberg Depression Rating Scale (MADRS); all are useful tests that can help aid in evaluation of a depressed older patient[87–89]. Each instrument has advantages and disadvantages. For example, the GDS is a self-report measure with yes or no answers that includes evaluation of subjective experience of cognitive impairment but minimizes somatic symptoms and suicidal ideation. The BDI is also self-report and has many more questions related to the somatic symptoms of depression so medically ill older patients can appear more depressed. The BDI does have an excellent question on suicidal ideation and comes in a short form, which abbreviates the questions without losing validity. The CSDD combines patient reports, interviewer observation and informant report for forming a general opinion, so reliability can be difficult if informants are not given specific instructions on how to answer the questions. The MADRS is observer reported and has been shown to be valid and reliable in a number of clinical settings. All these instruments can aid in the diagnosis but, most importantly, can track the severity of symptoms[90], and many of these rating scales are valid in medical diseases with high rates of co-morbid depression that are common in ageing such as Parkinson's disease[50].

LABORATORY TESTS

The common laboratory tests for depression may lose much of their specificity in demented patients. The dexamethasone suppression test (DST) was shown to be useful in mild dementia of Alzheimer's type in distinguishing depressed from non-depressed patients. However, findings in more severe dementia were less specific[91].

The sleep electroencephalogram, however, does maintain its specificity and is able to distinguish a group of elderly depressed patients from those with dementia[92]. Several biological markers have been associated with depression, such us higher platelet monoamine oxidase activity, platelet alpha2-adrenoreceptors, blunted thyroid stimulating hormone (TSH) response to thyroid releasing hormone (TRH), presence of a variant in a gene coding for a potassium channel, and genetic variation in a kainic acid-type glutamate receptor. Many other potential biological markers of depression have been identified[93].

Any physical illness that can potentially affect the central nervous system (CNS) can present with depressive and dementing symptoms; these illnesses include encephalitis, chronic subdural haematoma and normal pressure hydrocephalus. Depressive symptoms such as fatigue, insomnia, weight loss and concentration problems can occur in other illnesses that do not directly affect the CNS. These illnesses include infectious diseases (e.g. tuberculosis, influenza), cardiovascular disease (e.g. congestive heart failure), endocrine abnormalities (e.g. thyroid disease, diabetes), electrolyte disturbances (e.g. hyponatraemia, hypocalcaemia), and renal and hepatic disease. Cerebrovascular disease has also been linked to depression in the elderly, and both cerebral vascular accidents and periventricular white matter disease are related to depressive symptoms in the elderly[94,95].

MEDICAL WORK-UP

The work-up of medical conditions that present with depressive symptoms in the elderly includes a personal history of medical illness, mental status examination and laboratory tests[13,41,96]. Many of these medical conditions are reversible with proper treatment, and geriatric textbooks emphasize the importance of reversible conditions presenting as dementia in the assessment of demented older adults. However, the occurrence of a reversible dementia is actually quite rare in clinical practice[97]. Nevertheless, a basic laboratory work-up is important in the evaluation of depressed older adults, including those with cognitive impairment.

A complete medication history should be obtained. Medication, including the antihypertensive medications such as beta-blockers and centrally acting *a*-methyldopa and reserpine, has been shown to cause depressive symptoms. Medications including steroids, barbiturates and sedatives are also frequent causes of depression in the elderly. Patients at risk should be screened for heavy metals, including lead, arsenic and the organophosphates.

The typical laboratory screening for elderly patients with depressive symptoms is outlined in Table 91.1. Clearly, the medical history and physical examination would influence the laboratory testing that was actually done. The neurological examination should be particularly thorough and include an examination of both subtle (e.g. frontal release signs) and prominent (e.g. reflex changes) signs of neurological dysfunction.

SUMMARY

Depressive symptoms are common in the elderly, whereas the syndrome of a major depressive episode is relatively rare. Regardless, depressive symptoms can have a significant effect on functioning, quality of life and mortality in the elderly. Symptoms of depression can be manifestations of either dementing or medical illnesses, both of which are common in the elderly. Psychosocial factors that are unique to the elderly may be aetiological in the genesis of depressive symptoms, but nevertheless require the clinician to assess each patient fully and treat as appropriate. Successful treatment mandates a detailed history, often with collaboration from the family,

Table 91.1 Laboratory work-up in the depressed elderly patient

Laboratory test	*Underlying condition*
Complete blood count	Infectious disease Encephalitis Meningitis Sub-acute bacterial endocarditis Anaemia
Electrolytes and metabolic panel	Hypokaelemia Hyponatraemia Diabetes Uraemia
B12/folate	Pernicious anaemia
Homocysteine	Vascular disease
25-Hydroxyvitamine D	Vitamin D deficiency
Thyroid panel	Hypo/hyperthyroidism
Liver enzymes	Hepatitis Liver cancer
Calcium/phosphorus	Hyperparathyroidism
Guiaic stool	Colon disease
Urinalysis	Infection Renal disease
Additional tests	
Electrocardiogram	Particularly patients who complain of fatigue, oedema or shortness of breath, or who are being considered for antidepressant therapy
Electroencephalogram	For patients in delirium, particularly those with a seizure history and when non-convulsive status epilepticus is suspected
Urine drug screen	For lead (exposure to paint), mercury (textile manufacturing), organophosphates and arsenic (insecticides). Also drugs of abuse (e.g. opiates, marijuana etc.)
Human immune deficiency virus (HIV)	Exposure to potentially contaminated blood products (surgery, drug use) or a history of promiscuity or homosexuality
Brain computed tomography	Neoplasia, stroke
Brain magnetic resonance imaging	Particularly to view the posterior brainstem

and a thorough medical evaluation for other co-morbid illnesses that may contribute to the patient's current presentation. The treatment of depressive symptoms in the elderly requires an understanding of both the origin of these symptoms and the proper treatment of the underlying disorder, whether the symptoms are secondary to medical, cognitive or psychosocial factors.

Mania: Epidemiology and Risk Factors

Susan W. Lehmann

The Johns Hopkins University School of Medicine, Department of Psychiatry and Behavioral Sciences, Baltimore, MD, USA

In recent years there has been increased clinical interest and research regarding the syndrome of mania in the elderly. While it has become clearer that older persons with bipolar disorder are a heterogeneous group, many questions regarding differences between early-onset bipolar disorder and later-onset bipolar disorder remain. Much of the current work in this area has focused on the following: How does bipolar disorder in the elderly differ from that in younger people? Can age of onset be used to distinguish clinically meaningful subtypes of bipolar disorder?

EPIDEMIOLOGY

The manic phase of bipolar affective disorder, or mania, is an uncommon disorder in the elderly although the exact prevalence of bipolar disorder among older adults in the community is uncertain[1]. In the five-site Epidemiologic Catchment Area study of more than 20 000 non-institutionalized individuals, one-month prevalence rates for mania were 0.4–0.8% for 18–44 year olds and 0.2% in the 45- to 64-year-old group. Notably, no cases of mania were identified among people over age 64[2]. In a 12-month prevalence study of 2798 community-dwelling adults age 65 or older in Quebec, 0.6% were found to have had a manic episode[3].

Nevertheless, elderly patients with mania are seen in significant numbers in a variety of clinical settings. In Roth's[4] retrospective review of 464 psychogeriatric patients over age 60 in a long-term hospital, 14 cases were manic, representing 6% of the total number of cases of affective disorder. Two studies of first admissions to British psychiatric hospitals, using Department of Health statistics, found that the number of first admissions with mania either remained steady with age[5] or increased with advancing age[6]. In the USA, other studies in short-stay hospitals have reported that mania accounted for approximately 5% of elderly psychiatric admissions[7–9]. Elderly patients with bipolar disorder have been found to use disproportionately more outpatient mental health and day hospital services than older patients with unipolar major depression[10]. Most studies of elderly manic patients have found more females than males[7–9,11], though men have been reported to have an earlier age of onset[12].

For the majority of elderly bipolar patients, the first episode of affective disorder is usually a depression. Indeed, it is quite common for a first manic episode to occur 10 years or more after an initial depressive episode and to be preceded by multiple depressive episodes over many years[7,13,14]. Generally, elderly patients have been found to have suffered more episodes of depression before a first manic episode and to have had a long gap between an initial depression and a first manic episode than young manic patients[14].

It has been estimated that about 10% of older patients with bipolar disorder experienced onset of illness after age 50[15]. Still, at the present time, there is no agreed-upon standard regarding which age should serve as the dividing line between early- and late-onset bipolar disorder. This uncertainty is compounded by a lack of consensus regarding how to determine age of onset itself. Different criteria have been used among various investigators to identify age of onset of bipolar disorder, including first onset of any mood symptoms, first hospitalization and first time at which the patient met full criteria for the disorder[9].

Several studies have observed bi-modality in age of onset of mania among elderly patients. In these studies, one subgroup of patients was found to have developed bipolar disorder in early life with a mean age in their thirties, and another subgroup developed a first manic episode after age 60[9,14]. A study of first-episode mania presenting for psychiatric treatment over a 35-year period in London found a two-component distribution in age of onset with a peak in early adult life and a smaller peak in mid-life[16]. A bimodal age of onset of bipolar disorder has also been reported by others [17–19] although a trimodal distribution of age of onset has been proposed as well[20]. While controversy continues regarding how best to define early- and late-onset cases, results from numerous studies support the relevance of distinguishing between early- and late-onset bipolar disorder. Late-onset bipolar patients tend to have had a longer gap between first depression and first mania than early-onset bipolar patients[14] and in one study were more likely to be married or living with a significant other[9]. Elderly bipolar patients with late-onset have been reported to have a more favourable outcome and to be less likely to have rapid cycling compared with elderly patients with early-onset illness[21].

RISK FACTORS

A number of studies have reported that elderly bipolar patients who had an early age of onset were more likely to have had first-degree relatives with affective disorder than late-onset elderly bipolar patients[14,22]. This trend holds across studies that have used ages between 20 and 60 years to divide early and late cases and suggests that genetics plays a greater role in the disease of early-onset bipolar disorder. At the same time, many investigators have reported

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

associations between late-onset mania and cerebrovascular risk factors. In two studies comparing elderly patients with early- and late-onset bipolar disorder, researchers found that patients with late-onset mania had increased vascular risk factors[9,17].

In another recent study of 50 elderly bipolar patients with no known history of stroke or neurological disease, patients with late-onset bipolar disorder had higher stroke risk scores than patients with early-onset illness[19]. In a prospective study of mania in 35 patients over age 60, the elderly mania patients had more cortical atrophy on CT scans than age-matched controls[14]. However, no significant difference in cortical atrophy was found between elderly patients with early- and late-onset mania. In addition, subcortical hyperintensities have been reported on magnetic resonance imaging (MRI) in elderly patients with mania [23]. These hyperintensities are believed to be due to focal loss of brain parenchyma but they do not seem to be specific to elderly patients with mania, since subcortical hyperintensities have also been found in late-onset depression as well as late-onset paranoid disorders[24].

Krauthammer and Klerman[25] proposed criteria for secondary mania that included cases of no prior family history, no past psychiatric history and a definable medical or neurological aetiology. While it is true that organic factors may precipitate mania in some elderly patients, these cases appear to be in the minority. Manic episodes can be caused by such widely prescribed medications as levodopa, procyclidine, pergolide, selegiline and bromocriptine[26]. A variety of steroids have been reported to produce manic syndromes, as have thyroid supplements, and there have been case reports of mania associated with H_2-antagonists, antiarrhythmics, oestrogen and antitubercular agents[27]. In addition, mania can occur in association with systemic infections, such as influenza, Q fever and St. Louis type A encephalitis. Cases of mania secondary to space-occupying lesions, such as meningiomas, subarachnoid haemorrhages and metastases (usually in the non-dominant hemisphere), have also been reported[8]. In these cases, mania usually resolves with removal of the offending pharmacological agent or treatment of the underlying disorder.

More commonly, mania has been reported in elderly patients with cerebrovascular and neurological disorders. A cohort study comparing 50 elderly patients with mania to 50 age- and sex-matched patients with unipolar depression found that 36% of the manic patients had neurological disorders compared with only 8% of the depressed patients[28]. Interestingly, among these neurologically impaired manic patients, 33% had a positive family history of affective disorder in first-degree relatives. A prospective study found that 20% of patients with mania over the age of 60 had a first manic episode closely temporally related to a cerebral organic disorder[14]. Another prospective study of 20 manic patients with onset over age 50 found that 65% developed bipolar disorder after a silent cerebral infarction[29]. In particular, injury to the right hemisphere appears to be strongly associated with the development of mania.

Overall, however, mania following stroke is much less common than depression after a stroke. In one large study of 700 stroke victims only three developed manic syndromes[30]. There have been reports of secondary mania in patients with ischaemic injury to right-sided basal ganglia, orbitofrontal cortex, right basotemporal cortex[31] and right temporoparietal cortex[32]. There have also been two case reports of mania secondary to infarctions in the thalamic and perithalamic areas[33]. It has been hypothesized that these brain areas may be significant because of their connections to the limbic system and the modulation of emotion. Starkstein *et al*.[34] studied 11 patients who developed mania after stroke and found that eight had lesions involving limbic areas and nine had right hemispheric involvement. These patients also had significantly larger bifrontal and third ventricular brain ratios than matched control patients, indicating pre-existing anterior subcortical atrophy. Moreover, almost half of the patients had family history of affective disorder in a first-degree relative.

Taken together, the current literature on mania in patients with neurological and cerebrovascular disorder underscores that genetic loading is also a factor contributing to the development of mania in these patients. Furthermore, while up to a quarter of elderly manic patients in various studies have been found to have some evidence of concurrent cerebral disease, it is still unclear to what extent these impairments play an aetiological role in the development of mania. If cases in which subjects with a known previous history of affective disorder are excluded, few cases of clear secondary mania are found[8,14,22]. An exception to this is Shulman *et al*.[28], who felt that 36% of elderly patients they studied who were hospitalized with mania had true secondary mania associated temporally with clearly documented neurological disorders. Still, recent findings that late-onset mania is associated with greater vascular risk factors and greater cerebrovascular disease suggest that medical management of vascular risk factors in older patients with depressive disorders may minimize their vulnerability to developing mania[19].

Mania can occur in the setting of dementia, although it is rare. In a retrospective chart review of 134 patients with Alzheimer's disease 2% were found to have had mania[35], although others have reported higher rates[36]. A recent study of a large Danish cohort found that patients with dementia had an elevated probability of developing mania, depression or a first bipolar episode compared with patients with other chronic illnesses, and this risk remained increased throughout the rest of the patient's life[37].

As in younger patients, stressful life events have been felt by some investigators to precipitate mania in elderly patients. One study that reported on 10 elderly manic patients found that 70% had major changes in lifestyle in the six months preceding onset of mania. Stresses included marital discord and disruption of living arrangements[7].

INTRODUCTION

The term 'bipolar disorder' includes a wide spectrum of clinical expression ranging from early to very late onset, single to recurrent episodes, manic only to bipolar episodes and mild hypomania to severe mania. However, the defining feature of bipolar disorder has always been evidence of a manic or hypomanic episode. Recent notions have challenged the concept of 'bipolar disorder' to include other perspectives including treatment response and family history[1]. This review of bipolar disorder in later life will focus on features that are unique to older adults including its late age of onset, long-term clinical course and the high prevalence of co-morbidity including cognitive impairment, other psychiatric disorders and neurobiological features. Ultimately, we will attempt to synthesize the determinants of mania in old age and review the implications for assessment and clinical diagnosis before addressing management issues specific to older adults.

EPIDEMIOLOGY

Data on the community incidence and prevalence of mania and bipolar disorder in old age are confounded by a number of methodological concerns. Similar to patients who suffer from paranoid disorders, manic patients are not readily amenable to interview or cooperation with community surveys. Diagnostic uncertainty is also related to the high levels of co-morbidity that cloud the diagnostic horizon[2]. This includes the association with co-morbid medical and neurologic disorders. DSM-IV has categorized this as 'a mood disorder due to a general medical condition' (293.83). The assumption in that classification is that the mood disturbance is a 'direct physiologic consequence of the general medical condition'. However, because of the high levels of neurological and medical co-morbidity, it is difficult to ascertain with any degree of certainty whether this is the case. Further, the historical category of 'secondary mania' implies that cerebral organic factors are responsible for the syndrome[3]. The neurological literature complicates the issue by use of the term 'disinhibition syndrome', the features of which are identical to what is considered mania in the psychiatric literature. All of this conspires to create uncertainty as to the true incidence and prevalence of the disorder. Our best data, however, suggest that the prevalence of mania in the community decreases from a high of 1.4% in young adults to a negligible $< 0.1\%$ prevalence of mania in the over-65s[4–7].

Community epidemiological surveys, including the Epidemiologic Catchment Area Study (ECA)[4,8], found a very early age of onset, close to 20 years. However, in studies of mixed-age manic patients, the mean age of onset tends to be slightly higher at 30 years[9,10]. Despite this very early onset of bipolar disorder in the general population, only a relatively small number of elderly bipolar inpatients are known to experience their first manic episode before the age of 40[7,11]. The question 'where have all the young bipolar patients gone?' has not yet been answered.

A number of hypotheses for this phenomenon include the relatively high mortality rate from natural causes and suicide in bipolar patients[7] while the Iowa 500 data suggested evidence of 'burn out' of the disorder over a long-term course[12]. The latter phenomenon has been challenged in recent epidemiological surveys based on the Veterans Affairs database[13]. Outpatient samples may reveal a different pattern compared to hospitalized patients.

In contrast, hospital admission rates show an opposite trend to that of the community prevalence of bipolar illness. For inpatient psychogeriatric units, Yassa *et al.*[14] found a relatively high 'treated prevalence' ranging from 4 to 8%. In Britain, a national survey examining first admission rates for mania showed a modest increase in the extremes of old age[15,16], assuming that this was associated with the increased prevalence of dementia in late life. The development of specialized inpatient units for older adults included significant numbers of individuals with late-life bipolar disorders ranging from 7 to 10 admissions per year[11,14,17]. In Finland, 20% of first admissions with the diagnosis of bipolar disorder occurred after the age of 60[18]. Reconciling the opposing patterns of community prevalence and hospital admission rates has been a challenge. Are the 'bipolar' disorders in late life qualitatively different than those in younger adults or is the higher admission rate in older adults a reflection of increased frailty and the effect of neurological changes?

AGE OF ONSET

Age of onset is an important variable that might help to distinguish the subtypes of mania and reduce the genetic heterogeneity inherent in the bipolar spectrum[19]. Consensus seems to be heading towards a cut-off of age 50 as a distinguishing feature of 'early-' versus 'late-onset' bipolar disorder. Recently Moorhead and Young[20] used a UK psychiatric case registry to determine age of onset retrospectively in bipolar I patients. Those subjects without a family history tended to

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

have later age of onset with a modal age of onset at 49 years, consistent with the studies above. They concluded that non-genetic factors were more relevant in this subgroup and also suggested that age 50 would be a useful cut-off for the early- vs. late-onset designation. It is worth noting that age of onset is significantly influenced by the cut-off used for 'elderly' probands. Most studies use age 60 or 65 as a cut-off for 'geriatric', 'elderly' or 'older adult'.

Studies that have examined the relationship of family history with age of onset in older bipolar probands have shown a wide range of prevalence of psychiatric disorder in first-degree relatives ranging from 24% to 88%[7,11,21–24]. Methodological issues are significant because most of the studies are retrospective in nature and the rigorous use of criteria for positive family history are not consistent in these studies. Nonetheless, a general trend towards a higher rate of family history is evident in those with early age of onset[22,24]. The converse is true in those elderly bipolar probands with a neurological disorder mainly associated with a late onset of bipolar disorder. However, even in the 'neurological subgroup' of older bipolar patients, the prevalence of a positive family history in first-degree relatives remains quite high, at about 30%[7,11,25]. Thus, even in those manic or bipolar patients with evidence of co-morbid neurological lesions, familial vulnerability appears to be a contributory factor.

COURSE OF ILLNESS

Early retrospective studies of bipolar disorder in late life found that about half of all index patients experienced depression as their first mood episode[7,11,22,23]. Moreover, elderly bipolar patients whose first episode was depression (mean age of 50, went on to experience a very long latency (mean of 15 years) before their first manic episode became evident[11,17]. In the subgroup with a latency between first depression and first mania, 25% of this group experienced a latency of at least 25 years and half of this group suffered at least three consecutive depressive episodes before developing a manic episode[7,17,22], begging the question of the pathogenesis of a switch from unipolar depression to bipolarity. The switch mechanism has been attributed in part to the high prevalence of co-morbid neurological disorders and cognitive changes described further below[2], but may also be a function of normal degenerative changes allowing for uncovering of an underlying disposition to bipolarity.

Although little is written about a unipolar mania subtype, Shulman and Tohen[26] found that 12% of their sample met strict criteria for a course of unipolar mania. The criteria included at least three distinct manic episodes without major depression including a minimum period of 10 years follow-up from the time of their first admission for a manic episode. This group also had a relatively earlier age of onset (41 years) compared with a mean of 65 years for a larger group of elderly bipolar patients. However, further study of unipolar manic patients has not been forthcoming.

The long-term outcome of older bipolar patients has primarily been studied retrospectively[11,27,28]. Shulman *et al*.[11] found a high mortality rate in a cohort of elderly manic inpatients. About half of the manic patients had died at a mean six-year follow-up compared with only 20% of age- and sex-matched patients with depression. Berrios and Bakshi[27] found a poor prognosis in older bipolar patients with limited response to treatment and a higher prevalence of cognitive impairment and cerebrovascular dysfunction associated with persistent disturbances in psychosocial functioning. Dhingra and Rabins[28] observed a significant decline in cognition in their six-year mean follow-up study.

Lehmann and Rabins[29] used a retrospective chart review of patients over the age of 65 to identify factors that contributed to relapse and hospitalization in elderly bipolar patients. They noted a distribution of age of onset consistent with previous findings using a cut-off at about age 45 rather than 50 years for late onset. The early-onset patients tended to be more behaviourally disturbed prior to admission and were less adherent with prescribed psychiatric medications. Relapse and readmissions were very common in elderly manic patients with both early- and late-onset disorders. They emphasized the need for improved medication adherence in order to prevent recurrent episodes and admissions.

PSYCHIATRIC AND MEDICAL CO-MORBIDITY

Two recent studies have focused on the question of psychiatric co-morbidity with late-life bipolar disorders[30,31]. Sajatovic and Kales[32] used the Veterans Affairs database (National Psychosis Registry) to document a lower prevalence of substance abuse in older bipolar patients compared with mixed-age samples who had co-morbid substance abuse of over 60%. A total of 29% of older bipolar patients with a mean age of 70 years experienced either substance abuse, post-traumatic stress disorder, other anxiety disorders or dementia[32]. In this study, the anxiety disorders represented 15.2% of the sample, including post-traumatic stress disorder (PTSD) which occurred in 5.4% and other anxiety disorders in 9.8% of this group. Substance abuse was lower than other studies at 8.9% in this sample. Goldstein *et al*.[30] derived data from the National Epidemiology Survey on Alcohol Related Conditions (NESARC). Eighty-four elderly bipolar patients were identified and were found to have a lifetime and 12-month co-morbid prevalence of alcohol use disorders of 38%. Patients with generalized anxiety disorder had a lifetime prevalence of 20.5% and a 12-month prevalence of 9.5%. Prevalence figures for panic disorder showed a 19% lifetime prevalence and a 12-month prevalence of 11.9%. These studies show a consistently high co-morbidity that appears to be slightly lower than mixed-age and younger samples.

Medical co-morbidity has only recently been examined in bipolar elders[33,34]. Using a prospective sample of elderly bipolar patients, Gildengers *et al*.[33] undertook to determine the profile of disease burden between elderly patients with major depression compared to those with bipolar disorder. They hypothesized that medical burden would be greater for bipolar patients, particularly in endocrine/metabolic and cardiovascular disease given the association of bipolar disorder with obesity, diabetes mellitus, dyslipidaemia and hypertension. They did not find a significant difference between the depressive and bipolar groups on the Cumulative Illness Rating Scale for Geriatrics (CIRS-G) or body mass index (BMI). However, they did confirm that metabolic disease was higher in the bipolar group. This is consistent with the findings of Subramaniam *et al*.[34] who conducted a cross-sectional survey of elderly bipolar patients and showed that the late-onset group had higher stroke risk scores compared with the early-onset group of older bipolar patients but did not find any differences in cognitive functioning.

These recent studies confirm concerns that have been identified in a number of previous retrospective studies of late-life bipolar disorder where significant neurological co-morbidity was noted. This literature has consisted primarily of individual case reports and small case series, but showed a tendency for heterogeneous right hemisphere lesions to be associated with mania[35–38]. The findings were consistent with the psychiatric literature that used

the term 'secondary mania'[3] and the neurological literature that tended to use the term 'disinhibition syndrome'[39]. The phenomenon of pathological laughing has also been associated with right-sided lesions[40]. Moreover, the right orbital frontal circuit (OFC) has been implicated in the pathogenesis of manic syndromes[41,42]. This hypothesis is based on the observation that normal mood is dependent on the integrity of the frontal, limbic and basal ganglia circuits. Starkstein and Robinson[39] previously suggested that disinhibition syndromes or secondary mania cases are caused by a disruption of connections within the orbital frontal circuits. They note that the frontal lobes modulate motivational and psychomotor behaviour, limbic connections modulate emotions, and the biogenic amine nuclei in the hypothalamus, amygdala and brainstem modulate instinctive behaviours. This may be the neurobiological basis and pathogenesis for the development of mania in later life associated with a higher prevalence of neurological lesions[43].

Braun *et al*.[44] reviewed a series of published case reports involving focal unilateral cortical lesions, and also found a tendency towards right-sided lesions for what they termed 'mania and pseudomania'. Earlier retrospective studies of mania by Shulman *et al*.[11] noted a very high association of neurological disorders in the manic group (36%) compared with only 8% in a comparison group of elderly depressives. Moreover, very late-onset mania is strongly associated with neurological co-morbidity as well as high mortality due to cerebrovascular disease[25]. In this retrospective cohort study, 10 out of 14 elderly manic patients had evidence of neurological disorders, primarily due to cerebrovascular disease.

A heterogeneous group of neurological and medical disorders have been associated with secondary mania as reported by case reports including head injuries[45], endocrine conditions[46–48], HIV[49] and epilepsy[37]. However, the majority of case reports of secondary mania are associated with right-sided cerebrovascular lesions[2].

The presence of cerebrovascular disease associated with mania has led to the proposal of a bipolar vascular subtype[38]. Similar to the vascular depression hypothesis of Alexopoulos *et al*.[50], vascular mania is defined in the context of a finding of cerebrovascular disease based on clinical or neuroimaging findings with further evidence of cognitive impairment. The cohort of elderly manic patients with cerebrovascular disease may fit in the proposed vascular subtype although the hypothesis still needs better data for corroboration. Using a cut-off of 49 years, Wylie[51], found that the late-onset group had more cerebrovascular risk factors which are elaborated on below. Hays *et al*.[24] also found an increase in vascular co-morbidity in their sample of elderly bipolar patients whose mean age was 74 years. Silent cerebral infarctions were found to occur most commonly in late-onset mania when compared with age- and sex-matched group of depressive patients[52]. The proportion of manic patients over the age of 60 found to have silent cerebral infarctions was greater than 20% with a relatively modest family history in first-degree relatives.

NEUROIMAGING STUDIES

Most studies have focused on the presence of subcortical hyperintensities, decreased cerebral blood flow and evidence of silent cerebral infarctions[2]. The relationship of hyperintensities with risk factors such as hypertension, atherosclerotic heart disease and diabetes mellitus strengthens the relationship of mania to cerebrovascular pathology.

The potential for examining structural brain changes in late-life neuropsychiatric disorders implies that hypothesis-driven theses can now be performed[53]. New methods may be able to help understand the pathophysiology of bipolarity within specific neural circuits. The important side benefits of studying geriatric patients is also the opportunity to integrate MRI with postmortem analysis, thus generating new hypotheses[54].

Braun *et al*.[55] collected a second series of single-case reports of unilateral lesions involving at least one manic symptom. They assembled a subgroup of 59 clearly defined manic patients, the majority of whom had right hemisphere lesions. However, elation alone without a manic symptom complex was not significantly predicted by lesion side. Rather, the association of right hemisphere lesions with mania is primarily related to disinhibition rather than a shift of mood as a result of the release of left hemisphere influence. This hypothesis is illustrated in a recent case study from Japan in which a 78-year-old woman with major depression developed a right-sided infarction in the middle cerebral artery distribution followed by acute post-stroke mania. Single photon emission computed tomography (SPECT) scan showed a unique pattern of left orbital frontal hyperperfusion with extensive right frontal hypoperfusion. Similar to Braun *et al*.'s[55] theory, they postulate a functional imbalance within the right and left orbital frontal cortices that result in the development of mania[56].

The examination of cortical atrophy has not been as frequent as that of hyperintensities and silent cerebral infarcts but Beyer *et al*.[57] found a decreased right caudate volume in older bipolar patients compared with controls related to the duration of illness. This was most pronounced in a late-onset subgroup and points to the role of the caudate in the emotional brain circuitry involving the prefrontal cortex, the amygdala, thalamus and other basal ganglia structures. Another interesting associated finding from Beyer *et al*.[58] was an increase in left hippocampal volume in elderly bipolar patients. They hypothesized that lithium treatment may have been responsible for this and point to the possible neuroplasticity and cellular resilience in this region of the brain possibly induced by lithium[59].

COGNITIVE IMPAIRMENT

Young *et al*.[60] conducted a systematic literature review involving seven studies of elderly bipolar patients and also used a cross-sectional sample of 70 bipolar patients who completed the Mini-Mental State Examination (MMSE) and the Mattis Dementia Rating Scale. The literature review identified methodological problems and differences in assessing cognitive function but overall found a pattern of significant cognitive impairment. In their clinical sample, the manic patients had lower scores on the two rating instruments compared to a comparison group. The cognitive scores did not correlate with Young Mania Rating Scale scores and were considered persistent deficits.

Tsai *et al*.[61] used a retrospective chart review to study cognition in bipolar I patients over the age of 60. The cognitive screening instruments included the clock drawing test, the MMSE and the cognitive ability screening instrument (CASI). Their cut-off for early onset was age 40 and they found that 42% of early-onset euthymic older bipolar patients had impaired cognition. Gildengers *et al*.[62] studied euthymic older bipolar patients and found that half of this group scored below the mean of the comparison subjects. They concluded that these findings were persistent changes and not associated with an abnormal mood state, similar to the finding of Young *et al*.[60].

Despite the very significant association of cognitive dysfunction with late-life mania, earlier studies have not been able to establish a clinical course consistent with the development of dementia in this

group compared to age-matched controls. However, because of the finding by Alexopoulos *et al*.[50] that reversible dementia in major depression eventually led to irreversible dementia, this issue remains of concern. Of considerable interest has been the recent finding of neuroprotection associated with lithium treatment[63,64].

Terao *et al*.[65] conducted a retrospective study of clinical records to show that those patients with a history of lithium exposure as well as current lithium treatment had higher MMSE scores than their comparison subjects. The putative neuroprotective impact of lithium has been postulated to be associated with its ability to decrease the enzyme glycogen synthase kinase-3 (GSK-3) which leads to the accumulation of amyloid-beta proteins and senile plaques, as well as hyperphosphorylated tau and neurofibrillary tangles in Alzheimer's disease.

A number of recent studies have addressed the relationship between cognitive dysfunction and bipolar disorder with similar findings. Schouws *et al*.[66] studied a small sample of euthymic elderly patients over the age of 60 with onset less than 50 years. A comprehensive neuropsychological test battery found that these euthymic bipolar patients were impaired across a wide range of cognitive domains and were similar to the cognitive dysfunction found in younger bipolar patients. Depp *et al*.[67] used an outpatient sample and found that bipolar disorder was associated with significant neurocognitive impairment compared to comparison subjects, and that this pattern of impairment was distinct from that found in schizophrenia. They also confirmed that the cognitive deficits in the bipolar group were not related to either the severity or duration of the psychiatric or manic symptoms, but were related to their quality of life. Sajatovic *et al*.[31] found a co-morbid dementia in 4.5% of their sample of older bipolar patients in the Veterans Affairs database.

Similar to Tsai *et al*.[61], an Argentinian study[68] used a small sample of euthymic older patients with bipolar disorders to demonstrate that their pattern of cognitive and motor dysfunction was similar to that described in younger euthymic bipolar patients. Psychosocial functioning was correlated with this impairment. Euthymic bipolar elderly patients were also studied by Radanovic *et al*.[69] who demonstrated language impairment compared to control subjects.

Gunning-Dixon *et al*.[70], also using a small sample of non-demented manic bipolar patients, showed that their performance on executive functioning was worse than controls as well as comparison depressed subjects. They hypothesized that the executive dysfunction found in this group supported the possibility that specific frontostriatal network dysfunction was associated with late-life bipolar disorder.

Lin *et al*.[71] used two study cohorts identified in the Taiwan National Health Insurance Research Database. Patients hospitalized with bipolar disorder compared to those undergoing appendectomy had twice the likelihood of developing stroke.

CLINICAL PRESENTATION AND HEALTH SERVICE UTILIZATION

Various studies[13,23] suggest that the presentation of bipolar disorder remains fairly constant across the life span, including the general range of symptoms. There is also a consistently high use of health services by older bipolar patients[13,72]. Subsequent studies including those by Bartels *et al*.[72] report that elderly bipolar patients have greater severity of symptoms and impairment of community living skills compared with age-matched older adults with unipolar depression. Moreover, they use almost four times the total amount of mental health services, including hospitalization. Generally, bipolar patients are found to have greater medical co-morbidity, more cognitive impairment and a less robust response to treatment[13,72]. Depp *et al*.[73] noted that elderly bipolar patients were less likely to use hospital facilities compared to younger bipolar patients, but were more likely to use case management services.

Kessing[74] used a nation-wide psychiatric registry in Denmark to study different diagnostic subtypes of bipolar disorder in patients with late-onset (over 50) and early-onset. He found that those bipolar patients whose first psychiatric hospitalization occurred after the age of 50 tended to present with less psychotic manic episodes and more severe depressions including psychosis compared with younger onset patients.

Beyer *et al*.[75] examined stressful life events in older bipolar patients. They showed that the number of serious stressful life events in the 12 months prior to a manic episode was no different in older or younger bipolar patients. In general, negative life events were more prevalent in both older and younger bipolar patients compared to a control group. Depp *et al*.[76] noted that psychotic depressive symptoms as well as cognitive impairment in elderly adults with bipolar disorder contributed to the finding of a lower health-related quality of life and functioning in this sample.

In summary, older adults with new or persistent bipolar disorder are profoundly affected by their illness, resulting in a decrease in their quality of life. Moreover, these disorders represent a significant challenge to geriatric and psychiatric services because of the high levels of morbidity and mortality.

CLINICAL IMPLICATIONS OF A NEW DIAGNOSIS OF BIPOLAR DISORDER IN LATE LIFE

One of the unique features of mania and the switch into bipolarity in late life is the association with heterogeneous brain lesions, predominantly cerebrovascular disease. This suggests that any elderly patient presenting with a manic episode, particularly for the first time late in life, deserves a rigorous neurological workup, especially for evidence of cerebrovascular disease, including brain scanning. Consequently, the management of vascular risk factors becomes an important aspect of the management of this neuropsychiatric disorder and accounts for the high rate of medical co-morbidity and increased use of health services by this subgroup of patients[13,72]. Ruling out other neurological lesions or disorders is particularly important in late-onset cases and those without significant family history.

Our understanding of the determinants of manic illness in old age also point to the significant affective vulnerability in this subgroup manifest by a high familial prevalence of mood disorder in 50–80% of first-degree relatives[11,24]. However, our clinical experience suggests that affective vulnerability is not based solely on genetics but also on the psychological events of early life. Early loss and trauma in childhood and adolescence may very well be significant risk factors for affective vulnerability late in life. As Beyer *et al*.[75] have shown, stressful events in old age also play a role but are not more prevalent than in younger individuals with bipolar disorder. However, it is the perfect storm of genetics, psychological stressors and the localization of brain lesions to the right hemisphere involving the orbital frontal circuit that may be critical for the manifestation of mania in old age. These findings in older adults with mania and bipolar disorders may help to shed light on the pathogenesis of mania in the much larger mixed-age population of individuals with bipolar disorder. To what extent the management and pharmacological treatment is similar or different in older adult is the focus of the next section of this chapter.

MANAGEMENT OF THE OLDER ADULT WITH BIPOLAR DISORDER

The management of bipolar disorder in the elderly is fraught with multiple challenges (Table 93.1). As noted previously, rates of medical and psychiatric co-morbidity are extremely high in elderly bipolar patients, necessitating caution during arriving at a diagnosis and ordering investigations/laboratory or imaging assessment. A careful history and collaborative history is often required to rule out co-morbid substance abuse and anxiety disorders. The medical history should in particular focus on previous head injury, cerebrovascular disease and related cardiac risk factors. The use of concomitant medications must be documented in order to avoid or manage drug interactions. Baseline laboratory investigations should include a complete blood count (CBC), fasting glucose and lipid profile, liver function, kidney function, thyroid, urinalysis and an ECG. Neuroimaging has generally also been considered an essential component of the baseline investigations for elderly bipolar patients.

The next major challenge facing the clinician is the lack of randomized controlled trials and evidence-based treatment guidelines. At the present time, there is not a single published randomized trial of lithium, valproate, other mood stabilizers, antidepressants, antipsychotics, electroconvulsive therapy (ECT), or psychotherapy conducted with elderly bipolar patients. While there are numerous reviews on the management and pharmacotherapy of late-life bipolar disorders[77–80], none of the popular clinical practice guidelines[81,82] provide evidence-based, specific recommendations for the elderly. Unfortunately, the situation is also unlikely to improve in the near future. A review of the clinical trial registry[83] revealed only four trials recruiting geriatric bipolar patients. Of these four trials, none were placebo-controlled, three were open label, and only one was a randomized trial of lithium vs. valproate that has already been recruiting for several years.

Table 93.1 Challenges in the management of elderly patients with bipolar disorder

Diagnosis	Multiple psychiatric co-morbidities: dementia, anxiety and substance use disorders are the most likely particular concerns
	Multiple medical co-morbidity: metabolic/endocrine, cardiovascular and neurological diseases are particular concerns
Treatment	Lack of evidence-based treatment guidelines specific to geriatric bipolar disorder
	Age- related changes in drug metabolism
	Reduced tolerance to medication side effects (e.g. falls risk)
	Need to treat medical co-morbidity
	Multiple concomitant medications increase risk of drug interactions
	Age- specific adverse medication affects (e.g. mortality risk associated with antipsychotics)
Service delivery	Issues related to changes in social environment (isolation, communication or transportation difficulties) and treatment adherence
	Intensive service needs – increased need to coordinate care between health care providers, service agencies and/or family
	Projected shortage in specialty care clinicians and available services for geriatric populations

In the absence of specific data, guidelines from adult populations have of necessity been applied to geriatric populations. For example, in a small open-label trial of 31 elderly bipolar patients[84], standardized treatment protocols were applied based on the Systematic Treatment Enhanced Program for Bipolar Disorder (STEP-BD)[85]. The authors concluded that they were successfully able to apply standardized therapy even though most of the patients did not experience sustained recovery. Any adaptation of adult treatment guidelines however must consider age-specific pharmacological issues such as the fact that the elderly generally have a reduced capacity to metabolize drugs, they are more sensitive to adverse effects, and they are more likely to be taking concomitant medications, increasing the risk of drug interactions[86].

Treatment of Acute Mania in Older Adults

First-line therapy for acute mania would include lithium, divalproex (valproic acid), an atypical antipsychotic (olanzapine, risperidone, quetiapine, aripiprazole, ziprasidone) and the combination of lithium or divalproex with an atypical antipsychotic, based on recent evidence-based clinical practice guidelines for bipolar disorder[82]. Second-line therapy would include use of carbamazepine, oxcarbazepine, ECT, and the combination of lithium and divalproex. Clozapine is included under third-line agents in these guidelines. The choice of these agents would be reasonable for elderly bipolar patients as well, taking into consideration dosing and titration appropriate for the elderly.

While other first-line agents are being used more frequently, lithium remains a commonly used mood stabilizer in old age[87]. In fact, in the study of standardized treatment for elderly bipolar patients mentioned previously[84], lithium was the most commonly prescribed treatment used by over 60% of patients. Available data on the use of lithium in elderly manic patients comes from a small number of open-label case series, naturalistic and retrospective studies, which suggest lithium can be used safely and effectively[84,89–92]. Lithium therapy highlights many of the challenges associated with pharmacotherapy in elderly bipolar patients. Lithium is eliminated exclusively by the kidney, and age-related changes such as decreased creatinine clearance and glomerular filtration rate significantly affect lithium pharmacokinetics. In a study of lithium pharmacokinetics, Hardy *et al*.[93] determined that lithium excretion in the elderly was half the rate of younger patients. The elderly may also be more sensitive to adverse events and toxicity even with lithium serum levels considered 'normal' in adult populations[94–96]. This has led to some controversy regarding appropriate lithium dosages and serum levels for the elderly. Some have recommended serum levels as low as 0.5 mmol/l[97], though others have argued that higher levels are associated with better outcome[92,98]. A review of published studies in the elderly suggested that lithium dosages were 25–50% lower in the elderly with serum levels typically below 0.7 mmol/l[80]. In the study of standardized treatment of geriatric bipolar disorder, the average dose of lithium used was 657 mg per day with an average serum level of 0.67 mmol/l[84].

The potential adverse effects of lithium include a wide range of disturbances involving the central nervous system (CNS), gastrointestinal, kidney, cardiac and endocrine systems. Common CNS effects include lithium-induced tremor, aggravation of parkinsonian symptoms and spontaneous extrapyramidal effects. In an administrative

health database study of 2422 elderly new users of lithium, the rate of hospitalization for lithium-induced delirium was 2.5 per 100 person years, not significantly different from the rate of valproate-induced delirium[99]. The risk of lithium-induced hypothyroidism might be greater in elderly patients than that seen in younger populations. For example, in a community study of elderly lithium users, one-third were on thyroid replacement or had elevated levels of thyroid-stimulating hormone[87]. In a study of 1705 new elderly lithium users, 6% were treated for hypothyroidism, about twice the prevalence expected from a mixed-age population[100]. Finally, another major concern related to lithium use in the elderly is the risk of drug–drug interactions. Numerous commonly used concomitant medications can reduce lithium clearance including diuretics, angiotensin-converting enzyme (ACE) inhibitors and some non-steroidal anti-inflammatory drugs[77]. While thiazide diuretics were classically thought to be the drugs of greatest concern, these other agents might be even more problematic. In a population-based nested case–control study with 10 000 elderly lithium users, approximately 4% were hospitalized for lithium toxicity[101]. New use of a loop diuretic (e.g. furosemide) or an ACE-inhibitor independently increased the risk of hospitalization for lithium-induced toxicity by five- to sevenfold.

In the absence of controlled trial data, it is perhaps surprising that new use of valproate therapy for bipolar elders is surpassing that of lithium use. For example, in an administrative database study conducted between 1993 and 2000, new use of lithium carbonate fell consistently while valproic acid use increased, surpassing new lithium prescriptions midway through the observation period[88]. By the end of the observation period, there were almost three new prescriptions for valproate written for every prescription of lithium. While there are no published randomized controlled studies, naturalistic observational studies suggest the use of valproate for acute mania in the elderly is effective and reasonably well tolerated[84,92,102–108]. Dosages have ranged between 250 and 2250 mg per day and serum levels between 25 and 120 μg/ml with about 60% demonstrating some degree of benefit[77].

Based on case reports, valproate appears effective for elderly rapid-cycling bipolar patients as monotherapy[109] or in combination with lithium[110,111]. Successful use of intravenous valproate has also been documented for acutely manic elderly patients who refused oral medications[112]. There are significant dose-dependent changes in valproate pharmacokinetics in the elderly, including prolonged elimination half-life, especially important at higher doses, which might predispose the elderly to toxicity[113,114]. The most frequent adverse events associated with valproate are excessive sedation and gastrointestinal intolerance, though under-recognized and potentially important side effects in the elderly also include thrombocytopenia[115] and hyperammonaemia potentially leading to delirium[116]. In fact, while valproate is often considered a better tolerated, safer alternative to lithium for the elderly, one study found no differences in the rates of hospitalization for delirium comparing valproate to lithium[99]. Valproic acid is also highly protein-bound and a weak inhibitor of cytochrome P450 2D6. As a result, potential drug interactions exist, including drugs such as tricyclic antidepressants, acetylsalicylic acid, warfarin and diazepam[117].

There are no randomized controlled trials of the use of carbamazepine in the elderly and only a small number of naturalistic studies reported[118,119]. Some have raised concerns about the tolerability of carbamazepine in the elderly suggesting that relatively low serum levels (below 9 μg/ml) are necessary to avoid neurotoxicty[98]. Significant potential for important drug interactions may also limit its use in the elderly[117].

There are virtually no published studies on the use of other anticonvulsants such as oxcarbazepine, topiramate and zonisamide for mania in the elderly. One case series of gabapentin therapy in elderly manic patients suggested it was safe and effective[120].

Though typical antipsychotics are not considered first-line agents for mania[82], they are still used frequently in the elderly as adjunctive treatments for bipolar disorder. Typical antipsychotics can cause considerable side effects in the elderly, including anticholinergic effects, orthostatic hypotension and extrapyramidal effects[79]. Rates of incident tardive dyskinesia in the elderly associated with typical antipsychotics are high[121]. In contrast, rates of acute extrapyramidal effects and tardive dyskinesia are very much lower with atypical antipsychotics and as a result they are being used with increasing frequency for elderly manic patients[122]. Atypical antipsychotics also appear to have mood-stabilizing properties that have earned them recognition as first-line therapies for acute mania in evidence-based treatment guidelines[82]. However, in contrast to the numerous randomized controlled trials of atypical antipsychotics in elderly demented patients[123] and a smaller number of studies in elderly schizophrenic patients[124–127], there are no randomized controlled trials of atypical antipsychotics for elderly bipolar patients. While commonly used for mania in the elderly as monotherapy and adjunctive treatments[78], there are remarkably few naturalistic studies and even case series reported in the elderly. In one case series, risperidone was found to be effective for elderly bipolar patients[128] and clozapine has been reported to be effective in a couple of case reports[129,130]. In the case of clozapine, older adults are at greater risk of developing drug-related agranulocytosis compared with younger/mixed-age populations[131].

Besides their well-described metabolic adverse effects, the use of atypical antipsychotics may be associated with specific concerns in the elderly including the risk of cerebrovascular adverse events and mortality[132,133]. Interestingly, despite the obvious increases in weight, glucose intolerance and hyperlipidaemia associated with drugs like clozapine, olanzapine, quetiapine, and to a lesser extent risperidone, neither the randomized controlled trials in the elderly dementia patients, nor population-based studies have suggested a similar concern[133]. Whether this is because the elderly are less susceptible to these effects, or that the lower doses typically used for the elderly mitigate these effects is unclear. Despite the lack of a similar concern from the published data, it is important to note that elderly bipolar patients may have different susceptibility risks compared to dementia patients. Furthermore, it would seem prudent to be particularly cautious in patients who are at high risk for the metabolic consequences of atypical antipsychotics such as those with obesity and pre-existing diabetes and hyperlipidaemia.

With respect to cerebrovascular adverse events, while both risperidone and olanzapine carry black-box warnings for these events based on the randomized controlled trials in elderly dementia patients, it is likely that the other atypical antipsychotics as well as the typicals have similar risks[132]. Similarly, all antipsychotics, both typical and atypical, now carry black-box warnings for an increased risk of mortality based on the randomized controlled trials with dementia patients, as well as population-based observational studies[133]. Taken together, it is unclear whether elderly bipolar patients have similar susceptibility to these serious cardiovascular/elevated mortality adverse events demonstrated in elderly patients with dementia.

Finally, there are no specific data on the use of benzodiazepines, ECT, transcranial magnetic stimulation or psychosocial interventions for elderly manic patients, even though they are clearly being used and have been recommended for the elderly[86].

Treatment of Bipolar Depression in Older Adults

Bipolar depression is a severe and pervasive problem among all individuals with bipolar illness, and mixed-age individuals with bipolar disorder experience depressive symptoms three times more frequently than manic symptoms[134,135]. In addition to greater time duration, disability associated with bipolar depression is disproportionately greater than that associated with bipolar mania[136,137]. Underscoring the malignant effects of dysphoric mood states in bipolar populations, bipolar depression has been reported as a major contributor to completed suicide[138].

An analysis by Depp and colleagues[76] evaluated health-related quality of life among middle-aged and older adults with bipolar disorder, finding that depressive symptoms, along with psychosis and cognitive impairment significantly contribute to reduced quality of life. In depressed bipolar elders, treatments directed at mood dysregulation can alleviate disability[139], and may help avoid 'behavioural disuse atrophy'[140,141].

While the earliest and largest number of prospective randomized controlled bipolar treatment trials have evaluated the anti-manic activity of various drug treatments[142], the most salient issue for individuals with bipolar disorder appears to be efficacy of treatments for bipolar depression. A recent study involving 469 individuals with bipolar disorder found that patients prioritized reduction of depression severity over mania severity[143].

Unfortunately, there are few established treatments for bipolar depression, and the topic area has been severely neglected up until very recently[144]. Commonly utilized drug therapies in mixed-age patients include lithium, the anticonvulsants valproate, lamotrigine and carbamazepine as well as the atypical antipsychotics and combination therapy with antidepressant medications adjunct to mood stabilizers[145,146]. Fountoulakis and Vieta[144] noted that good research-based evidence supported by at least one placebo-controlled trial of 'sufficient' magnitude exists for selected atypical antipsychotic agents (olanzapine, quetiapine both as monotherapy or olanzapine in combination with fluoxetine). A recent International Consensus Group (ICG) suggested that only three monotherapies (lithium, lamotrigine, quetiapine) have first-level evidence for the treatment of acute and long-term bipolar depression[147]. In addition, the use of antidepressants is controversial in bipolar depression because of potential negative consequences (switching, rapid cycling), and the ICG has not supported their general use for bipolar depression[147]. The American Psychiatric Association (APA) guidelines for the treatment of Bipolar Disorder[148] recommend that the use of antidepressant agents in bipolar populations be approached cautiously and parsimoniously.

Uncontrolled and secondary analyses in geriatric bipolar depression suggest a possible role for the traditional mood-stabilizing medication lithium and for lamotrigine[149,150]. In addition, a group of US investigators have recently initiated a preliminary, open-label trial of adjunct lamotrigine therapy in geriatric (age 60 and over) bipolar depressed populations utilizing a geriatric bipolar trials network. Preliminary data from the first seven patients (intention to treat) demonstrated significant reduction in change from baseline Montgomery Asberg Depression Rating (MADRS) scores (baseline mean 28, endpoint last observation carried forward (LOCF) mean 14.7, $P = 0.005$, with good tolerability of lamotrigine by bipolar depressed elders[151].

Some atypical antipsychotic drugs, widely used in mixed-age bipolar populations may also be of benefit in bipolar elders. Sajatovic and Paulsson[152] conducted a secondary analysis of combined results from two eight-week, double-blind, randomized, placebo-controlled studies of quetiapine in fixed doses (300 or 600 mg/day) in the treatment of depressive episodes associated with bipolar I or II disorder[153,154]. The primary efficacy endpoint was MADRS total score change from baseline to week 8. Efficacy populations included 72 adults aged 55–65 years (mean ± SD 58.4 ± 2.6 years; $n = 23$, 23 and 26 for quetiapine 300 mg/day, quetiapine 600 mg/day and placebo, respectively) and 906 adults aged 18 to <55 years (mean 35.7 ± 9.9 years; $n = 304$, 298 and 304, respectively). Illness characteristics, including DSM-IV diagnoses and baseline MADRS and Hamilton Depression Scale (HAM-D) scores were broadly similar between older and younger adults receiving quetiapine or placebo. In older adults, least square mean ± SE MADRS score decreased 13.4 ± 2.4 with quetiapine 300 mg/day and 14.2 ± 2.5 with quetiapine 600 mg/day vs. 8.0 ± 2.3 with placebo ($P = 0.097$ and 0.057, respectively, vs. placebo). In younger adults, mean MADRS score decreased 16.8 ± 0.7 and 16.5 ± 0.7 vs. 11.2 ± 0.7, respectively ($P < 0.001$, both doses vs. placebo). Quetiapine (both doses) significantly decreased HAM-D and CGI-S scores and increased CGI-I scores relative to placebo in older and younger adults. The most frequent adverse effects associated with quetiapine in older and younger adults were dry mouth, somnolence, sedation and dizziness. Rates of treatment-related withdrawals were similar in older and younger adults.

Aripiprazole, an atypical antipsychotic compound which is approved by the US Food and Drug Administration (FDA) for the treatment of bipolar mania and for the long-term treatment of bipolar disorder was recently prospectively tested in a small sample ($N = 20$) of bipolar older adults[155]. Older bipolar I adults who were suboptimally responsive to their bipolar pharmacological treatments received 12 weeks of open- label aripiprazole added on to existing mood stabilizer[156]. Aripiprazole was initiated at 5 mg daily and increased as tolerated. Efficacy outcomes included psychopathology scores (Young Mania Rating Scale (YMRS), HAM-D), extrapyramidal symptom assessments, and level of functioning measurement (Global Assessment Scale (GAS)). Mean age of the sample was 59.6 years, range 50–83 years. The majority of individuals had bipolar depression. Individuals had significant reductions in HAM-D and YMRS scores. There were also significant improvements in the GAS. Mean daily dose of aripiprazole was 10.26 mg/day SD ± 4.9, range 5–20 mg/day. Overall, aripiprazole was efficacious and relatively well tolerated. Of particular note, aripiprazole therapy was associated with improvements in bipolar depression in this older population. While atypical antipsychotics offer potential promise in treating geriatric bipolar depression, this must be tempered by concerns regarding antipsychotic drugs in elders discussed above.

While the role of antidepressant agents to treat bipolar depression in mixed-age populations is controversial due to concerns regarding manic switching, mixed episodes and rapid cycling[148,144], preliminary data in geriatric bipolar depression suggest that antidepressants can have beneficial effects on selected health outcomes. One analysis found decreased rates of hospitalization for manic/mixed episodes during a 5135 person-years follow-up study of antidepressant use among older adults with bipolar disorder[156]. Another report suggested that older bipolar adults with a recent history of suicide attempts were less likely to have received treatment with mood stabilizers and antidepressants compared to older bipolar individuals with no recent history of suicide attempts[157]. Finally, ECT must be mentioned as an efficacious and well-tolerated somatic therapy for bipolar depressed elderly individuals[158].

Maintenance Treatment of Bipolar Disorder in Older Adults

Maintenance or longer term treatments for geriatric bipolar disorder are minimally presented in the psychiatric literature. A recent retrospective analysis of elders with unipolar depression and elders with bipolar disorder compared each patient to his or her own clinical course before and after lithium treatment[159]. In this analysis lithium maintenance significantly reduced the probability of relapse and recurrence, suicidal behaviour, and severity of mood disturbance[159].

A secondary analysis of older adults (age 55 and older) from two placebo-controlled, double-blind bipolar maintenance treatment studies compared patients randomized to treatment with lamotrigine, lithium or placebo for up to 18 months[160]. The primary endpoint was time-to-intervention for any mood episode; secondary measures included time-to-intervention for depression and mania/hypomania/mixed mood. The group of 638 patients included 98 older adults. Mean age of the older adult sample was 61 years (± SD 6.0, range 55–82 years). In the group of older adults, lamotrigine, but not lithium, significantly delayed time-to-intervention for any mood episode compared with placebo. Lamotrigine also significantly delayed time-to-intervention for a depressive episode compared with lithium and placebo. Lithium did significantly better than lamotrigine for time-to-intervention for mania. Side effects for both lamotrigine and lithium were generally mild to moderate in severity including similar rates of skin rash (3% for lamotrigine, 5% for lithium). Lamotrigine and lithium daily doses were 240 mg/day and 750 mg/day, respectively.

Elderly and young adults from the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) were compared on prescription patterns and recovery status[161]. STEP-BD was a multicentre National Institute of Mental Health (NIMH)-funded project designed to evaluate the longitudinal outcome of patients with bipolar disorder that involved extensive assessment across multiple domains including demographic data, diagnosis, symptom severity, treatment and clinical status. Patients achieved 'recovered' status when they experienced eight consecutive weeks without significant symptoms. Treatment regimes and doses were compared between younger participants ($N = 3364$) 20–59 years old, and older participants 60 and above ($N = 246$). Of the 3615 STEP-BD patients, 67.6% ($N = 2442$) achieved a recovered status – 78.5% ($N = 193$) of older patients vs. 66.8% of the younger patients. On average, participants who reached a recovered status took 2.05 medications with no difference between age groups. Lithium was prescribed to 37.8% of younger patients vs. 29.5% of older patients. Younger and older patients differed significantly on dosages prescribed of lithium, valproate and risperidone (lower dose for elderly). Significant reduction in lithium dosing was observed among individuals aged 50 and older although 42.1% of recovered bipolar elders achieved recovery with lithium alone compared with only 21.3% of the younger cohort. Thus, while recovery is achievable in the elderly, more than one medication is generally needed regardless of age.

Psychotherapy may improve illness self-management in bipolar elders. For example, McBride and Bauer[162] have suggested that older adults with bipolar disorder appear to benefit from psychosocial interventions that assist in managing both mental illness and ageing-related issues. A manual-based medical care model (BCM) developed by Kilbourne and colleagues[163] appears feasible for implementation in bipolar older adult populations. The BCM includes sessions on bipolar symptom patient self-management, use of nurse-run coordination/management, and dissemination of guidelines to care providers on cardiovascular disease risk in bipolar elders[163]. Given the generally substantial medical co-morbidity seen in elderly bipolar patients, integrated therapies that address both bipolar and medical conditions are likely to be critical in order for optimal outcomes.

Emerging evidence suggests a possible neuroprotective/neurotrophic of maintenance lithium treatment[164–166]. As noted above, lithium has been found to inhibit glycogen synthase kinase-3, which is a key enzyme in the metabolism of amyloid precursor protein and in the phosphorylation of tau protein involved in the pathogenesis of Alzheimer's disease[59,144,167]. A cross-sectional, case–control study from Brazil found that long-term lithium treatment reduced the prevalence of Alzheimer's disease in elderly patients with bipolar disorder to levels consistent with those seen in the general population[166]. Similarly, results from a nation-wide Danish register-based study suggest that maintenance lithium treatment may be associated with a reduced rate of dementia[164]. In addition, in bipolar elders (mean age 66.0 ± 9.7 years), brain lithium levels and *N*-acetylaspartate (NAA), a marker of neuronal integrity, seems to be positively associated on magnetic resonance spectroscopy[165].

Adherence to Treatment

It has been demonstrated that nearly 1 in 2 individuals with bipolar disorder is non-adherent with prescribed medications[168,169]. Age, marital status, gender, educational level, and psychiatric co-morbidity, in particular substance abuse, have all been reported to be related to treatment non-adherence[168,170,171]. One study[172] evaluated antipsychotic medication adherence among older (age 60 and older) vs. younger individuals with bipolar disorder using a large Veterans Affairs case registry ($N = 73\,964$). Medication adherence was evaluated using pharmacy refill patterns. Among older adults, 61.0% ($N = 3350$) were fully adherent, while 19% ($N = 1043$) were partially adherent and 20% ($N = 1098$) were non-adherent. Among younger adults, 49.5% ($N = 10\,644$) were fully adherent, while 21.8% ($N = 4680$) were partially adherent, and 28.7% ($N = 6170$) were non-adherent. In both groups, co-morbid substance abuse and homelessness were predictors of bipolar medication non-adherence.

Additional studies in populations prescribed mood-stabilizing medications note that patient knowledge of mood stabilizers correlates negatively with age, whereas sex and duration of treatment seem unrelated to knowledge[74,173]. Older individuals on mood stabilizers have been found to have more negative views on the doctor–patient relationship and more negative views on mood stabilizers in general[74] compared to younger patients. While non-adherent rates in bipolar elders can be substantial, it is possible that adherence behaviours could be modified via intensive efforts at improving illness and medication knowledge as well as approaches that improve the doctor–patient relationship.

CONCLUSIONS

While the literature on late-life bipolarity has increased in recent years, there remain numerous and important gaps in the published data on the neurobiology, epidemiology, phenomenology and evidence base of treatment of geriatric bipolar affective disorder. This knowledge deficit limits our ability to fully understand and anticipate future healthcare requirements or to plan an optimal care-system.

Older adults with bipolar illness often experience substantial symptomotology, impaired physical and psychosocial functioning, and utilize extensive health care resources. More research is critically needed to understand expected illness trajectory, relationship to cognitive status and treatments that optimize all levels of health and functioning.

There is very limited evidence to support specific biologic or psychosocial interventions for either acute or longer term care of older adults with bipolar disorder. The current literature, based mainly on retrospective analyses or small sample and mixed-age studies, suggests that medication treatments for bipolar elders will generally require modification in dosing and titration, and should be guided by medical burden/frailty as well as the presence of medications that are co-prescribed for medical illnesses. Elderly patients with bipolar illness may be prone to specific drug-related side effects such as renal failure or extrapyramidal symptoms, and when side effects occur, the sequelae may lead to marked disability (for example, a fall leading to hip fracture). Family members and/or caregivers should be involved in treatment planning if at all possible, and clinicians need to be alert to the important issues of ageing-related reduced ability to metabolize/clear psychotropic drugs, treatment adherence and the development of medication intolerance that may develop over time. The ageing process will also often require modifications in psychosocial treatments for bipolar illness. Finally, bipolar elders will generally require close clinical monitoring, flexibility on the part of treatment providers, and utilization of available supports such as ancillary care staff and family.

Part F

Schizophrenic Disorders and Mood-Incongruent Paranoid States

Late-Life Psychotic Disorders: Nosology and Classification

Nicole M. Lanouette, Lisa T. Eyler and Dilip V. Jeste

University of California, San Diego, La Jolla, CA, USA

With the 5th edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-V) and 11th edition of the International Classification of Diseases (ICD-11) currently under development, it is timely to review the history of the nomenclature of psychiatric disorders. The notion that mental disorders could occur in particular periods of life, such as old age, first appeared only in the latter half of the nineteenth century[1]. During this short history, there has been great inconsistency regarding the nosology and classification of late-life mental disorders, particularly psychotic disorders.

There are two groups of adults with late-life non-affective psychotic disorders. The first includes individuals who are now older, but whose psychotic illness (e.g. schizophrenia, delusional disorder) emerged early in life. Debates about the classification of these patients are the same as those for younger adults (e.g. degree of overlap between psychosis and affective disorders, issues of duration and course), and there is general consensus that these patients should retain their original diagnosis into old age unless symptoms change dramatically enough to warrant a different diagnosis. The second group of patients includes those with new onset of non-affective psychosis late in life. In the majority of these cases, psychosis is secondary to a general medical condition such as dementia. As there has been little controversy about how to classify these 'organic' psychoses in the elderly, this group is not discussed in the present chapter. In contrast, there has been extensive debate about how to classify late-onset, non-affective, non-organic psychoses. The history of the nosology of this group is replete with overlapping terms, inconsistent age cut-offs, multiple definitions of the same nomenclature, and different methods of conceptualizing similar disorders. In an effort to bring greater consistency to the field, experts in late-life psychotic disorders from 12 countries convened in 1998 and produced an international consensus statement[2]. This statement presented an agreed-upon set of terms to describe late-life psychotic disorders, and recommended that late-onset schizophrenia (LOS, with onset of symptoms after age 40) be designated a formal subtype of schizophrenia. However, neither the ICD-10[3] nor the DSM-IV-TR[4] incorporated this recommendation, continuing the debate over how to best categorize late-onset psychotic disorders.

EARLY HISTORY

Kraepelin was one of the first clinical researchers to recognize that non-affective psychoses could arise in middle age or later in life. Although the term 'dementia praecox', with its inherent emphasis on an early age of onset, would seem to exclude late-onset cases, Kraepelin himself reported that one-third of his patients had symptom onset after age 30[5]. Kraepelin also studied a group of patients he described as suffering from 'paraphrenia'. This term had been used earlier by Guislain as a synonym for the syndrome of 'folly'[6], and was used by Kraepelin to characterize a group of patients with minimal volitional and affective disturbance, prominent paranoia and a relatively preserved personality. While some of the subgroups of paraphrenia he described had a relatively later age of onset, Kraepelin did not consider paraphrenia to be exclusively a late-onset disorder. Furthermore, follow-up studies of these patients showed that they did not differ greatly from those classified as dementia praecox[7,8]. Thus, many of Kraepelin's followers ultimately came to believe that dementia praecox and paraphrenia were the same disorder and that this disorder could arise early or late in life.

Other clinician investigators working during this time, however, felt that psychotic disorders arising for the first time in late life should be classified separately. The history of these classifications has been thoroughly reviewed[9]. Gaupp[10] distinguished between dementia praecox and a disorder diagnosed for the first time in postmenopausal women that was characterized by depressive agitation, resulting in 'mental weakness'. Stransky[11] used the term 'dementia tardiva' to describe late-onset dementia praecox. Some authors emphasized the prevalence of paranoid symptoms among those with onset of psychosis late in life by using terms such as 'paranoia chronica'[12] or 'involutional paranoia'[13]. Following this tradition, Albrecht's[14] classification of late-onset psychotic patients distinguished between patients with paranoid symptoms and little personality disturbance ('presenile paraphrenia') and those with 'depressive madness resulting in imbecility'. The latter category seemed somewhat similar to a late-onset form of dementia praecox. Others who described syndromes of late-onset dementia

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

praecox used the terms 'involutional paraphrenia'[15], 'stiffening involutional psychosis'[16] and 'paraphrenia'[17]. Unfortunately, the use of 'paraphrenia' to indicate an age of onset distinction led to a great deal of later confusion. Some psychiatrists employed the term to indicate a separate phenomenology independent of age of onset (much like Kraepelin's original use; e.g. Leonhard[18]), while others used that diagnosis to encompass most late-onset psychoses.

1940–1970

Using his father's term for dementia praecox, 'schizophrenia', Manfred Bleuler[19] described individuals with 'late-onset schizophrenia' as those with onset after age 40 exhibiting symptoms similar to those with an earlier onset of the disorder and no evidence of brain disease. Very few of these patients had onset after the age of 60. This classification was adopted by most subsequent German authors[9].

In the UK during this period, however, the classification of late-onset psychotic disorders took a somewhat different path. Studying a group of patients with onset after age 60, Roth and Morrissey[20] described a syndrome of paranoid delusions and hallucinations in the context of preserved intellect, personality and affect. Because of the phenomenological similarity to Kraepelin's 'paraphrenia' and due to its late onset, Roth and colleagues termed this disorder 'late paraphrenia'[21,22], a name that was designed to encompass all late-onset, non-affective, non-organic psychoses in which paranoid symptoms were prominent. Thus, the term was both broader than late-onset schizophrenia, in that it encompassed late-onset delusional disorder, and more restrictive, in that it did not include non-paranoid forms of late-onset psychosis. Post[23] developed a different descriptive system. He divided late-onset (after age 50) psychoses into paranoid hallucinosis, schizophreniform syndrome, and schizophrenic syndrome. Based on a three-year follow-up, however, he concluded that these three diseases were actually a continuum of the same disorder with slightly different symptom profiles.

European debates and developments were slow to influence the classification system used in the USA. The first Diagnostic and Statistical Manual of Mental Disorders (DSM-I)[24] used the term 'involutional psychotic reaction', which encompassed both paranoid ideation and depression in older patients. This amalgam of affective and psychotic symptoms in the elderly was split in the second edition (DSM-II)[25] in favour of 'involutional paranoid state (involutional paraphrenia)' and 'involutional melancholia'. The former disorder, like Roth's late paraphrenia, was characterized by 'delusion formation with onset in the involutional period. The absence of conspicuous thought disorders typical of schizophrenia distinguishes it from that group'[25]. Schizophrenia could be diagnosed in individuals with any age of onset.

1970–PRESENT

As European psychiatrists began to study patients with late paraphrenia more systematically, new classification systems in the USA were restricting the diagnosis of late-onset psychosis. One of the five Feighner Research Criteria[26] for schizophrenia was age of onset before age 40. In the third edition of the DSM (DSM-III)[27], a diagnosis of schizophrenia could not be made if the onset of symptoms was after age 45. Late-onset psychosis that involved persistent persecutory delusions with prominent hallucinations could be given a diagnosis of 'paranoid disorder'. This classification system was in stark contrast to both earlier RDC (research diagnostic criteria)[28] and to the ninth version of the International Classification of Diseases (ICD-9)[29], neither of which imposed age-of-onset restrictions for schizophrenia. The ICD-9 also allowed for a diagnosis of paraphrenia at any age. The revised version of DSM-III (DSM-III-R)[30] rectified the omission of late-onset schizophrenia by providing a separate diagnostic category for those diagnosed with schizophrenia after age 45. In the most recent versions of the DSM (DSM-IV-TR)[4] and the ICD (ICD-10)[3], no special categories exist for late-onset psychoses, although schizophrenia may be diagnosed at any age.

TOWARD A CONSENSUS

It is clear from this historical review that there has been little consensus regarding the classification of late-onset, non-affective, non-organic psychoses. Two opposing lines of thought have pulled the terminology in different directions. On the one hand, some authors have preferred to emphasize the similarity of late-onset psychoses to the corresponding early onset disorders. This has resulted either in the use of terms such as 'late-onset schizophrenia' and 'late-onset delusional disorder' or has prompted a move toward ignoring age of onset altogether in classification (e.g. DSM-IV-TR[4], ICD-10[3]). On the other hand, some members of the psychiatry community (mainly in Europe) have preferred to emphasize differences between the phenomenology of late- and early onset psychosis and thus have tended to use distinct terminology, such as 'paraphrenia' or 'late paraphrenia'[31].

Thus, questions remain about which terminology would optimally serve the clinical and research communities. These questions have become particularly timely with the development of DSM-V[32,33] and ICD-11. There are at least two overlapping issues to consider. First, how similar or different are the late-onset, non-affective, non-organic psychoses from early onset disorders? If late-onset patients are no different from early onset patients in terms of demography, phenomenology, aetiological factors, prognosis and treatment, then it would be redundant to classify them in a separate category. If, however, such features differ between early onset and late-onset individuals, then it would seem important to preserve a distinct diagnostic category in order to encourage further research and allow for optimal prognostic evaluation and treatment. The magnitude or extent of the differences between early-and late-onset individuals should also influence the terminology chosen for the diagnostic categorization. If a majority of critical clinical features are shared with an early onset disorder, then it would make sense to adopt a term such as 'late-onset schizophrenia'. If the extent of differences is sufficiently large, a separate term would be warranted. A second issue to consider in determining the best classification scheme is what age of onset should be called 'late'. Most of the American studies of late-onset, non-affective, non-organic psychosis have included patients with onset after age 45 and generally before age 65. In addition, among the patients in Bleuler's late-onset schizophrenia studies, only 4% had an onset after age 60[9]. In contrast, most studies of late paraphrenia have been conducted with patients whose onset was after age 65. Differences in age of onset between late-onset schizophrenia and late paraphrenia studies may help to explain some of the diagnostic confusions that have persisted.

Only relatively recently has the weight of evidence become sufficiently great in the field of late-life psychoses to allow for adequate consideration of these issues. In 1998, the International Late-Onset Schizophrenia Group met to present reviews of published data on

Table 94.1 Comparison of typical-onset (age 15–40) schizophrenia, middle-age-onset (age 41–65) schizophrenia and very-late-onset (age ≥ 65) schizophrenia-like psychosis

	Typical onset	*Middle-age onset*	*Very late onset*
Female : male ratio	0.6 : 1	2 : 1	up to 8 : 1
Poor premorbid functioning	++	+	−
Family history of schizophrenia	++	++	−
Sensory deficits	−	−	+
Negative symptoms	+++	++	−
Thought disorder	+++	+++	−
Structural brain abnormalities (strokes, tumours)	−	−	+
Antipsychotic dose	+++	++	+
Tardive dyskinesia risk	+	+	++

+, presence; −, absence; number of symbols indicates degree of presence.

late-onset, non-affective, non-organic psychosis and to develop a consensus statement regarding diagnostic categories[2]. The statement recognizes two illness classifications: late-onset (onset after the age of 40 years) schizophrenia and a very-late onset (onset after age 60) schizophrenia-like psychosis. Thus, the group determined that it was important to recognize a diagnostic distinction based on age of onset, due to differences between late- and early onset patients, but that the disorders were not sufficiently different to warrant a separate nomenclature. In addition, the group felt that a further distinction was warranted within late-onset patients between those with onset in middle age and those with very late onset, based on major differences between these groups.

The similarities and differences among early onset schizophrenia, late-onset schizophrenia and very-late-onset schizophrenia-like psychosis are summarized in Table 94.1. There are many areas of similarity between both late-onset groups and early onset schizophrenia, such as symptoms[34–36], family history[35], brain imaging findings[37–39], and nature of cognitive impairments[38]. The decision to retain the word 'schizophrenia' in the nomenclature of both disorders was driven by these strong similarities. However, while the nature of cognitive impairments and symptoms are similar, late-onset patients typically show less severe cognitive impairment compared to early onset patients[35,40], and a recent study found late-onset patients had less severe overall psychopathology[41]. On the other hand, the consensus statement's distinction between those with middle-age-onset and old-age-onset psychoses was motivated by epidemiological, aetiological and symptom differences between these two groups. Very-late-onset schizophrenia-like psychosis is different from both early- and late-onset schizophrenia, in that these cases tend to be associated with sensory impairment and social isolation[22], although these may be consequences rather than causes of these disorders[42]. Patients with very-late-onset schizophrenia are also less likely to exhibit formal thought disorder, negative symptoms[35,43] and a wide range of cognitive biases[44], but are more likely to have visual hallucinations[28,37,45] and have less familial aggregation of schizophrenia[46]. A recent magnetic resonance diffusion tensor imaging study of frontal cortex white matter connections found no structural differences between normal controls and patients with onset of psychosis after age 60[47]. It should be emphasized that the members of the International Late-Onset Schizophrenia Group were not unanimous in their support of the particular age cut-offs given in the consensus statement and also felt that the proposed nomenclature was not an end but a beginning of future research into this important topic. Their proposed groupings have been at least partially supported by subsequent research[41], but more investigations are needed.

Late-onset schizoaffective disorder and late-onset delusional disorder are not specifically addressed in the consensus statement. Late-onset schizoaffective disorder appears to share a majority of critical clinical and demographic features with late-onset schizophrenia[48]. Thus, late-onset schizoaffective disorder appears to be a subgroup of late-onset schizophrenia in which mood symptoms are also present. Late-onset delusional disorder, by contrast, can be distinguished from late-onset schizophrenia by a unique preoccupation with non-bizarre delusions in the context of preserved affective and personality functioning in other domains[49]. In addition, treatment of these individuals may be more challenging than in schizophrenia due to a difficulty in establishing rapport with therapists[50]. Cognitive function, however, is somewhat more preserved in older patients with delusional disorder than in those with schizophrenia[50]. Unfortunately, there is a lack of research comparing early- and late-onset delusional disorder.

Further research is needed to clarify the classification of late-onset psychotic disorders. Specifically, longitudinal follow-up studies are necessary to determine whether the course of illness is different in the three groups of patients and how the course of late-onset disorders compares to that of early onset syndromes. The consensus classification provided a framework for these investigations, although it remains to be seen how those guidelines will be incorporated in DSM-V and ICD-11. In summary, despite a tumultuous history, the future for research and clinical work in late-onset psychotic disorders appears to be on firmer footing.

Schizophrenic Disorder and Mood-Incongruent Paranoid States: Epidemiology and Course

Cynthia D. Fields and Peter V. Rabins

Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, USA

OVERVIEW OF SCHIZOPHRENIA AND RELATED DISORDERS

Schizophrenia is a psychotic illness characterized by positive symptoms (hallucinations, delusions, disorganized speech with thought disorder, and disorganized behaviour), negative symptoms (inexpressive or 'flat' affect, poverty of speech, inability to initiate activity) and progressive impairment of social and occupational functioning. Typically, schizophrenia begins in late adolescence or early adulthood and follows a chronic course. Age of onset is, on average, 10 years earlier in males than in females. Recovery to baseline personality and social functioning is rare. The Diagnostic and Statistical Manual of Mental Disorders, fourth edition, text revision (DSM-IV-TR) requires that symptoms be present for six months as a means of ensuring chronicity. To qualify for a diagnosis of schizophrenia, symptoms cannot be due to a primary mood disorder, such as major depression or bipolar disorder, cognitive impairment, including delirium, an acute medical condition or the effects of a substance.

Less commonly, schizophrenia can begin in middle or late life. Summing up the epidemiological studies, Harris and Jeste concluded that almost one quarter of schizophrenia patients had onset of illness after the age of 40[1]. In addition, late-onset psychotic symptoms, such as hallucinations and delusions, can be seen in a variety of disorders, ranging from delirium to bipolar disorder. Schizophrenia should be distinguished from delusional disorder, which tends to begin in midlife and is characterized by the presence of non-bizarre, fixed, false beliefs. In delusional disorder, hallucinations, when present, are not prominent, and psychosocial functioning is not markedly impaired. Several subtypes of this disorder exist, with persecutory delusions being the most common in the elderly.

EARLY-ONSET VERSUS LATE-ONSET DISORDERS

It remains unclear whether early-onset and late-onset schizophrenias (EOS and LOS, respectively) are distinct disorders. Both EOS and LOS are characterized by the presence of positive symptoms, particularly systematized delusions. In late-onset cases delusions most often are of the persecutory or partition type, with partition delusions being almost unique to that group. Partition delusions refer to the belief that persons or forces (such as gas or electricity), usually of a threatening nature, are operating or entering the home through the walls, ceilings, floors or doors, attempting to interfere. Hallucinations can also be seen in both EOS and LOS. Multimodal hallucinations (i.e. auditory, visual, sensory, gustatory and tactile) are characteristic of the late-onset group[2], while early-onset cases typically have auditory hallucinations only. Schneiderian first-rank symptoms, e.g. hearing a running commentary or two or more voices conversing, can be seen in both groups[3].

Important differences between early- and late-onset cases include infrequent formal thought disorder and fewer negative symptoms, such as affective flattening, in late-onset cases, as well as better premorbid functioning, including better occupational and marital histories. Mental functioning and personality remain relatively well preserved in late-onset cases. Jeste *et al*. compared three groups – younger persons with EOS, older persons with EOS, and LOS – and found a similar overall pattern of neuropsychological impairment, but with some slight differences favouring the late-onset group[4]. Likewise, a recent review by Rajji and Mulsant compared older patients with EOS versus LOS and found them to be equally cognitively impaired, exhibiting deficits in executive functioning, visuo-spatial ability and verbal fluency[5]. Both groups respond well to neuroleptics but later onset cases have a more favourable short-term prognosis than those with onset before 40. In spite of the many similarities, the preservation of personality and lack of deterioration in function lead some experts to challenge the inclusion of later onset cases in the traditional definition of schizophrenia.

INTERPRETATION OF EPIDEMIOLOGICAL DATA

Epidemiological studies of schizophrenia and associated disorders in the elderly face several challenges. First, terminology has changed over time. In 1912 Emil Kraepelin introduced the term 'paraphrenia' to describe a condition characterized by schizophrenia-like delusions and hallucinations not associated with mood disorder, but in the last edition of his text book classified such individuals as having schizophrenia because the course of their illness followed that disease. Roth later revived and modified the phrase 'late paraphrenia' to describe a late-life-onset disorder characterized by prominent paranoid delusions but an absence of social and functional deterioration[6].

Second, diagnostic criteria pertaining to age cut-offs have changed over time. Prior to DSM-III-R, schizophrenia could not be diagnosed in individuals who had onset of symptoms after age 44. Beginning with DSM-III-R, onset after 44 was allowed but cut-offs for what could be defined as 'late-onset' schizophrenia have varied. More recently, a consensus statement proposed by an international group of experts in the field defined late-onset schizophrenia as arising after 40 years of age and very-late-onset schizophrenia-like psychosis (VLOSLP)as arising after 60 years of age[7].

Methodological challenges are a third reason why estimates of the incidence and prevalence of schizophrenic illness in late life vary widely. For example, suspicious individuals are more likely to refuse to participate in population-based surveys and this is compounded by the likelihood that such individuals are socially isolated. Furthermore, individuals with cognitive impairment are often excluded from studies in both community and institutional settings, resulting in an underestimate of the true incidence and prevalence of psychosis in the elderly. Finally, since the prevalence of psychotic disorders is much lower than that of cognitive or affective disorders, misattribution of psychotic symptoms to these other disorders is likely.

INCIDENCE AND PREVALENCE OF PSYCHOTIC DISORDERS

Methodological challenges aside, the incidence and prevalence of psychotic disorders in late life are rather low. Data from community samples suggests that the prevalence of schizophrenia is 1% or less in older age groups, regardless of age of onset. The Epidemiologic Catchment Area Study[8], a large multisite community survey in the United States conducted in the early 1980s, estimated the prevalence of schizophrenia in the community to be 0.6% in the age group 45–64 years, and 0.2% in the 65 and over age group using DSM-III criteria. These rates were approximately one-half that of the younger age groups. Almost twenty years later, Copeland *et al*. sampled general practitioner lists in the UK and found similarly low rates of DSM-III-R schizophrenia (0.12%) and delusional disorder (0.04%) in the 65+ age group[9]. Copeland's group also reported on incidence, with 3.0 new cases of schizophrenia and 15.6 cases of delusional disorder having developed per 100 000 per year.

In a recent large study of the prevalence of psychotic disorders in the Finnish population, Perala *et al*. reported DSM-IV schizophrenia in 1.15% of 45–54 year-olds, 0.86% of 55–64 year-olds and 0.92% of those aged 65 and over. Almost 0.5% of the 65 and over age group met criteria for delusional disorder, whereas delusional disorder was not found in persons under age 45[10]. It is important to note that Perala *et al*.'s use of multiple sources of information, including case notes, may have resulted in higher prevalence estimates. Incidence estimates primarily come from clinical samples and suggest that the development of schizophrenia in late life is rare.

In 1975 Kay used first-admission data from England and Wales to assess the incidence of LOS and found the rates of schizophrenic illness (broadly defined) in ages 65+ to be 10–15 and 20–25 per 100 000 per year in men and women, respectively[11]. These estimates were similar to those reported years later by Holden, with an estimated annual incidence of VLOSLP between 17 and 24 per 100 000 population[12]. The incidence of LOS was reported in another Camberwell study to be 12.6 per 100 000, half that for the under 25 age group. Conversely, van Os *et al*., using first-admission data, found that, over the age of 60, the annual incidence of schizophrenia-like psychosis increased by 11% with each 5-year increase in age[13].

INCIDENCE AND PREVALENCE OF SINGLE PSYCHOTIC SYMPTOMS

The prevalence of psychotic symptoms in the elderly in disorders other than LOS and VLOSLP is high. For example, estimates of the point prevalence of isolated persecutory or paranoid ideation in the general elderly population are between 4% and 6%, while the incidence of auditory hallucinations and delusions in community-dwelling elderly has been estimated at 6.0% over a period of 3.6 years. Tien's analysis of ECA data showed a general rise in the incidence of hallucinations, including auditory, visual and somatic, with advanced age, especially after about age 65 or 70[14]. Visual hallucinations have been shown to be significantly associated with visual impairment in the elderly. The label Charles Bonnet syndrome is applied to isolated vivid visual hallucinations seen in the setting of ocular pathology, in which insight is at least partially retained. Among non-demented 85-year-olds in Sweden, Ostling and Skoog reported the prevalence of hallucinations as 6.9%; 5.5% had delusions and 6.9% had paranoid ideation not of delusional proportions[15]. Similarly high prevalence estimates were also found in a later sample of non-demented 95-year-olds[16]. As noted above, these high rates are likely due, at least in part, to the use of multiple sources of information, such as key informants and medical records, rather than a reliance on examination by researchers alone. In a related study, Ostling's group also reported a cumulative incidence of first-onset psychotic symptoms at almost 20% in non-demented elderly who survive until age 85.

RISK FACTORS SEEN IN ASSOCIATION WITH LOS AND VLOSLP

The most prominent risk factor associated with late-onset schizophrenia is female gender, with the ratio of women to men being approximately 7:1. Incidence curves for men and women also differ, with early-onset cases developing on average one decade later in women. Hearing loss and ocular pathology also appear to be risk factors. In a review of 27 studies of sensory impairment in psychotic patients, a significant association was found between hearing impairment and late-onset schizophrenia or paranoid disorder[17]. Premorbid schizoid and paranoid personality traits are further risk factors that predispose to the development of schizophrenia. Because very-late-onset cases often live alone, social isolation is thought to play a role. In general, family history of psychotic disorder is less common than in early-onset cases, although the evidence for genetic factors is inconsistent. Some studies have found no increased prevalence of schizophrenia in the first-degree relatives of late-onset schizophrenic probands, while others have determined the risk to be intermediate between that of the general population and earlier-onset cases. Some immigrant populations have also been shown to have significantly higher rates of VLOSLP than indigenous elders.

LONGITUDINAL COURSE AND LATER DEVELOPMENT OF DEMENTIA

Not much is known about the long-term course of schizophrenia in the elderly because most longitudinal studies provide data for only several years. The Vermont Longitudinal Study[18] is exceptional in that it prospectively followed a large cohort of chronic patients, most of whom had been diagnosed with DSM-I schizophrenia at a young age, for over thirty years after their release from the

state hospital. Harding found that one third to one half of these patients did not have the expected deterioration and actually showed functional improvement. In the second part of this study[19], Harding *et al*. reassessed the patients and found that almost one half of those who retrospectively met criteria for DSM-III schizophrenia at their index hospitalization had no symptoms (either positive or negative) at follow-up. Harding's studies demonstrate the heterogeneity of functioning at outcome, even when more stringent diagnostic criteria for schizophrenia are used.

Outcomes related to the development of dementia have been of particular interest. In 1955, Roth published the results from his landmark study of a group of 'late paraphrenia' patients, in which only 1 out of 45 patients (i.e. 2%) went on to develop dementia after 3–4 ½ years of observation[6]. Many years later, using Roth's criteria, Holden found higher rates, reporting that 13 out of 37 (i.e. 35%) patients with late paraphrenia progressed to dementia within 3 years of follow-up[12]. Overall, most studies of LOS and VLOSLP have shown that cognitive deficits are relatively stable over time and that these disorders are not precursors to the development of dementia[20]. It has been reported that hallucinations, especially visual, but not delusions, predict the later development of dementia[21]. Korner *et al*. recently studied the Danish nationwide registers of all hospital in- and outpatients making first-ever contact with late (≥ 40 years of age) or very-late (≥ 60 years) schizophrenia or osteoarthritis during an eight-year period[22]. Over twenty thousand individuals were identified and followed to a first diagnosis of dementia. Korner's group demonstrated that, when compared to patients with osteoarthritis, patients with late as well as very-late first-contact schizophrenia have a three times higher risk of subsequently getting a first diagnosis of dementia.

Clinical Assessment and Differential Diagnosis

David N. Anderson

Mossley Hill Hospital, Liverpool, UK

The schizophrenias of late life, previously called late paraphrenia[1] and paranoid states in old age, present fascinating, complex, biopsychosocial problems that span the whole of psychiatry and medicine. The characteristics and associations of schizophrenia with onset in later life have been summarized by an international consensus group[2]. These conditions usually present with paranoid ideation, most commonly persecutory in nature, with or without other schizophrenia-like symptoms.

The central abnormality implied by the term 'paranoid' is a morbid distortion of beliefs, but not all distorted beliefs are delusions and not all elderly people expressing them are mentally ill. Many aspects of old age increase vulnerability, exposing elderly people to abuse and victimization, and a thoughtful appreciation of this situation is needed when assessing the paranoid elderly patient. Furthermore, not all patients with delusions have schizophrenia[3] and the first aim of assessment will be to clarify the nature of paranoid symptoms and consider a differential diagnosis. In most cases a diagnosis will be clear from the detailed historical account of symptoms and their course, abnormalities of mental state and simple physical investigations. Assessment must, then, evaluate the individual's level of functioning, independence, vulnerability, social and family support, and physical health, which will all be of relevance to aetiology and management. The assessment will aim to consider patients and their symptoms within the wider context of their social environment, and physical and psychological limitations. It is, therefore, necessary to have knowledge of premorbid personality, lifestyle, life experience and cultural background, remembering that young and older generations have important cultural differences.

Ideally, the assessment will take place in the patient's home, when environment may be maximally appreciated. Home assessment provides a more complete picture of the patient's circumstances and helps put the problem into a living context. Commonly, paranoid ideas in old age relate to the patient's immediate, local environment and people within it. Herbert and Jacobson[4] used the term 'partition delusions' to describe the belief that things were happening just the other side of the wall, floor or ceiling. Post[5] found that paranoid symptoms often temporarily disappeared when the patient was removed from the hostile environment, which can give a misleading impression of their nature and a reason to avoid admission to hospital when it will become difficult to gauge response to treatment.

The floridly deluded and hallucinated patient is easily recognized, but in old age paranoid ideation may be almost plausible when complaints of being abused, victimized, stolen from or manipulated are not beyond the bounds of possibility. Trying to establish the validity of such claims requires observation and information from a variety of sources.

Table 96.1 Differential diagnosis

Delirium
Dementia
Organic delusional/hallucinatory disorder, secondary to physical illness or drugs
Late-onset schizophrenia
Delusional disorder
Depression
Mania
Schizoaffective disorder
Paranoid personality disorder
Factual (basis in fact)
Sensory impairment

We need, first, to consider the differential diagnosis of paranoid symptoms (Table 96.1) and how clinical assessment helps to differentiate diagnostic categories before discussing the process of assessment in more detail.

DIFFERENTIAL DIAGNOSIS

The point prevalence of paranoid ideas in the general elderly population is 4–6%[6–8]. A population-based study from Sweden found 8% of non-demented 70-year olds developed first-onset psychotic symptoms during a 20-year follow-up and of those surviving to age 85 the cumulative incidence was 20%[9]. These were most commonly visual hallucinations and persecutory delusions. The more common conditions will be reviewed briefly from the perspective of clinical differentiation, although for detailed consideration reference should be made to the relevant chapters.

Delirium (Acute Confusion)

The history is short, usually days or a few weeks, and the onset rapid. A structured assessment, using validated instruments, of 100 people with delirium (17% also had dementia) found 50% experienced perceptual disturbances and hallucinations and 31% delusions[10]. These are typically poorly organized, fluctuating and variable in content,

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

while hallucinations most commonly occur in the visual modality and can be vivid and complex. Other features of delirium will normally be present.

Alcohol intoxication and withdrawal from alcohol, benzodiazepines and barbiturates may all cause paranoid delirium, and withdrawal syndromes should be particularly considered when psychosis develops shortly after a hospital admission.

Dementia (Chronic Confusion)

Ballinger *et al.*[11] found delusions and hallucinations in 38% and 34%, respectively, of 100 dementia admissions. Another study of 178 Alzheimer's patients revealed persecutory ideation (20%), delusions (16%) and hallucinations (17%) to be common[12]. Fifty per cent of patients with multi-infarct dementia may have delusions at some time[13]. Paulsen *et al.*[14] reported a cumulative incidence for hallucinations and delusions of 51% over four years for people with probable Alzheimer's disease. The clinical course of diffuse Lewy body disease is particularly characterized by psychotic symptoms, and visual hallucination is a defining characaterisic[15]. In this case the hallucinations may precede other evidence of the disorder.

The manifestations of progressive, global, cognitive impairment will usually be present, although dementia may present with paranoid symptoms that can be indistinguishable from functional illness[16]. Paranoid ideas are frequently related to cognitive deficits, especially memory, leading to accusations of theft or problems arising from perceptual difficulties and misidentification[12]. Like delirium, these fluctuate and may be ferociously denied, or forgotten, at interview, although the theme and content remain fairly consistent.

Depression

If depression is of delusional proportions, biological and characteristic depressive symptoms are usually marked. Delusions and hallucinations, occurring in all sensory modalities, are normally mood-congruent but incongruent symptoms occur and may be difficult to distinguish from those of primary paranoid disorders.

Kay *et al.*[17] suggested six historical variables that help distinguish affective and paranoid psychoses: life events and family history of affective illness favoured an affective diagnosis, while low social class, few surviving children and social deafness favoured paranoid disorder. Premorbid personality proved the best discriminator, with paranoid patients being solitary, shy, touchy, suspicious and emotionally aloof, and patients with affective disorders reporting subjective ratings of high premorbid anxiety.

Mania

Traditional teaching suggested that mania in old age was both rare and atypical in presentation. Broadhead and Jacoby's[18] prospective study found that young and older-onset patients were clinically very similar. The onset of mania in old age is more common than once thought[19] and the majority of patients will have a history of affective disorder, some 50% having had three or more depressive episodes, with a latency of 15–17 years from first depression to mania[18–21].

Organic Delusional/Hallucinatory Disorder

Paranoid hallucinatory disorders have been associated with a variety of organic conditions[3,8,22–25] and pharmacological agents[3,26,27]. The symptoms may be typical of functional disorders[28] and the diagnosis depends on establishing a clear aetiological link and temporal relationships between a physical disorder or drug and mental disturbance. As Kay put it, 'Had the organic diagnosis not been reached independently of the psychiatric symptomatology, most of the cases would have been regarded as, indubitably, schizophrenic'[28].

The more common causes encountered in clinical practice include hypothyroidism, intra- and extracerebral tumours, epilepsy and cerebrovascular disease, and pharmacological agents such as psychostimulants, anti-parkinsonian and dopaminergic drugs, and steroids.

Possibly the most common is the psychosis of Parkinson's disease. This may be seen in the presence or absence of dementia complicating Parkinson's disease, and psychotic symptoms may occur at any stage. Up to 50% of people may develop psychotic symptoms and 30% experience visual hallucinations within the first five years[29,30]. Visual hallucinations are most common though auditory hallucination and delusions can occur.

Paranoid Personality Disorder

This is necessarily a life-long problem, which must be demonstrable from early adulthood. It is characterized by a sensitive and defensive attitude that causes people to feel they are victims of life and interpret events in a self-referential way. The effects of ageing and the vicissitudes of later life may accentuate these traits and, if dementia or functional illness supervenes, will colour the symptomatology.

Late-onset Schizophrenia

The development of ICD-10[31] and DSM-IV[32] saw the disappearance of age-defined categories of schizophrenia. This reflects the evidence that the symptoms are essentially the same regardless of age, certainly positive symptoms. It is estimated that 23.5% develops after age 40[33], and first admission data suggests the annual incidence of schizophrenia-like psychosis increases by 11% for every five-year period for people over the age of 60[34].

Though positive symptoms are similar regardless of age, negative symptoms are much less common with onset after age 60, when visual hallucination may be more common[2].

Familial risk and genetic contributions to aetiology decline with increasing age of onset. With onset over age 60, the association is weak but associations with sensory impairment, particularly deafness, and social isolation are more evident. These differences led an international consensus to recommend the nomenclature of late onset to refer to onset after age 40 and very late onset after age 60[2]. The preponderance of females in the very-late-onset group appears to be consistent, and very-late-onset cases seem more likely to have premorbid paranoid or schizoid traits though not amounting to personality disorder. Later onset is typically associated with better premobid educational, occupational and psychosocial functioning than early onset[2].

However, prevalence and gender ratio have been shown to vary in a study of first contacts with onset after age 60 in migrant populations in London[35,36].

Roth and Kay[37] provide a thoughtful discussion of the apparent similarities and differences of the associated features of late- and early-onset schizophrenia.

Delusional Disorders

These are conditions characterized by a persistent, circumscribed delusional theme, and if hallucinations occur they are not prominent.

They are defined by their delusional content, which may be erotic, jealous, hypochondriacal, persecutory or grandiose. These conditions have not been the subject of systematic study in old age, when they are thought to be relatively rare[26]. Onset is usually in middle age but as patients normally function well outside their particular delusion and symptoms frequently persist, they may present in old age. Unlike late-onset schizophrenia, delusional disorder seems not to be associated with premorbid paranoid personality or deafness[38], although querulent paranoia has been related to deviant personality structure[39].

Familially they appear unrelated to affective or schizophrenic illnesses[40,41]. Howard *et al*.[42] found dilatation of lateral and third ventricle volumes by magnetic resonance imaging (MRI) to be more a feature of delusional disorder than schizophrenia in old age, as defined by ICD-10 criteria.

A small retrospective study comparing paraphrenia (schizophrenia of late onset) with paranoia (delusional disorder of late onset) found cerebral infarction on CT brain scan to be a feature of paranoia rather than paraphrenia. Furthermore, social isolation and being unmarried were not features of paranoiacs with cerebral infarction, suggesting separate groups defined by organic or social associations. Response to antipsychotic drugs was worse for paranoia[43].

ASSESSMENT

Interview

Interviewing paranoid elderly people may be complicated by deafness, speech problems or visual handicap, so time and patience are essential. An informant history is mandatory and often several sources may be required.

It is crucial to establish the interview situation, explain its purpose, allay anxieties and put patients at their ease. Many patients will be anxious and fearful. The patients should decide whether they prefer to be seen in private or with a confidant(e) as another's presence may equally inhibit or encourage the disclosure of sensitive material. For similar reasons an informant may wish to speak privately though discussions should never appear clandestine.

Deafness and communication problems should be openly acknowledged, hearing aids worn and working, and extraneous noise eliminated, otherwise false impressions of cognitive state may be formed. If a patient is seen in a hospital setting, insist on a separate, quiet interview room, otherwise conversation will be inhibited and information lost. Posture and attitude convey sincerity, concern and how seriously problems are considered. The patient needs to form a trusting relationship, and a respectful, honest but never patronizing approach is normally accepted. A sympathetic hand can reassure and encourage an anxious or fearful patient.

The importance of establishing a positive therapeutic relationship at this early stage cannot be overstated, as it can have far-reaching effects, not only for the openness of discussion but also for future compliance and prognosis.

History

The nature of psychotic symptoms, their form, content and course must be detailed. Late-onset schizophrenia may develop insidiously over months or a year or more, delusional depression over weeks or a few months, delirium over days and dementia over one to two years. The intensity of paranoid ideas and their effect on behaviour assist diagnosis and the evaluation of risk. Associated symptoms, particularly affective and cognitive, should then be elicited.

Current and past medical problems and their temporal relationship to the onset of paranoid symptoms must be clearly established, including visual or auditory failure. Aetiologically significant hearing loss in very-late-onset schizophrenia is typically of long duration, severe and due to bilateral middle ear disease, often originating in early life. Details of prescribed and non-prescribed drugs, dosages and recent alterations are essential.

Previous episodes of mental disorder should be confirmed from medical records, when past diagnoses and response to treatment may quickly clarify a diagnostic dilemma. Careful enquiry might uncover past episodes of untreated, self-limiting illness, and changes in behaviour may date the onset of current problems.

Premorbid personality and behaviour are important because departures from these in old age usually signify the onset of a morbid process. Forty to fifty per cent of late-onset schizophrenics have schizoid or paranoid premorbid traits[2,3] and the diagnosis of personality disorder depends on establishing a life-long attitude. Brenes Jette and Winnett[44] emphasized the interaction of narcissistic personality traits and the psychosocial consequences of ageing in their psychodynamic formulation of late-onset paranoid disorder.

The genetic loading of schizophrenia in old age is less marked than with younger patients but a positive family history may be found. Odd behaviour or suicide among family members may be discovered when formal psychiatric treatment is absent.

Current social circumstances and recent change are of relevance to aetiology and management. The schizophrenias of late life are particularly associated with social isolation, but rarely with precipitating life events. Paranoid patients frequently have poor socioeconomic status and multiple difficulties[6], and social support has prognostic implications. Enquiring about alcohol and drug abuse must not be avoided for fear of offending a respectable elderly person. The elderly are not without vice and may be less inclined to confess it.

Mental State Examination

The detailed psychopathology of these conditions is described elsewhere and only points relevant to the process of mental state examination in this context will be mentioned here.

It is important to ensure that the patient understands the terminology used to elicit abnormal experiences and that a common language is being used. Eliciting paranoid and psychotic symptoms can be difficult, but with tact and careful choice of words most patients will participate in an exchange of ideas about their experiences. This must be an unthreatening process for the patient and it is unwise to challenge or trivialize complaints at an early stage. A neutral position is advisable until a firm relationship is established, when complaints may be gradually reframed so that they can be viewed by the patient as problems that can be relieved, rather than unchangeable realities that are not amenable to therapeutic intervention. Suggesting that 'it's all imagination' will be considered insulting and the patient's confidence will be lost.

Perceptual disturbance, thought process and content, mood and cognitive function are areas of particular focus.

Insight is rarely retained and patients may not volunteer experiences if they interpret questions as purely an enquiry into the state of their health. Patients have limited ability to accept the presence of illness or recognize psychiatric experiences as pathological[45]. Needless to say, the mental state examination must be thorough.

Physical Examination

A complete physical examination should be performed routinely, with particular emphasis on neurological status and sensory function. The association between sensory impairment and very-late-onset schizophrenia makes attention to this area important, and remediable conditions may be found. Visual impairment, particularly due to cataracts, is often found in association with delusions and deafness[46], and visual hallucinations may be as much to do with ocular pathology as psychiatric diagnosis[47]. A particular form of acute, elaborate visual hallucinosis, the Charles Bonnet syndrome, is usually related to eye disease or cerebral organic disorder[48]. Simple clinical interview and self-reporting underestimate sensory impairment, and more detailed ophthalmic and audiometric examination may be necessary. A simple battery of laboratory investigations is required for all patients, including haematology, biochemistry, thyroid function, urinalysis and chest radiography.

Advanced neuroradiological techniques promise much for the future but have limited clinical application at the present time. Some authors recommend the routine use of computed tomography (CT) and magnetic resonance imaging (MRI).

Structural cerebral abnormalities, including increased ventricular size and volume reduction in various brain areas, are found in schizophrenia regardless of age at onset[2] and deep white matter hyperintensities in depression of late onset[49]. They appear to bear little relationship to clinical state or outcome in the schizophrenia-like disorders[50,51] but in mood disorder may indicate relative treatment resistance and associated executive dysfunction[52]. Structural imaging is important for excluding conditions like space-occupying lesions.

Functional imaging also shows abnormalities in schizophrenia and depression[2,52].

In dementia neuroimaging has diagnostic significance and has become a routine procedure. MRI is recommended in all cases of dementia[53] and single photon emission computed tomography (SPECT) has considerable diagnostic power in dementia associated with Lewy bodies and Parkinson's disease[54–56].

Psychometric testing may provide a useful baseline measure that can be serially repeated when the possibility of dementia arises. Psychometric testing certainly reveals cognitive deficits in late-onset schizophrenic patients, particularly affecting frontal lobe and memory function[2]. These rarely signify dementia and are more like the deficits found with early-onset schizophrenia than Alzheimer's disease. They do not correlate with severity of psychosis or other clinical parameters. However, it appears that late-onset schizophrenia or psychotic symptoms, particularly visual hallucinations, do predict an increased risk of dementia[9,57].

CONCLUSION

Most patients with late-onset schizophrenia, delusional disorders, dementia and psychotic symptoms will be adequately and preferably managed from home. The need to admit to hospital seems to have declined[58] and may be determined more by social and physical factors or treatment compliance as degree of psychopathology. This is unlikely to be the case for conditions like delirium or psychotic mood disorder, which are often life threatening. For the patient requiring more than outpatient treatment, a day hospital can provide more intensive assessment of mental state, physical health and functional level.

The multifactorial contributions from ageing, physical disability, sensory impairment and social factors demand a multi-professional approach and all relevant disciplines must be available and involved. The evaluation of these conditions requires clinical skill, rigorous attention to detail and a holistic approach. The accuracy of diagnosis and success of management will depend on the quality of initial assessment and if diagnostic doubts exist, treatment should be postponed until the situation becomes clear. Occasionally a diagnostic trial of treatment will be justified.

The paranoid disorders of old age are stimulating, complex, challenging clinical problems that encompass the breadth of psychiatry, medicine and social sciences in their assessment and management.

Treatment of Late-Life Psychosis

Peter Connelly and Neil Prentice
Murray Royal Hospital, Perth, UK

The treatment of late-life psychosis raises a considerable number of practical and ethical issues. People with this diagnosis are likely to have developed the prodrome of their illness over a significant period of time, often measured in years, during which they might have been considered to be 'eccentric' by the general public and by health and social service professionals. Reeves *et al*.[1] found an average duration of three years of formal symptoms prior to presentation to specialist services. Compared to people with affective disorders, historical data[2] would suggest that they are more likely to live alone and more likely to suffer hearing loss or other sensory impairment. A significant number[3] will have evidence of a premorbid paranoid personality, with associated poor interpersonal relationships, hypochondriasis, which may have alienated them from primary care services, and depressive symptoms, which inhibit their ability to initiate help-seeking behaviour. Although it is important to avoid stereotypes, and to recognize that people with psychosis in late life tend to have more family contact than younger adults with schizophrenia[4], the description of a typical case in the key study by Kay *et al*.[5] of a shy, reserved, touchy, suspicious person with difficulty in maintaining or establishing relationships and less likely to display sympathy towards their peers, may lead to individuals with late-life psychosis becoming intensely socially isolated with little in the way of external input during the development of their delusions, at a point where some rationalization of developing beliefs might have helped to prevent them becoming chronically established.

ETHICAL ISSUES

Although there is a fundamental need to protect the health and safety of individuals with late-life psychosis and that of their perceived persecutors – who are often neighbours or relatives – immediate recourse to emergency mental health legislation may undermine the potential to develop a therapeutic relationship in which the necessary challenges to their delusional thinking can take place. The elderly person with a well-developed and long-standing delusional system is unlikely to accept that it is they who are suffering from an illness. Much more likely they will be of the view that some intervention is required to deal with the people who are causing them problems. Patients who are intensely frightened at the thought of others being able to get into their house, despite often elaborate security systems, may well be willing to consider a change of location or temporary admission to hospital, but in many cases the only option will be to try to treat people with late-life psychosis in their existing environment. Legislation may well become necessary if there is evidence of severe self-neglect, violence or other offending behaviour towards those involved in their delusions or their property.

Persuading the patient with chronic delusions or hallucinations to take antipsychotic drugs can be problematic. Such patients will see no logic in the view that were they to take a drug it would somehow change the behaviour of people in the next block of flats. Suggesting that someone takes an antipsychotic as a way of 'protecting their body' while professionals have the opportunity to get to work on their persecutors to try to reduce the frequency or intensity of their alleged toxic behaviour can be seen as coercive and out of keeping with existing legislation on mental capacity, yet such an explanation may be readily understandable to a patient who has taken steps to protect the fabric of their property from toxic waves or sprays and is in keeping with the non-confrontational exploration of beliefs necessary to try to build cooperation. People who are fearful may accept that antipsychotics or antidepressants may have a role in reducing anxiety and agree to take medication but even with this explanation an ethical debate will continue. Although there does not appear to be specific literature on this topic, it may be surprising to find that whatever explanation has been given to the patient about antipsychotics, compliance with treatment can be surprisingly good.

DRUG THERAPY

While antipsychotics are used extensively in older patients to treat a variety of symptoms, including psychotic symptoms as features of behavioural and psychological symptoms in dementia, much of their use in treating late-life psychosis is inferred from studies of treatment for psychosis in younger patients. This is particularly problematic since older patients are more likely to suffer from major physical illness as a co-morbid feature, and a number of studies have drawn into focus concerns about the over-use of antipsychotic medication, particularly in nursing homes[6], and excess mortality associated with antipsychotic prescribing in the elderly[7].

While the majority of people with late-life psychotic symptoms will have hallucinations and delusions from delirium secondary to a physical cause, as a behavioural and psychological symptom of dementia, or indeed as part of an affective illness, those with schizophrenia or other late-life psychosis comprise 0.1–0.5% of the population over the age of 65[8]. Of all people over the age of 65 with schizophrenia, the majority will have developed their illness prior to age 45[9]. While there are benefits from extrapolating data derived from adults

under 65, in the absence of large multicentre double-blind placebo-controlled studies into treatment of late-life psychosis, there are a number of problems associated with this approach. Primarily the difficulties fall into areas including metabolic side effects, increased risk of extrapyramidal side effects and movement disorder, and the problems of polypharmacy, co-morbid major physical illness and pharmacokinetic changes associated with ageing.

Typical antipsychotics have been used extensively in treating older people with psychosis despite the fact that their high affinity for dopamine D2 receptors is associated with increasing extrapyramidal side effects in older people[10]. In addition these medications tend to be sedating and associated with quite marked anticholinergic side effects, which can cause additional confusion and disorientation in patients with mild cognitive impairment or dementia. By contrast, atypical antipsychotics are associated with less in the way of significant side effects in older people[11] and less hospitalization by comparison to typicals[12]. Both olanzapine and quetiapine are associated with a lower incidence of extrapyramidal side effects than typical antipsychotics[13], though sedation can be problematic and there are additional issues in relation to olanzapine and increased risk of diabetes[14]. Risperidone has been used extensively principally because of the low incidence of sedation or anticholinergic side effects. Clozapine has been used extensively in younger patients, though hypersalivation, neutropaenia and increased risk of agranulocytosis, particularly in older patients, limit its use[15]. Much of the evidence for efficacy of antipsychotics in late-onset psychosis consists of case reports and open studies though these are at times conflicting and there is not clear evidence to suggest that atypical antipsychotics are any more effective in this group of patients. However, compliance is better[16].

In the absence of robust double-blind placebo-controlled data for meta-analysis, guidelines for management of late-onset psychosis focus primarily on the expert consensus approach. Focusing on the management of schizophrenia, the use of atypical antipsychotics is clearly favoured, with 93% of experts rating risperidone as first-line treatment in this group of patients, perhaps because of its low incidence of anticholinergic or sedative side effects. While quetiapine and olanzapine were also rated as first-line treatments by 67% of experts and aripiprazole by 60%, the doses recommended in this group of patients were higher than the treatment doses used in psychosis in dementia[17].

A recent study of attitudes to antipsychotic prescribing in Australian specialists working within old age psychiatry identified a preference for the use of atypical antipsychotics as opposed to typical antipsychotics in an elderly population although no clear preference for any individual atypical antipsychotic was apparent[18]. The principal reasons for this centred on the impression that not only were atypical antipsychotics less likely to be associated with adverse events, particularly in an elderly population who were more likely to be suffering from co-morbid physical conditions, but they were also perceived as being clinically more effective than typical antipsychotics. This was supported by clinical global impression of change data within the clinicians' own patient groups, where 33% of patients with schizophrenia were rated as having improved from moderately ill to mildly ill while on atypical antipsychotics. This is similar to rates of reduction in PANSS[19] total score for elderly patients with psychotic illness treated with amisulpride and risperidone[20] though a more recent open label study of amisulpride treatment for very-late-onset schizophrenia-like psychosis showed significant improvement over a variety of measures and 46.6% reduction in PANSS total score[21].

Taking into account the likelihood of co-morbid physical or psychiatric symptoms in elderly patients and the altered pharmacodynamics and pharmacokinetics of older people, the limited evidence available suggests that treatment with atypical antipsychotic medication may be useful. Although there are recent concerns in relation to increased cerebrovascular risk in older patients with dementia treated with atypical antipsychotic medication[22] and also concerns in relation to excess mortality associated with these drugs[7], their cautious utilization continues to be appropriate in the absence of any clear alternative treatments.

The use of depot medication may not lead to additional advantages. Reeves *et al*.[1] found that treatment response was not increased by the use of depot and concluded that regular contact with a community psychiatric nurse, an intervention likely to increase social exposure, may be as important in maintaining treatment response.

COGNITIVE BEHAVIOURAL THERAPY

The most common types of delusions are those of reference, control or hypochondriasis[23]. Partition delusions[24] are also over-represented in the late-life onset group. A detailed description of cognitive models and cognitive behavioural interventions lies outwith the scope of this chapter, but an understanding of the development of delusions comes from cognitive behavioural work with younger adults. Cognitive models have been used to explain delusion formation and maintenance[25]. Similar errors in attribution have been proposed as mechanisms leading to hallucinations[26], although some exploratory work to examine the cognitive aetiology of delusions in people with late-life psychosis[27,28] suggests that the wider range of cognitive distortions described in younger adults with schizophrenia may not be as pertinent in older people.

Bentall *et al*.[29] describe the development of persecutory thinking as a way of the person protecting themselves from perceived assaults on their self-esteem by allowing them to attribute negative events to external causes. Since many patients with late-life onset psychoses have a history of such attribution during most of their adult life, it is easy to understand the continuum of a person feeling that others are in some way hostile towards them, through the development of more eccentric beliefs with associated social withdrawal and finally explicit persecutory delusions in an intensely isolated individual. Protective behaviours become increasingly explicit and the picture of a chronically isolated, elderly lady sitting in a cold, dark house, unheated because she believes the neighbours are stealing her electricity through some tenuously understandable process, and covering surfaces of her furniture or cooking utensils with silver foil to prevent the effects of toxic spray used by the same neighbours will not be unfamiliar to clinicians treating this group of people.

Although techniques were first described by Beck in 1952[30], cognitive behavioural therapy (CBT) studies in people with psychosis began to appear more frequently in the early 1990s. The literature is well reviewed by Rathod *et al*.[31], who conclude that CBT has emerged as an effective adjuvant to antipsychotic medication in the treatment of schizophrenia. However, the guidelines of the National Institute for Health and Clinical Excellence in the UK[32] concluded that CBT may improve depressive symptoms but is unlikely to improve psychotic symptoms. Enlarging on this, a detailed review by Wykes *et al*.[33] suggested a clear relationship between the methodological quality of CBT studies and the effect size that they report, with better quality studies reporting a lower effect size.

Fewer CBT studies specifically report outcome with respect to delusions and hallucinations. Of these, fewer still involve a randomized design and report results with standard deviations. Durham *et al*.[34] is one of these few and they report no benefit for CBT over supportive psychotherapy in these domains. CBT was associated with a greater number of people achieving a 25% improvement in the overall PANSS score but with a relatively high number needed to treat of 13. No patient in this study was aged over 65 and only 2 (of 66) had delusional disorder. The review of long-term outcomes by Durham *et al*.[35] found a reduction of symptom severity when used for anxiety but not psychosis. McCulloch *et al*.[27] suggested that people with late-onset psychosis had no evidence of either overt depression or low self-esteem, so a different form of psychological approach may be required. Drawing conclusions about the effectiveness of CBT in late-life onset psychosis would be best done through quality research rather than extrapolation from younger people but limited benefits at best are likely to result. The improvement in socialization that may occur through engagement in CBT programmes may be at least as helpful[31].

There are few studies looking at interventions in middle or late life. Patterson *et al*.[36] described benefits in the field of everyday living skills among older Latino patients attending a specialized clinic in the USA, such as improved use of public transportation, but no significant change in psychopathology was noted in this pilot study. Granholm *et al*.[37] explored the effect of cognitive behavioural social skills training in a randomized controlled trial over 24 weeks. Again, social functioning was improved, though benefits in achieving greater insight into psychotic symptoms were not significant overall and were lost after a further six months follow-up[38]. Repetition of the programme led to no additional benefits[37], though social improvements were maintained at follow-up[38].

OTHER NON-PHARMACOLOGICAL INTERVENTIONS

A search of the Cochrane Database of Systematic Reviews reveals many interventions that have been tested in randomized controlled trials in people with schizophrenia. The list includes art therapy, music therapy, compliance therapy, assertive community treatment, distraction techniques, drama therapy and exercise. Of all the studies reviewed in these areas, virtually none include people over 65. The effects reported are influenced by the inconsistency of the data in many areas and it is difficult to recommend any of these be used routinely when dealing with someone with late-life psychosis.

One Chinese study[39] of a family psychoeducational programme included people up to 80 years old, but the number over 65 is not reported and would be very small. It is possible that group may have consisted of people with affective disorder rather than schizophrenia. The improvement in families of their understanding of the patient's illness and an improved problem-solving approach led to better treatment compliance by patients and less inappropriate care delivered by families. Although the culture in China is very different from Western society, these lessons are equally pertinent when considering how to maximize the effectiveness of mental health team input. The area of non-pharmacological interventions for late-life psychosis is likely to prove to be a fruitful ground for research.

UNMET NEED

There has been very little systematic research into the needs of older people with psychoses, especially the generation who have aged in an era where, in the UK at least, the emphasis on care provision in the community has been more common than dependence on long stay care.

McNulty *et al*.[40] interviewed 58 people over 65 with a mean of 75 years, 54 of whom had schizophrenia and 2 delusional disorder. They found a total of 152 'needs' in that population, i.e. a problem requiring action for which a suitable intervention exists but which has not been given a recent adequate trial. Of these 56 lay in the social field, with an absence of social life and accommodation problems being uppermost. This group found a considerable level of cognitive impairment among their population, with a mean Mini-Mental State Examination (MMSE) score[41] of 20/30 among their participants. This is considerably lower than a more recent London-based study[42], which found a mean MMSE score of 26.5 among its 77 participants. That group also found social activity, day care and housing among the needs unmet because of lack of service, although unmet needs because of patient refusal of social activity or day care was almost four times higher.

The higher prevalence of cognitive impairment in the former study may reflect the level of deprivation in their population, although a high level of young-onset dementia[43,44] and cerebrovascular disease[45] has also been described in the same geographical region. Services managing people with late-life psychoses should, however, be aware of the possibility of concurrent cognitive impairment, which may have detrimental effects on emotion, motivation and daily living skills, as well as further impairment of reasoning and judgement. This may complicate discussions about potential changes of accommodation, and capacity-based legislation may require to be used.

REHOUSING

The delusions experienced by people with late-life onset psychoses are often highly circumscribed and tend to be local to their present accommodation. However, although there is a plethora of literature which relates to how people hospitalized because of psychoses adapt to community living following discharge[46], there appears to be none which examines the effect of rehousing people in alternative accommodation in the community. In fact a systematic review of the health effects of housing improvement[47] found little evidence linking housing and health, and Blackman *et al*.[48] found that people over 50 had disappointing health improvement results when moved because of medical priority although this group was less likely than younger people to be rehoused on medical grounds.

LONELINESS

Among the consequences of chronic isolation resulting from late-life psychosis is the presence of loneliness. This may have adverse effects on physical health, particularly higher blood pressure, poor sleep and poor cognition[49]. The importance of regular physical health checks, in people who may have disengaged with health services over long periods of time, cannot be over-emphasized.

VIOLENCE

The traditional view that older people are rarely perpetrators of violence is somewhat dispelled by the Healthcare Commission National Audit of Violence 2006–2007[50], which found that more nurses on

older people's inpatient wards reported that they had been physically assaulted than in services for adults of working age. Although the risk of physical assault was greatest in services for people with organic disorders, more than half of the nursing staff on functional units had been assaulted.

Staff may be aware of the risk of potential assault when dealing with a delusional person at home and be careful about how they challenge the delusional beliefs. However, as Taylor[51] points out, relatives and friends may be much more blunt in their challenges and be at increased risk of violence. It may be necessary to include advice to the carer when formulating any treatment plan. This may include training relatives or friends in how to discuss delusional beliefs without exposing themselves to potential violence.

CONCLUSION

The treatment of older people with psychosis is an area in which high-quality research is limited. A clearer understanding of the needs of these people is required urgently. Up to one fifth of non-demented older people who survive to age 85 develop first-onset psychotic symptoms[52] and 2.4% of 95-year-olds meet operational criteria for schizophrenia[53]. An increased number of people with these disorders is inevitable.

As with younger adults, the use of drugs alone is insufficient to achieve stability. The place of psychological therapies is yet to be fully established and the need for an evidence base for both pharmacological and non-pharmacological interventions needs to be expanded. Reduction of social isolation and helping family members cope with the constant expression of delusional material will both help engagement with treatment. Attention to physical care and unmet social needs is vital. Realistically, the goal of treatment is to maintain people in the community and reduce the impact of symptoms. Long-term follow-up of the effects of relocation on individuals would help professionals decide on the risk and benefits of such a move.

Neuroses (Anxiety Disorders)

Nosology and Classification of Neurotic Disorders

David Bienenfeld

Department of Psychiatry, Wright State University Boonshoft School of Medicine, Dayton, OH, USA

INTRODUCTION

The grouping of a variety of psychopathological entities under the heading of 'neurotic disorders' represents the current attempt to solve a nosological tangle dating back further than the time of Sigmund Freud. The contemporary categorization is controversial and less than satisfying to many. A brief look at its historical roots offers some explanation of the sense behind the current ICD-10 and DSM-IV structures.

HISTORY OF THE CLASSIFICATION OF THE NEUROSES

It was Hippolyte-Marie Bernheim who introduced the term 'psychoneurosis' for hysteria and allied conditions. Freud, who studied with Bernheim, differentiated the 'actual neuroses' (including neurasthenia, anxiety neurosis and hypochondria) from the psychoneuroses. The latter category included not only the 'transference neuroses', such as hysteria and obsessive neurosis, but also the psychoses (paraphrenia, schizophrenia, paranoia and manic depression), perversions and neurotic character. Both types of neurosis were related to sexual disturbance; the actual neuroses were direct somatic consequences of a noxious physical influence resulting from misdirected sexual energy; the psychoneuroses were caused by unconscious conflict between instinctual and counter-instinctual forces[1]. Although Freud's thinking on the precise nature of the mental aetiology of the psychoneuroses changed over the years from about 1894 to 1906, he remained consistent in his stance that the psychoneuroses were defined by their aetiology rather than by their phenomenology[2]. Eventually, the psychoses were classified independently, consistent with the views of Kraepelin.

In 1952, the American Psychiatric Association published the first Diagnostic and Statistical Manual of Mental Disorders (DSM-I). It identified the subtypes of psychoneurotic disorders as anxiety, dissociative, conversion, phobic, obsessive-compulsive and depressive reactions[3]. By the mid-1960s, the major diagnostic schemata, ICD-8 and DSM-II, codified the selection of the descriptive framework for identifying the neuroses. Anxiety was seen as the chief characteristic, whether felt and expressed directly or diverted unconsciously into other symptoms. The neuroses were also grouped by severity; they were more specifically symptomatic than the personality disorders, but entailed no gross distortion or impairment of reality testing, as in the psychoses. Categories included in the 300-code section were anxiety, hysterical, phobic, obsessive-compulsive, depressive, neurasthenic, depersonalization and hypochondriacal neuroses. Transient situational disturbances constituted their own category (code 307)[4].

The descriptive focus was emphasized in ICD-9 with the substitution of the term 'neurotic disorders' for 'neuroses', although the categorization was not significantly modified[5]. In 1980, the American Psychiatric Association published the DSM-III[6], which took a substantial leap towards atheoretical descriptive diagnosis by adopting empirically validated criteria based on research diagnostic criteria. One of the most controversial changes was the elimination of the entire class of neuroses. The neurotic disorders were included in the affective, anxiety, somatoform, dissociative and psychosexual disorders[7]. The grouping by severity was abandoned in favour of clusters based on similarity of features. The diagnostic entities retained numerical codes compatible with ICD-9 and ICD-9-CM.

The other revolutionary change introduced with DSM-III was the use of a multiaxial system for diagnosis. Under this scheme, personality disorders, which often predispose individuals to the development of specific neurotic (and other) syndromes, were relegated to a separate and parallel Axis II. The 1987 revision, DSM-III-R, changed some names and criteria but retained the same hierarchy of the neurotic disorders and the same multiaxial formula[8]. DSM-IV, published in 1994, was a more substantive revision overall than DSM-III-R, with only a few changes relevant to the neurotic disorders. The diagnosis of Acute Stress Disorder was added for compatibility with ICD-10. Dissociative Identity Disorder was added to Axis I to replace Multiple Personality Disorder, which was removed from Axis II. Simple Phobia was renamed Specific Phobia for compatibility with ICD-10[9].

Neurotic Disorders in ICD-10 and DSM-IV

The creators of ICD-10 were faced with a formidable challenge, as this version, unlike its nine predecessors, was to be designed as the last of the series to be scheduled for regular revisions[10]. It therefore had to contain a format that would allow for flexibility in minor revisions while establishing a more permanent structure than versions 1–9. While following the lead of the phenomenological school in separating out a major category for mood disorders that includes both psychotic and neurotic levels of severity, it retains the major classification of neurotic disorders, including somatoform

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

disorders and stress-related disorders[11]. This grouping solves the objection that the term 'neurosis' groups together entities which could be better classified, e.g. by placing neurotic types of depression together with other mood disorders, rather than with anxiety disorders. It does, however, retain the historical commonality that traces to Freud's original stress on the aetiological similarity of the psychoneuroses, acknowledging the current state of scientific knowledge that is, at best, ambiguous concerning the aetiology of these disorders[12,13].

Table 98.1 compares the relative positions of the neurotic disorders in ICD-10 and Axis I of DSM-IV. The alphanumeric organization of the International Classification requires the constraint of all mental disorders to 10 major categories. DSM-IV, under no such limitation, separates out anxiety, somatoform and dissociative disorders but keeps them within the same gradient of severity between mood disorders and sexual disorders. Adjustment disorders are removed to a position implying less severity, as well as an implied direction that higher ranking diagnoses are to be made or eliminated first. Personality disorders, of course, are assigned to Axis II.

Under the category of the neurotic disorders, the international and American systems differ in their organization, as outlined in Table 98.2. DSM-IV groups the phobic disorders, obsessive compulsive disorder, post-traumatic stress disorder and generalized anxiety disorder together as anxiety disorders. ICD-10 separates phobic disorders, anxiety disorders and obsessive compulsive disorders. Post-traumatic stress disorders are classified with adjustment disorders. Both schemes separate dissociative and somatoform disorders. ICD-10 groups conversion disorder with dissociative states, consistent with the historical, aetiologically based classification of the hysterias. DSM-IV combines it with the somatoform disorders, based on their phenomenological similarities. ICD-10 retains the diagnosis of neurasthenia; while DSMIII- R refers the clinician to dysthymia, categorized unequivocally as a mood disorder, DSM-IV eliminates the term entirely[8,9,11].

DIAGNOSTIC FEATURES OF NEUROTIC DISORDERS

While each of the major categories of neurotic disorders is described in the chapters that follow, the clinical features of the seven ICD-10 groupings are presented here for overview and comparison[11].

Phobic disorders are a set of disorders in which anxiety is invoked only, or predominantly, by well-defined situations that are not in themselves dangerous. By definition, the object of the fear is external to the individual, so that fears of bodily processes are more appropriately relegated to the category of somatoform disorders. The feared objects are characteristically avoided, and anticipatory anxiety is common.

Other anxiety disorders are those in which anxiety is the major symptom but which are not restricted to specific situations. They include panic disorder, generalized anxiety disorder, and mixed anxiety and depressive disorder. The latter is reserved for cases where symptoms of both are present, neither is predominant, and the depression is not severe enough to be classified under mild depressive disorder.

Obsessive-compulsive disorder is characterized by recurrent obsessional thoughts or compulsive acts, or both. These thoughts and acts are subjectively distressing. Subjective anxiety is usually present and depressive features are common.

Reactions to severe stress and adjustment disorders represent a unique category, in that the component disorders are identified on the grounds of both symptomatology and causation. In these disorders, anxiety follows an exceptionally stressful life event or a significant life change. While psychosocial stressors may precipitate a wide variety of psychiatric syndromes, they are elsewhere neither necessary nor sufficient to explain the occurrence and form of the disorder. The stress and adjustment disorders, however, are seen as arising as a direct consequence of the trauma or life change.

Dissociative disorder is a group of entities that share a partial or complete loss of the normal integration between memory of the past, awareness of identity and immediate sensations, and control of

Table 98.1 Relative positions of neurotic disorders in the diagnostic schemata

ICD 10	*DSM-IV*
F0 Organic mental disorders	Disorders usually first evident in infancy, childhood or adolescence
F1 Mental and behavioural disorders due to psychoactive substance uses	Delirium; dementia and amnestic and other cognitive disorders
F2 Schizophrenia, schizotypal states and delusional disorders	Mental disorders due to a general medical condition not elsewhere classified
F3 Mood disorders	Substance-related disorders
F4 NEUROTIC, STRESS-RELATED AND SOMATOFORM DISORDERS	Schizophrenia and other psychotic disorders
F5 Behavioral syndromes and mental disorders associated with physiological dysfunction and hormonal changes	Mood disorders
F6 Abnormalities of adult personality and behaviour	ANXIETY DISORDERS
F7 Mental retardation	SOMATOFORM DISORDERS
F8 Developmental disorders	DISSOCIATIVE DISORDERS
F9 Behavioural and emotional disorders with onset usually occurring in childhood or adolescence	Factitious disorders
	Sexual and gender identity disorders
	Eating disorders
	Sleep disorders
	Impulse-control disorders not elsewhere classified

Table 98.2 Classification of neurotic disorders

ICD-10	*DSM-IV*
F40 *Phobic disorder*	*Anxiety disorders*
40.0 Agoraphobia	300.21 Panic disorder with agoraphobia
.00 Without panic disorder	300.01 Panic disorder without agoraphobia
.01 With panic disorder	300.22 Agoraphobia without history of panic disorder
40.1 Social phobias	300.29 Specific phobia
40.2 Specific (isolated) phobias	300.23 Social phobia
F41 *Other anxiety disorders*	300.3 Obsessive-compulsive disorder
41.0 Panic disorder	309.89 Post-traumatic stress disorder
41.1 Generalized anxiety disorder	308.3 Acute stress disorder
41.2 Mixed anxiety and depressive disorder	300.02 Generalized anxiety disorder
F42 *Obsessive-compulsive disorder*	*Somatoform disorders*
42.0 Predominantly obsessional thoughts	300.81 Somatization disorder
42.1 Predominantly compulsive acts	300.11 Conversion disorder
F43 *Reaction to severe stress and adjustment disorders*	307 Pain disorder
43.0 Acute stress reaction	300.7 Hypochondriasis
43.1 Post-traumatic stress disorder	300.7 Body dysmorphic disorder
43.2 Adjustment disorder	*Dissociative disorders*
.20 Brief depressive reaction	300.12 Dissociative amnesia
.21 Prolonged depressive reaction	300.13 Dissociative fugue
.22 With predominant disturbance of other emotions	300.14 Dissociative identity disorder
.23 With predominant disturbance of conduct	300.6 Depersonalization disorder
.24 With mixed disturbance of emotions and conduct	*Adjustment disorder*
F44 *Dissociative and conversion disorder*	309.0 With depressed mood
44.0 Psychogenic amnesia	309.24 With anxiety
44.1 Psychogenic fugue	309.40 With mixed disturbances of emotions and conduct
44.2 Psychogenic stupor	309.28 With mixed anxiety and depressed mood
44.3 Trance and possession states	309.3 With disturbance of conduct
44.4 Psychogenic movement disorders	
44.5 Psychogenic convulsions	
44.6 Psychogenic anaesthesia and sensory loss	
F45 *Somatoform disorders*	
45.0 Multiple somatization disorder	
45.1 Undifferentiated somatoform disorder	
45.2 Hypochondriacal syndrome	
45.3 Psychogenic autonomic dysfunction	
45.4 Psychogenic pain	
F48 *Other neurotic disorders*	
48.0 Neurasthenia	
48.1 Depersonalization–derealization syndrome	

bodily movements. It is presumed that, in these disorders, the ability to exert conscious and selective control over memory, sensation or bodily function is impaired.

Somatoform disorders are those in which physical symptoms are repeatedly presented with requests for investigation or treatment, in spite of the absence of physical findings to substantiate the perception. Compared with patients who suffer from psychogenic movement or sensory disorders, those with somatoform disorders will demand attention and usually resent physicians who fail to believe in the physical nature of their illnesses. Even when the onset of symptoms is temporally related to a stressful life event, or when external manifestations of depression or anxiety are obvious to others, these patients will frequently resist speculation about psychological causation.

Other neurotic disorders feature two clinical entities, neurasthenia and depersonalization–derealization syndrome. The former, recalling the pre-Freudian nomenclature, is a controversial category in contemporary psychiatry. Its main feature is fatigue, which may occur upon either mental or physical exercise. The diagnosis is to be made only after depressive and anxiety disorders have been ruled out. Depersonalization–derealization syndrome is a rare disorder in which the patient feels that his/her own mental activity, body or surroundings are changed in quality so as to be unreal or remote. This phenomenon is more commonly observed as a feature of depression, phobias, obsessive-compulsive disorder and some psychoses.

Special Considerations in Geriatric Patients

Anxiety, both as a symptom and as a disorder, is common among the elderly, but not remarkably more or less so than at other ages. The nature of worry and its clinical manifestations, however, change

with increasing age. The intricate relationships among psychosocial stress, physical illness, depression and anxiety in late life make the recognition, diagnosis and classification of neurotic disorders in the elderly quite complex[14–16].

The clinician can usually compare the fears and concerns of a younger patient against those of his/her own peers and arrive at a credible assessment of whether or not the anxieties are pathological. The aged, however, have different fears; they worry about physical illness, crime, institutionalization, financial disaster, senility and physical dependency. It is often hard for the younger physician to determine whether the subjective interpretation of events, or the anticipation of future events, is in the realm of clinical anxiety or constitutes adaptive concern. Anxiety results from feelings of vulnerability, and the elderly are truly vulnerable in many ways. It is no easy task to diagnose agoraphobia in an 80-year-old person whose fear of crime in her neighbourhood may exceed its statistical likelihood. The clinician walks a fine line between pathologizing a healthy response and failing to recognize neurotic dysfunction[14].

Physical illnesses with psychiatric manifestations increase in prevalence with age, as does the need to take medications with emotional or behavioural side effects. Emphysema, for example, may produce features indistinguishable from those of panic disorder. Hyperthyroidism is commonly accompanied by symptoms resembling those of generalized anxiety disorder. Further, the guiding symptom profiles for the underlying disorders may be absent or muted in the ageing person. 'Silent myocardial infarction' and afebrile pneumonia are fairly common. Finally, the elderly consume significantly more medication than do younger people and exhibit psychiatric side effects at lower doses and serum levels. Bronchodilators may produce the symptoms of many anxiety states; recommended doses of over-the- counter medications for sleep or colds may induce presentations resembling dissociative states[16].

As could be expected, the diagnosis of somatoform disorders and hypochondriasis is particularly complicated in the elderly. Somatic complaints are common. To some extent, the somatic presentation of emotional disorders is a sociocultural cohort phenomenon. The generation of people over 70 in the 2000s, for example, grew up in the 1940s and earlier. At that time, words such as 'depression' and 'anxiety' were not commonplace parts of everyday conversation. Emotional introspection was not culturally normative. Thus, the older person who complains today of having 'butterflies in my stomach' may be aware of the physical concomitants of anxiety, but not of the emotional state underlying it. The clinician must 'translate' somatically phrased complaints to help determine the affective condition. Furthermore, the increase in prevalence of almost all physical illnesses with age confounds the determination of pathological perception and behaviour, necessary for making diagnoses of somatoform disorders. Both DSM-IV and ICD-10 leave room for a subjective judgement of whether the presence of physical symptoms is sufficient to explain the intensity of the patient's response. There are no objective grounds for deciding when a complaint of abdominal pain constitutes a somatoform disorder in a person with concurrent emphysema, arthritis and congestive heart failure[14,17].

While the delineation of the diagnosis and treatment of post-traumatic stress disorder (PTSD) followed the societal impact of returning Vietnam War veterans, the syndrome is not uncommon in older individuals. The trauma may have been a different war (Second World War or Korea), a natural disaster or a personal event such as physical assault. Symptoms may occur early and continue for decades. In many cases, symptoms may not even be manifest until many years after the traumatic event. Often, the symptoms of delayed PTSD are precipitated by a psychologically reminiscent contemporary event; a concentration camp survivor may not experience stress-related symptoms overtly until becoming widowed and being institutionalized half a century later[14,15].

SUMMARY

The current classification of neurotic disorders is the most recent step in the evolution of the nosological understanding of a diverse group of syndromes. The ICD-10 grouping represents a compromise between the phenomenological grouping of neurotic conditions on a scale of severity between healthy and psychotic function, and the aetiological clustering of disorders presumed to arise from internal conflicts and vulnerabilities to external stressors. The ambiguities inherent in this system reflect the incomplete state of knowledge about the aetiologies of the constituent conditions. The North American schema of DSM-IV sets aside questions of aetiology, except in the case of adjustment disorders, and relies on ostensibly atheoretical phenomenological criteria. Although the diagnostic criteria are technically independent of the age of the patient in both systems, ageing affects the presentation of many of these disorders and makes clinical diagnosis challenging. The multiple biological and social stressors of late life blur the distinction between 'normal' and 'pathological' responses to these threats. Physical illnesses, which increase in frequency with ageing, may produce clinical symptoms easily mistaken for neurotic anxiety. The prevalence of somatic pathology forces subjective judgements about the presence of somatoform and conversion disorders. Chronic and delayed stress reactions are clinically distinct from the acute forms seen in younger individuals. The lack of clarity in the classification of these disorders, however, is probably less a manifestation of the shortcomings of the nosological systems than a reflection of the complicated function of the human mind. The neurotic disorders, as well as current science can determine, are a product not of brain disease but of human response to a complicated and stressful world. Simplicity in their nosology would belie the challenges they pose to patients and clinicians.

The Epidemiology of Depression and Anxiety

Robert Stewart[1] and James Lindesay[2]

[1]*Section of Epidemiology, Institute of Psychiatry, King's College London, London, UK*
[2]*Department of Health Sciences, University of Leicester, Leicester, UK*

GENERAL CONSIDERATIONS

Depression and anxiety are common and important disorders in later life. Before reviewing their epidemiology, it is important to consider some issues around research in old age, to the extent that these impinge on research findings.

What is Old Age?

Research in 'older people' often arbitrarily focuses on people aged 65 years and over, that is, above the usual retirement age in Western nations. This '65+' range includes very varied populations: those within a decade after retirement who can reasonably expect to be in good health, through to more advanced decades where physical and mental decline become much more common and where profound social changes are more frequent, such as bereavement and challenges to independent living. The '65+' cut-off already has little social meaning in many nations and will become steadily less relevant as retirement ages become more flexible in the West. For anxiety and depression, at least two age-group targets may be more appropriate. Retirement itself is a major life-event and may exert a substantial impact on later health; for example, whether the retirement was planned, the retiree's earlier attitude to financial planning and the resources they have put aside, their ability to find alternative occupation, and the quality of interpersonal relationships as life becomes more home centred. Research around this life-transition should have a broader age focus that includes the decade or more leading up to retirement, in order to understand better what happens afterwards. At the other extreme, more 'traditional' late-life research into the impact of physical ill health and social stressors should shift its focus towards older age groups where these have highest salience.

Constructs of Anxiety and Depressive Disorders

Anxiety and depression are applied to mental states where there are no clearly identifiable boundaries between normality and abnormality. The way in which a syndrome is defined is an important consideration. Instruments which define case-level symptoms in a broad and inclusive way will give rise to higher prevalence estimates than those which define in a more selective manner. More restricted syndromes have a higher individual impact, but more 'mild' cases may have a stronger societal impact, because of their substantially higher prevalence. Restrictive criteria are often favoured by researchers because it is easier to achieve comparability between studies. However, they frequently encompass only a small proportion of cases seen routinely by clinical services and underestimate substantially the syndrome's wider impact. It is best not to view one approach as 'better' or 'worse' than another; they are merely different, and these differences should be taken into account when between-study comparisons are made.

Underlying Dimensions

Hypertension is an artificial category applied to a known physiological parameter (blood pressure), and it is likely that the same can be said for anxiety and depression. However, the underlying parameters are much less well understood, may not be unitary, and may not perfectly reflect traditional 'diagnosis' constructs. Criteria for depression as a diagnosis do not simply reflect the pervasiveness of depressed mood but also take into account its manifestations (tearfulness, anhedonia etc.) as well as the presence of other symptoms (e.g. appetite disturbance, insomnia), the quality of other symptoms (e.g. early morning wakening rather than initial insomnia), the manifestation of the overall syndrome (e.g. duration, pervasiveness, diurnal fluctuation) and the degree to which this affects daily life. The concept of the 'syndrome' is core to psychiatric nosology. However, a substantial part of this lies in tradition rather than empirical evidence, and it may be preferable for research to clarify underlying symptoms before assuming the validity of syndromes. For example, the EURO-D instrument generates two underlying dimensions (motivation and affective distress) which have different correlates (lower motivation associated with increased age, affective distress associated with female gender[1]). It is not yet established whether these findings apply beyond this instrument; however, they at least suggest that a more flexible attitude is needed towards categories and dimensions.

Are Anxiety and Depression Different Disorders?

Although anxiety and depression have traditionally been defined as separate conditions, this tradition has evolved in secondary and tertiary care settings. In community samples of any age group, mixed syndromes predominate. Furthermore, the impact of common mental

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

disorders appears to depend principally on the number of symptoms rather than whether they are anxious or depressive[2]. An exception to this is mortality as an outcome, where U-shaped associations with anxiety symptom load have been found compared to more linear associations with number of depressive symptoms[3], which may reflect differences in health service access and use. For example, delay in breast cancer presentation was found to be positively associated with previous depressive disorder but negatively associated with previous phobic disorder[4]. In this chapter, we shall consider depressive and anxiety disorders separately for the most part, but limitations in this approach should be borne in mind.

EPIDEMIOLOGY AND COURSE OF DEPRESSION: PREVALENCE, INCIDENCE AND OUTCOME

'Depression' as a diagnosis generally requires persistent low mood which is accompanied by other symptoms (such as disturbance of sleep and appetite), and which is causing significant distress and/or disablement. However, mood states vary across a spectrum of normality to abnormality and the prevalence of depression (i.e. how common it is in a given population) depends substantially on the cut-off severity applied. As discussed earlier, severe depressive syndromes have a high individual impact but are rare, while milder syndromes have a lower individual impact but affect many more people.

Prevalence studies using more restrictive criteria include the Epidemiologic Catchment Area (ECA) surveys in five areas of the USA, in which the Diagnostic Interview Schedule (DIS) was administered, and which found major depression in 0.4% of men and 1.4% of women aged 65 years and over[5]. Other estimates include those from the Cache County Study in Utah, also using the DIS, finding major depression in 2.7% of men and 4.4% of women aged 65 years and over[6], as well as a survey in the Netherlands finding major depression in 2.0% of residents aged 65 years and over[7].

An alternative approach has sought to define 'depression of clinical significance'; that is, a syndrome severity which would warrant clinical intervention. This construct in older people tends to be found 5–10-times more commonly than major depression, with prevalence ranging from 10 to 20% in most studies. These include studies which have measured 'clinically significant depressive symptoms' using brief instruments such as the Centre for Epidemiologic Studies Depression scale (CES-D); for example 16% and 9% of older residents scoring at case level (16+) in two US studies[8,9]. A more diagnostic approach is taken by the structured Geriatric Mental State (GMS) interview schedule with its accompanying AGECAT computerized diagnostic algorithm[10,11], which has probably the most wide international use including the EURODEP collaboration of late-life depression surveys in Western Europe[12], the UK Medical Research Council Cognitive Function and Ageing Study[13] and the 10/66 surveys of older people in low- and middle-income countries[14]. The EURO-D instrument was derived from the GMS and has been applied to EURODEP data[1,12,15] as well as used more recently in the Study of Health and Retirement in Europe (SHARE) surveys[16,17]. Principal findings from the EURODEP collaboration were GMS depression prevalence ranging from 8.8% (Iceland) to 23.6% (Munich) with a weighted average of 12.3% in total: 14.1% in women and 8.6% in men[12]. The SHARE surveys using the EURO-D reported lowest prevalence in Denmark (18.1%) and Germany (18.8%) and highest prevalence in the three Western Mediterranean sites – France (33.3%), Italy (33.7%) and Spain (36.8%). These differences largely persisted following standardization for demographic profiles[17]. Prevalence estimates for similar definitions of late-life depression in other world regions have been broadly comparable – for example a 14.8% prevalence of depressed mood in a meta-analysis of studies in China[18]. In three Latin American sites (Peru, Mexico and Venezuela) of the 10/66 population-based survey programme, prevalence ranges were 1.3–2.8% for DSM-IV major depression, 4.5–5.1% for ICD-10 depressive episode, 30.0–35.9% for GMS-AGECAT 'clinically significant' depression, and 26.1–31.2% for EURO-D caseness[19].

Prevalence of depression is a product of both new cases arising (incidence) and duration of case-level disorder. A higher prevalence in one site or group compared to another may be because of higher incidence or delayed recovery. For late-life depression it could also be accounted for by delayed case mortality, although mortality has been found to be higher in older people with depression[20]. Incidence of late-life depression has been less commonly measured. Major depression incidence was 0.15% per year in the ECA studies and, in a Swedish cohort, 0.12% per year in men and 0.30% in women[21]. One-year incidence of a broader depression syndrome (17% baseline prevalence) in the north London Gospel Oak study was 12%[22], and 2.5 year incidence in Korea using the GMS (baseline prevalence 14%) was also 12%[23]. Persistence of depression in the Gospel Oak cohort after a one-year interval was 63%[22]. However, two-point surveys give relatively crude information on clinical course. Incidence is underestimated (because depression episodes in the intervening period which have recovered by the follow-up point will be missed), and persistence is over-estimated (since some of those with depression at both times may have had an intervening period of recovery).

The course of depression, a classically fluctuating condition, is therefore poorly represented by binary concepts such as 'incidence' and 'maintenance', particularly in two-wave studies. An alternative approach has described clinical course in a more qualitative manner. The Longitudinal Ageing Study of Amsterdam investigated the six-year outcome of depression defined both by the CES-D and DIS. Only 14% of episodes were found to be short lived. Remission occurred in 23%, an unfavourable but fluctuating course was followed by 44%, and a severe, chronic course by 33%[24]. These are similar to findings from a very early study of late-life depression where, over six years, 31% recovered, 28% had one or more relapse, 23% had a partial recovery and 17% remained depressed[25]. In another early study with a one-year follow-up, 35% had a good recovery, 48% had had a recurrence or continuation of the syndrome, 3% had developed dementia, and 14% had died[26]. In a more recent review of depression prognosis, no clinically significant differences were found in response to pharmacotherapy or ECT by older/younger age of onset, although older people had a higher risk of future episodes. Medical co-morbidity was a potential confounder, being more common in older people and associated with a worse prognosis. Older people with early onset depression had a larger number of previous episodes, which also contributed to a worse prognosis[27].

AETIOLOGY OF DEPRESSION

Age

The prevalence of depressive disorders increases from young to mid-adult age groups, often followed by a fall in prevalence for older people within a decade of the retirement age[28]. However, studies that have focused upon depressive symptoms and broader depressive syndromes indicate either an increase in their frequency, or

stability with increasing age[29]. Blazer concluded that, if a symptom factor structure was examined, there were no age, race or gender differences in scores[21]. Where positive associations between age and depression prevalence are found, the high prevalence of physical and social stressors in these more advanced age groups is most likely to be responsible. The exclusion, in DSM diagnostic criteria[30], of symptoms that are considered to be primarily attributable to bereavement and physical illness may account in part for the apparent lower prevalence of thus-defined depressive disorders in older people. The expression of depression may also be qualitatively different in older people: for example, a higher age of onset for melancholic symptoms such as non-interaction, psychomotor retardation, and agitation[31], concurring with the positive association between increased age and diminished motivation in the EURO-D scale, both in EURODEP[1] and SHARE centres[17].

Cross-sectional associations with age may reflect birth cohort effects as well as chronological age, but these have been poorly captured to date. On the one hand, rapid improvements in health and economic prosperity for the 'young elderly' (e.g. 65–75 years) have been a particular feature of demographic ageing. On the other hand, there may be a reduction in 'stoicism' and 'resilience' as well as possible differences in willingness to admit to depressive symptoms. Birth cohort differences can only really be evaluated by repeated surveys covering the same population using similar measurements and case definitions; data which have not so far been available for late-life depression.

As well as the age distribution, some research has attempted to estimate the age of onset of late-life depression; that is, the proportion which occurs as new episodes. For example, an Australian study estimated that 52% of cases had their onset at age 60 or above[32], while a US study of people receiving home care estimated that 71% of those who were depressed were experiencing their first episode[33]. However, this approach depends on accurate recall of previous episodes, an assumption which is questioned by a prospective study in Sweden of people who had been hospitalized 25 years earlier for major depression. Of those traced, only 50% recalled sufficient details for diagnostic criteria to be applied and 30% did not recall the episode at all[34]. Recollections of more mild forms of depression are likely to be substantially more inaccurate.

Gender and Marital Status

Higher prevalence of depression is usually found in women compared to men, but this difference is substantially less than that found in younger age groups[35]. The EURODEP consortium[1] reported an excess of depression symptoms in older women in 13 out of 14 European centres. This association was consistently modified by marital status, with marriage being protective for men but associated with higher risk for women. These findings are consistent with the observation from several studies that married older men cite their wife as their main confidant, whereas women more often cite a friend outside the home, and with the association between married status and relatively low mortality or good health being stronger for men than for women.

Social Support/Activity

A consistent finding has been the salience to mood and morale in older people of contact with friends, in particular intimate and confiding relationships. While older people typically receive instrumental support from spouses and relatives, they value friends for the companionship and emotional support which they can provide. However, this generalization does not take into account the fact that some individuals may prefer a relatively isolated existence and find higher levels of social contact stressful. In the longitudinal Gospel Oak study, no contact with friends was the only social support variable prospectively associated with the onset of depression[22]. In this study, lack of social support and social participation were associated with maintenance rather than onset of depression, and the same has been found in a prospective French study where both social activity and disablement were associated with CES-D depressive symptoms at baseline but, for those with case-level symptoms at baseline, only higher levels of social activity predicted a reduction in symptoms at follow-up[36]. Physical health, age and gender may modify or explain to some extent the association between social support and late-life depression. There are large gender differences in late-life social support, with women typically having more supportive and extensive networks of friends than men. These may deteriorate following bereavement. Social engagement, such as visiting friends, is impaired by disability, indicating complex relationships between these exposures.

Social Adversity and Life Events

Many surveys find associations between late-life depression and relative disadvantage in income; poverty, for example, was one of the top five correlates of late-life depression along with disability, illness, isolation and bereavement[37]. These are highly correlated characteristics, and it will always be difficult to determine the effect of one independent of the others. At least some of the effect of poverty may be confounded by and/or mediated through physical health. Environmental measures have received less attention, although one study found that worse quality of the internal home environment was an independent predictor of incident depression one year later[38], particularly for cohabiting residents. Poverty, isolation and poor housing represent chronic stressors. The importance of acute stressors has also been investigated, with most studies finding some association[39,40] although varying in exposure and outcome measurement. Specific life events may have particular salience, such as bereavement, threats to health and interpersonal conflicts[41,42]. In British residents aged 16–74 years, associations between recent life events and common mental disorder increased in strength from early to midlife and then decreased in the oldest (65–74 year) group. Lifetime events suggesting adverse childhood exposures, however, remained strongly associated with mental disorder[43]. In younger people, early adversity is believed to act as a vulnerability factor, increasing the risk of depression in the presence of a life event[44], but this was not found in the British survey.

The Inter-Relationship between Depression and Chronic Non-Communicable Diseases

Worse physical health may be an acute or chronic stressor. However, depression is also a risk factor for worse physical health. A large part of the relationship between worse physical health and depression is mediated through higher disability levels reflecting loss of function[45]. In Gospel Oak, handicap was the most important risk factor for incident depression, with a population attributable risk fraction of 0.78[22]. However, as discussed above, the association appears to be with onset rather than with maintenance[22,36]. Three studies

have suggested an interaction between disablement and social support, with the strongest effect of disablement in those with the least social support[45–48].

The 'vascular depression' hypothesis

Evidence for disorder-specific risk of depression (beyond what would be expected through disability) is fairly scant. Possibly the strongest candidate is stroke, where depression occurs very commonly[49] and where this association frequently remains robust to adjustment for disability[50,51]. However, associations with specific arterial territory involvement have not been consistent[52], and it is quite possible that there are additional personal impacts of stroke which account for the high risk of depression, rather than cerebral damage. Incidence of depression is also increased after myocardial infarction (15–30% major depression), principally in the first month[53]. However, associations with conventional risk factors for cardiovascular disease have been absent or accounted for by disability[50,51,54], and a recent study found that vascular disorders (compared to non-vascular disorders), while specifically related to cognitive impairment, showed no specificity as correlates of mental disorder[55]. The concept of 'vascular depression'[56] therefore appears to have little epidemiological support, although may still apply to the more rare and severe (and/or treatment resistant) syndromes seen in secondary care.

Depression, mortality and cardiovascular outcomes

There is substantial excess all-cause mortality associated with mental disorder. Depression, studied most extensively, is associated with an approximately 70% increased risk[57]. In a French study of late-life depression, associations with mortality varied by gender with mortality predicted by symptom severity and previous antidepressant use in men, but in women only by severe untreated depression[20]. Associations with mortality may be mediated by disability, but not apparently by cardiovascular disease, cardiovascular risk factors or antidepressant use. There is strong evidence for associations between depression and outcomes such as angina, non-fatal and fatal myocardial infarction[58], as well as stroke[59]; in many studies after 10 years or more, ruling out depression induced by preclinical cardiovascular disease as an explanation. The associations are, surprisingly, independent of vascular risk factors such as obesity, smoking and hypertension. A prospective neuroimaging study found that depression also predicted worsening of white matter hyperintensities[60].

Co-morbid depression is a consistent and independent predictor of adverse outcomes after non-fatal myocardial infarction, such as recurrent coronary heart disease (CHD) events, CHD mortality, and all-cause mortality[58]; explained partly by poor adherence to prophylactic behaviour and lifestyle changes. Post-stroke depression is also associated with worse functional outcomes[61] and substantially higher mortality[62].

Depression and dementia

Dementia and depression have strong interrelationships in older people. Depression occurs commonly in people with dementia, and late-life depression is also a predictor of dementia[63], although it has not been clarified whether this is because depression is a risk factor or an early symptom. Common risk factors may also operate and interact over a long period. These could include cardiovascular risk factors, cerebrovascular disease and social isolation or deprivation (predisposing to cognitive decline, and impacting negatively on access to health and social care).

Recent research strongly supports an overarching model, in which it is the disability and restriction in social participation associated with any chronic health condition that most parsimoniously explains the increased risk for late-life depression. This finding, highlighted in the UK Gospel Oak study, has been subsequently confirmed in several other cohorts.

Genetic Factors

Gene–environment interactions have attracted increasing interest for depression, with several studies finding that stressful life events are stronger risk factors in the presence of a risk allele of the serotonin transporter (*5HTLPR*) gene[64]. This was replicated for stressful life events and GMS-defined depression in an elderly sample in Korea, with brain derived neurotrophic factor (*BDNF*) also implicated[23]. Similar interactions have also been found in this sample for other environmental stressors such as number of chronic disorders with *5HTTLPR*[65], and incident stroke with *BDNF*[66] which, taken together, suggest that gene–environment interactions may persist into later life. However, the interaction between stressful life events and *5HTTLPR* genotype could not be replicated for CES-D caseness in an older French population[67].

THE EPIDEMIOLOGY OF ANXIETY

Anxiety symptoms and disorders are also common in elderly populations, particularly those suffering with chronic physical illness. Like depression, they are distressing and disabling, and associated with increased mortality. However, they remain under-diagnosed and under-treated in both primary and secondary care. However, there is still uncertainty about the nature of anxiety in late life and its relationship with other disorders, such as depression and dementia.

The Nature of Anxiety in Old Age

As with depression, the experience and phenomenology of anxiety in old age may differ from that in young adulthood, and these differences may make identification difficult, in both clinical and research settings. Most instruments and diagnostic criteria were developed and validated in young populations, and may under-diagnose anxiety in older adults[68,69]. Attributing physical symptoms to anxiety can be problematic in late life, particularly with co-morbid physical illness[70,71], and 'somatization' of distress[68]. Psychological and cognitive components may also differ; for example, worry appears to be less common in late life and more strongly associated with mental disorder[72]. Severity and duration of anxiety symptoms may also alter with increasing age. Anxiety disorders might be less severe in late life because of reduced reactivity to stress, 'healthy survivor' cohort effects and better coping skills born of greater maturity and experience[73]. If so, then diagnostic severity thresholds defined for younger adults may not be appropriate for elderly individuals.

The Prevalence of Anxiety in Old Age

In a recent review by Bryant *et al.*[74], a systematic database search was carried out for articles published between 1980 and 2007 reporting data on anxiety disorders or symptoms in community or clinical

populations, in subjects aged 60 years and above. A total of 49 articles met their criteria, reporting results from a wide range of North American and European epidemiological studies; however, heterogeneity precluded formal meta-analysis.

This review found wide variation in the estimated prevalence of anxiety and its disorders. A few studies reported the prevalence of anxiety symptoms, which ranged from 15% (two or more symptoms on HSC[75]) to 52.3% (one or more symptoms on GMS[76]). Regarding anxiety disorders, overall prevalence rate ranged from 1.2% (GMS-AGECAT[77]) to 14% (DSM-IV[78]). The prevalence of phobic disorders ranged from 1.4% (GMS-AGECAT[77]) to 25.6% (PDS[79]), with specific phobia the most common phobic disorder, and social phobia the least common. Generalized anxiety disorder (GAD) prevalence ranged from 1.3% (CIDI[80]) to 7.1% (HSC[81]) and, overall, was the commonest anxiety disorder reported. Prevalence data on the less common anxiety disorders in old age are much more limited. The Longitudinal Aging Study in Amsterdam reported six-month prevalence of 0.9% for case-level PTSD and 13.1% for sub-threshold PTSD[82]. The episodic nature of panic attacks and panic disorder render them difficult to capture in cross-sectional surveys, so it is not surprising that very low prevalence has been found of 1% or less.

In clinical studies, data are limited, but overall the results are again very variable, with anxiety symptoms ranging from 15% (geriatric hospital, GMS-AGECAT[83]) to 56% (general hospital, GMS-AGECAT[84]), and anxiety disorders from 1% (general hospital, GMS-AGECAT[84]) to 24% (primary care, CIDI-SF[85]).

While some of the differences in the reported prevalence rates may reflect genuine differences between populations, Bryant *et al*.[74] conclude that much is due to conceptual and methodological differences between studies. As with depression, a key factor is variation in the level of severity that is used to define a case. Studies using GMS-AGECAT demonstrate this: typically, they report quite high prevalence for sub-cases but very low prevalence for cases, indicating a high threshold. Another important factor is the application of different diagnostic rules. Instruments and diagnostic algorithms applying hierarchical rules exclude cases of anxiety co-occurring with other disorders such as depression and dementia (e.g. GMS-AGECAT, DIS-DSM-III) and, not surprisingly, identify far fewer cases of anxiety disorder than measures that do not operate such rules. The magnitude of this effect in relation to phobic disorders is shown by Lindesay and Banerjee[79], who applied different diagnostic criteria to the same population; a hierarchical system (GMS-AGECAT) yielded a prevalence of 3.6% as against 25.6% when a non-hierarchical system (PDS) was used. This problem is most pronounced in elderly populations, where there is extensive co-morbidity between depression and anxiety, particularly GAD[86–88]. Indeed, the extent of this co-morbidity has led some to question the utility of depression and GAD as distinct diagnoses, and propose instead a dimensional construct[89–91].

To what extent do the prevalence rates of anxiety disorders change with increasing age? A number of epidemiological studies have examined prevalence across the adult age-range, but findings have been heterogeneous. In the US ECA study, the prevalence of anxiety disorders generally declined with increasing age, although this was less pronounced for some categories, such as phobic disorder. In the UK National Survey of Psychiatric Morbidity, the prevalence of GAD peaked in 50s and declined thereafter. Few studies report data on the very oldest age groups, but there is some suggestion that rates of anxiety may increase in extreme old age. However, most findings are drawn from cross-sectional data which must be interpreted with caution. Although it is possible that vulnerability diminishes with age, findings may also be the result of excess mortality associated with anxiety, or birth cohort differences[92]. Measurement validity may also vary, with risk of under-diagnosis in elderly subjects[93].

Evidence regarding the incidence rates of anxiety in older age groups is still sparse. In studies that have looked retrospectively at age of onset, such as the ECA, most of the cases of GAD had their onset prior to the age of 65 years[94]. In a three-year follow-up of the Liverpool survey using GMS-AGECAT[95], the estimated incidence rate of neurotic disorders overall was 0.44% per year; the limitations of two-point surveys to determine incidence discussed above should be noted, however.

Risk Factors for Anxiety in Old Age

Factors influencing the risk of developing an episode of anxiety may be classed as premorbid vulnerability factors, those that trigger the onset of a particular episode (destabilization), and those that determine the duration of the episode (restitution)[96]. It is likely that the exposure to and impact of specific risk factors will change over the lifespan, with some, for example chronic physical ill health and disability, having more effect in old age compared to young adulthood, and vice versa. However, ageing *per se* does not appear to be a risk factor for anxiety[97]; indeed, it may be protective[98]. Vink *et al*.[99] reviewed studies of factors associated with anxiety and depression in elderly subjects published between 1995 and 2005. The number of studies of risk factors for anxiety, either alone or with depression, was limited compared to the number examining depression alone. Heterogeneity between the studies was also high and no formal meta-analysis was attempted. Risk factors were classified as biological, psychological or social. The principal biological risk factors associated with anxiety disorders in cross-sectional studies were: number of chronic health problems, poor self-perceived health, and functional limitation[91,100]. Evidence from the few longitudinal studies was limited, with only poor self-perceived health and sensory deprivations emerging as predictors of anxiety symptoms[82,101]. The psychological risk factors for anxiety identified in both cross-sectional and longitudinal studies were: external locus of control and neuroticism, poor coping strategies, and psychopathology[82,91,100]. Not many studies have examined social risk factors for anxiety in late life in any detail. Social demographic associations such as female gender and lower educational level are reported[91,97,98], and the size and quality of social network has been identified in some studies[82,97,102]. The evidence base for social risk factors for depression is larger, and there are some differences. In comparative studies, infrequent social contacts, childlessness, adverse life events and low income were associated with anxiety only, whereas small social network size and being unmarried were associated with depression. Regarding life events, depression seems to be associated more with losses, and anxiety with threats and trauma. Overall, however, the risk profile for anxiety and depression and for symptoms and disorders appear very similar, supporting the dimensional rather than categorical modelling of these conditions[99].

CONCLUSIONS

While there are many commonalities in the epidemiology of depression and anxiety across the adult lifespan, there are also some important differences due to the effects of ageing, survival and changes in the physical and social environment. These point to the need for some different interventions for older adults, aimed at increasing

social engagement and reducing the impact of physical disability, if these disorders are to be effectively prevented.

Psychopharmacological Treatment of Anxiety

John L. Beyer

Duke University Medical Center, Durham, NC, USA

INTRODUCTION

Though the prevalence of anxiety disorders declines with age (a finding consistent with most other mental disorders), anxiety disorders remain the most common psychiatric illness in the elderly[1]. An estimated 10–20% of older adults experience clinically significant symptoms of anxiety[2]. Unfortunately, many individuals may never seek treatment, or their anxiety may not be recognized. The result has been a significant under treatment of a very treatable illness.

There are no 'perfect' anxiolytic medications for treating the elderly[3,4]. Medications may vary in effectiveness or have problems with side effects. Further, there are significant gaps in the literature about best treatment practices, which makes evidence-based decisions difficult[5]. Therefore, we will first review general considerations about treating anxiety in the elderly before reviewing current pharmacological options. Classes of medications rather than specific recommendations for each anxiety disorder will be reviewed since research has not clarified primary treatments for most anxiety disorders in the elderly. Finally, guidelines for the evaluation and selection of pharmacological treatments are suggested.

GENERAL CONSIDERATIONS

Recognition of Anxiety

Despite the ubiquity of anxiety, either as a disorder or a symptom, recognition is not always apparent. This is especially true in treating the elderly patient. Elders often are less willing to discuss 'anxiety', but may report 'anxiety-equivalent' symptoms and physical illnesses. Thus a patient may deny feeling 'anxious', but admit to feeling 'jittery', 'sick', 'uneasy', 'flustered', 'restless', 'ill', 'achy' or 'bad'. Alternatively, the patient may deny having anxiety, but report having physical symptoms, such as 'heart pain', 'insomnia' or 'indigestion'. These complaints may obscure the true diagnosis or complicate another. The physician must therefore be sensitive, not reactive, to the presenting complaint.

Differential Diagnosis

The DSM-IV-TR has identified 12 types of anxiety disorders (Table 100.1). They are based on a cluster of symptoms with a characteristic course and treatment. Anxiety may present as a primary disorder (such as panic disorder, generalized anxiety disorder, obsessive-compulsive disorder etc.) or as a symptom of another disorder. For example, many common medical disorders (like chronic obstructive pulmonary disease, coronary artery disease, early dementia) or common prescription and non-prescription medications (especially caffeine-containing products, cold and flu medications, alcohol or nicotine withdrawal, and certain herbal remedies) may cause anxiety (see Table 100.2). Finally, environmental and social stressors common to late life, such as bereavement, relocation or hospitalization may also cause anxiety. Thus, differentiating the source or sources of anxiety may be difficult.

When to Treat

When considering the treatment of anxiety in older adults, it is important to remember that anxiety is an adaptive emotion that occurs as a normal consequence of stressful experiences[6]. Stressful life events that frequently occur with age, such as loneliness, fear of isolation, diminished sensory abilities, diminished physical abilities, increased incidence of illness, financial limitations, and the prospect of dying, often generate considerable amounts of anxiety[7]. While anxiety may be a normal response to life events, it may also become maladaptive, meeting criteria for one of the 12 anxiety disorders. The decision to treat the anxious older patient with medication depends on the severity of the anxiety and the degree to which it interferes with the patient's functioning[8,9]. This frequently is seen in decreased coping skills, worsening of cognitive function, exacerbation of physical illnesses, or even a breakdown in support systems[10]. Therefore, the first task is to assess the impact of the anxiety symptoms on social and emotional functioning or the severity of a co-existing physical illness.

Challenge of Treatment

Research in the treatment of anxiety disorders for elderly patients is limited. A National Institute of Mental Health Workshop on Late-Life Anxiety[5] noted three significant research gaps: (i) little consensus on the 'best' approach to measure and count anxiety symptoms, syndromes, or disorders in late life; (ii) insufficient numbers of studies that examine anxiety among older adults; and (iii) limited knowledge of the differences in 'early' and 'later' onset of various anxiety disorders. These limitations become especially significant when making treatment recommendations for elderly anxiety patients. There are very few controlled clinical trials of medication or psychosocial interventions for anxiety disorders in the elderly[4]. Most recommendations

are usually based on case reports or open-label studies in the elderly, or extrapolated from the clinical studies of younger mixed-age adult populations and personal clinical experience. For the most part, there is little reason to doubt the applicability of the studies to the elderly patient, yet the clinician should be aware of the limitations of the research, and sensitive to the developing research in this area.

Special Adaptations for the Elderly Patient

Before prescribing anti-anxiety medicines for the elderly, the physician should also be aware of the several age-related physiological changes that may alter drug pharmacokinetics and contribute to increased risk of adverse reactions (see also Chapter 10). These include changes in drug absorption, drug distribution, protein binding, cardiac output, hepatic metabolism and renal clearance[11–13]. In addition, changes in neurotransmitter and receptor function in the central nervous system (CNS) may make a patient more sensitive to psychotropic drugs[14]. In general, the usual starting dose of psychotropic drugs for elderly patients is roughly one-half of the starting dose for younger adult patients.

PSYCHOPHARMACOLOGICAL DRUGS

Over the past century, a variety of agents have been used for the treatment of anxiety and anxiety disorders, with varying degrees of success. These include antidepressants, antihistamines, antipsychotics, benzodiazepines, beta-blockers and buspirone. Despite the multiple medicines available, Zimmer and Gershon's (1991) conclusion[15] that the 'ideal geriatric anxiolytic' has yet to be developed still holds true today. Therefore, effective treatment for excessive anxiety is especially dependent upon a thoughtful, accurate assessment of the patient, as well as a thorough knowledge of the patient's medication history, medical problems and social support/stress.

BENZODIAZEPINES

Since the 1960s, the benzodiazepines have been the mainstay of drug treatment for patients with situational anxiety, generalized anxiety disorder, and panic disorder[16]. They are also frequently prescribed for insomnia, relaxation prior to medical procedures, seizure disorders or 'agitation'. However, in the last two decades, increased attention has been given to the prescription pattern of benzodiazepines in the elderly. In the recent past, benzodiazepines were prescribed at a much higher rate among elderly patients than that of the general population[17,18]. The percentage of use has declined, especially since the introduction of the SSRIs; however, benzodiazepines remain extensively used in the elderly.

Steroids
Sympathomimetics
Alcohol
Narcotics
Sedative-hypnotics

Benzodiazepines are usually classified in two groups based primarily on their length of action: anxiolytics and sedative-hypnotics. Currently, seven benzodiazepines are available for the treatment of anxiety. Listed in their order of introduction, they are chlordiazepoxide, diazepam, oxazepam, clorazepate, lorazepam, alprazolam and clonazepam[19]. The most common sedative-hypnotics are triazolam, temazepam and flurazepam. Table 100.3 lists the currently available benzodiazepines and their individual characteristics.

Pharmacokinetics

Each benzodiazepine follows one of two biotransformative pathways: oxidation or glucuronide conjugation. Oxidative transformation occurs slowly, contributing to a longer half-life and producing many active metabolites. Conjugative transformation usually occurs

Table 100.3 Commonly used benzodiazepines in the elderly

Generic name	*Trade name*	*Onset of action*	*Indication*	*Half-life (h)*	*Metabolism*	*Active metabolites*	*Geriatric dose (mg/day)*	*Route of administration*
Short to intermediate half-life								
Triazolam	Halcion	Fast	Hypnotic	2–5	Conjugation	None	0.125–0.5	Oral
Oxazepam	Serax	Intermediate to slow	Anxiolytic	5–15	Conjugation	None	5–30	Oral
Alprazolam	Xanax	Intermediate	Anxiolytic	6–15	Oxidation	Yes	0.125–3.0	Oral
Lorazepam	Ativan	Intermediate	Anxiolytic	10–20	Conjugation	None	0.5–3.0	Oral, IV, IM
Temazepam	Restoril	Intermediate to slow	Hypnotic	12–24	Conjugation	None	15–30	Oral
Long half-life								
Chlordiazepoxide	Librium	Intermediate	Anxiolytic	8–30	Oxidation	Yes	5–30	Oral, IV, IM
Diazepam	Valium	Fastest	Anxiolytic	26–53	Oxidation	Yes	2–10	Oral, IV, IM
Clorazepate	Tranxene	Fast	Anxiolytic	30–200	Oxidation	Yes	7.5–15	Oral
Clonazepam	Klonopin	Intermediate	Anxiolytic	30–40	Oxidation	Yes	0.25–3.0	Oral
Flurazepam	Dalmane	Fast	Hypnotic	64–150	Oxidation	Yes	15	Oral

more rapidly and the metabolic products are pharmacologically inactive. As a general rule, benzodiazepines that are inactivated by conjugation are less likely to interact with other medications. For example, cimetidine has been found to inhibit the metabolism of benzodiazepines that require oxidation, but not benzodiazepines inactivated by conjugation. Table 100.4 lists several important drug interactions with benzodiazepines.

When used for their sedative properties in the elderly, effects of ultra-short, short and intermediate half-life benzodiazepines do not extend to the next day[20]. Ultra-short benzodiazepines are generally used to treat insomnia rather than daytime anxiety. However, they can cause rebound insomnia after abrupt discontinuation. Safety concerns about triazolam (i.e. after being noted to cause confusion, agitation and hallucinations) have led to its ban in several European countries[18]. Benzodiazepines with long half-lives can significantly contribute to increased risk of falls and hip fracture in elderly patients[21].

The onset of action after a single dose is primarily dependent upon the drug's absorption rate. Most benzodiazepines are highly lipophilic. Benzodiazepines that are more lipid soluble have a faster onset of action because they are absorbed and diffused into central synapses more rapidly[22,23]. This rapid onset of action can produce euphoria and thereby enhance abuse potential.

Table 100.4 Drug interactions with the benzodiazepines

Drug	*Effect*
Alcohol	Increased CNS sedation
Neuroleptics	Increased CNS sedation
Narcotics	Increased CNS sedation
Antihistamines	Increased CNS sedation
MAO inhibitors	Increased CNS sedation
Cimetidine	Increased elimination half-life and decreased clearance of alprazolam, diazepam and chlordiazepoxide
Isoniazid	Decreased metabolism of diazepam
Rifampicin	Increased metabolism of diazepam
Antacids	Decreased absorption of clorazepate and chlordiazepoxide
Digoxin	Increased digoxin levels
Levodopa	Decreased control of parkinsonism by levodopa
Fluvoxamine	Increased levels of alprazolam

Efficacy

Although benzodiazepines have been shown to be effective in younger populations, systematic studies in the elderly are lacking. Benzodiazepines are effective for generalized anxiety disorder (GAD). Clonazepam has been shown to be effective for social phobia. Clonazepam and alprazolam are effective in panic disorder. Efficacy and use in posttraumatic stress disorder (PTSD) is limited. A paradoxical reaction has been documented when some patients with PTSD are treated with benzodiazepines. None of the benzodiazepines appear effective for obsessive-compulsive disorder. Of note, though short-term efficacy has been well documented, there are no data on long-term results.

Dependence and Withdrawal

True physiological dependence, resulting in a withdrawal and abstinence syndrome, develops for benzodiazepines usually after three to four months of daily use[14]. Withdrawal symptoms are likely to be more severe with abrupt discontinued therapy, and with patients receiving short half-life benzodiazepines, or higher daily doses. The symptoms of withdrawal include tachycardia, orthostasis, intention tremors, diaphoresis, hyper-reflexia, anxiety, insomnia, nightmares, malaise, anorexia, headache, muscle pain and twitching, tinnitus, hyperacusis, photophobia, metallic taste, strange smells and, in more severe cases, hyperthermia, nausea, vomiting, delirium, seizures and psychosis.

Side Effects

Adverse drug reactions with benzodiazepines are almost twice as common in patients over the age of 70 years compared with those aged 40 years or less[24]. Benzodiazepines have a greater effect on the central nervous system of the elderly than younger patients[8,12,13]. The most common side effect is a dose-dependent dampening of central nervous system activity. The resulting symptoms include fatigue,

drowsiness, muscle weakness, blurred vision, nystagmus and (of special concern in the elderly) impaired psychomotor and cognitive performance that may lead to falls and fractures[12,25,26]. The impairment of motor coordination causes drivers taking benzodiazepines to be five-times more likely to be involved in a serious road accident[27]. Cognitive impairment can be severe enough to present as a pseudodementia in susceptible elderly patients. The risks of side effects appear to persist or worsen with chronic treatment[28], making the risk/benefit ratio for benzodiazepines appear unfavourable in the long-term treatment of anxiety disorders in the elderly[6].

Benzodiazepines may also cause a paradoxical reaction of restlessness, confusion, irritability and even aggression. Outbursts of anger in elderly patients receiving benzodiazepines may indicate the need to consider an alternative medicine. Benzodiazepines may cause mild respiratory depression in patients with chronic obstructive lung disease. Mixing benzodiazepines with other CNS depressants such as alcohol can lead to severe intoxication or (potentially lethal) respiratory depression.

Selection

In general, benzodiazepines are equivalent in terms of overall efficacy[29]. The selection of a particular benzodiazepine is primarily based upon the patient's particular problem and the medication properties (route of metabolism, length of half-life, onset of action and presence of active metabolites)[30]. In general, the following guidelines should be considered when using a benzodiazepine:

1. Benzodiazepines which undergo conjugation (e.g. temazepam, lorazepam, oxazepam) have no active metabolites and their pharmacokinetics are not significantly changed by the ageing process[12]. They are probably the wisest choice for elderly patients with impaired hepatic function.
2. Short (but not ultra-short) half-life drugs are preferable to long half-life medications since they appear less likely to increase the risk for hip fractures[21].
3. Accumulation of benzodiazepines is directly related to the amount of fat. Therefore, the thin or medically frail patients may be at increased risk.
4. Avoid benzodiazepine use in patients dependent on alcohol or other drugs.
5. Begin with lower doses and titrate upwards gradually. ('Start low and go slow.')
6. Try to limit the length of use to three to four months. Taper benzodiazepines over a four to eight week period.
7. Evidence suggests that early anxiolytic benefits from benzodiazepines improve overall compliance to antidepressant treatments in older patients[31].

BUSPIRONE

Buspirone is a novel anti-anxiety medicine whose mechanism of action is probably related to its high affinity for the serotonin type 5-HT_{1A} receptor, which causes reduced serotonergic activity. In addition, it enhances brain dopaminergic and noradrenergic activity[32,33].

Efficacy

Buspirone was shown to be effective in the treatment of generalized anxiety disorder (GAD) in the elderly in a small (40 patient) and short (four week) double-blind study[34]. It is well tolerated and as effective as the benzodiazepines for GAD[35–37]; however, buspirone does not appear effective in the treatment of panic disorder[38]. Some researchers suggest that buspirone may be helpful in mixed anxiety/depression symptoms. It may also be effective as an adjunct treatment for obsessive-compulsive disorder. Its use in posttraumatic stress disorder and social phobia appears to be limited.

Administration

Therapeutic doses of buspirone range from 20 to 60 mg daily. Because of its short half-life, buspirone is usually given three times a day. Further, as opposed to benzodiazepines, the anxiolytic effect of buspirone may not become apparent for one to three weeks. Some researchers have also suggested that the efficacy of buspirone may be reduced in patients who have previously been treated with benzodiazepines[39].

Side Effects

Buspirone is usually very well tolerated, but potential side effects may include nausea, headache, nervousness, dizziness, lightheadedness and fatigue. Unlike the benzodiazepines, buspirone does not appear to cause psychomotor impairment, dependence, withdrawal or abuse[40]. Further, it does not interact with alcohol and other sedative drugs. Therefore, it may be of particular value in the treatment of patients unable to tolerate the sedative effects of benzodiazepines[41], or patients with a history of substance abuse.

ANTIDEPRESSANTS

Tricyclic Antidepressants

Efficacy

Tricyclic antidepressants (TCAs) have been shown to be effective in treating mixed anxiety-depression states, panic disorder, and generalized anxiety disorder in the elderly[42–45]. In the general adult population, TCAs are frequently used in posttraumatic stress disorder, and clomipramine has been approved by the FDA to treat obsessive-compulsive disorder. However, the overall use of TCAs has decreased as other options (especially the SSRIs) have become available. This is primarily due to the significant side effects TCAs have at therapeutic doses, which also increases the risk to physically ill patients and potentiates toxicity in overdose. Further, like all other medications used for the treatment of anxiety (except the benzodiazepines), TCAs usually require several weeks to show maximal benefit. Despite their shortcomings, tricyclic antidepressants remain an alternative treatment for generalized anxiety disorder[46].

Side effects

Common side effects may be mediated by alpha-adrenergic blockade, anticholinergic effects and antihistaminergic effects. The alpha-adrenergic blockade of TCAs may cause significant orthostatic hypotension or cardiac conduction irregularities. The elderly are particularly susceptible to injury from orthostatic falls. Patients with complete heart block should not be given TCAs because these medications can cause a prolonged QRS complex. Trazodone, a

heterocyclic antidepressant, is sometimes used as a sedative or in the treatment of agitation for demented patients, but the side effects of postural hypotension may limit its use[20].

Anticholinergic side effects of TCAs are dry mouth, blurred vision, constipation, urinary retention and confusion or even psychosis. This may be particularly significant in patients with Alzheimer's disease or other disorders which impair memory. The major antihistaminergic effect is sedation.

Guidelines for use

Imipramine and amitriptyline have long been established in the adult population for use in various anxiety disorders. However, their tertiary amine structure tends to cause increased anticholinergic, adrenergic and sedative side effects. The secondary amines, nortriptyline and desipramine, are preferred for use in the elderly due to their less intense side effects. In general, anxiety disorders appear to respond at doses lower than those used in mood disorders. A baseline EKG is highly recommended prior to starting therapy since TCAs can cause a prolonged QRS complex.

Monoamine Oxidase Inhibitors (MAOIs)

Monoamine oxidase inhibitors have been effective in treating mixed anxiety-depression and panic disorder but not pure generalized anxiety[43,44]. MAOIs are rarely used now because of their potential side effects (especially the drug/diet interactions) and the wider availability of newer antidepressant choices. Phenelzine and tranylcypromine are the best MAOI choice for the elderly in the United States[9]. Interestingly, phenelzine was found to be more effective in the elderly than in younger patients[43], and just as well tolerated as nortriptyline[47]. The starting dose is 15 mg daily in the morning, increasing by 15 mg every few days to an average dose of 45–60 mg[48].

Orthostatic hypotension is a frequent side effect of MAOIs; however, the major concern is the possibility of an acute hypertensive crisis due to the drug and dietary interactions.

Selective Serotonin Re-Uptake Inhibitors (SSRIs)

Efficacy

The introduction of selective serotonin re-uptake inhibitors has transformed the treatment of both depression and anxiety in the adult population. Seven SSRIs are now available for use in the US: fluoxetine, sertraline, paroxetine, paroxetine CR (controlled release), fluvoxamine, citalopram and escitalopram. Since their introduction, certain SSRIs have obtained indications for the treatment of not only depression, but also panic disorder, bulimia, obsessive-compulsive disorder and social phobia. They have also been shown to be effective for use in posttraumatic stress disorder and generalized anxiety disorder. Surprisingly, there has still been little research into the use of SSRIs for the treatment of anxiety disorders in the elderly. Fluoxetine has been shown to be effective in treatment of elderly depressed patients with agitation[20]. Fluvoxamine was found to be effective in a sample of elderly patients with a mixture of anxiety disorders (mostly GAD)[49], though near-maximal doses of fluvoxamine were needed to achieve remission. A study of 60 elderly patients with anxiety disorders (primarily GAD) found citalopram to be effective, with improvements noted through the first 20 weeks of treatment[50]. Fluvoxamine and fluoxetine have been shown to be effective in clinical trials for obsessive-compulsive disorder that have included some elderly patients[51,52]. Case studies have shown sertraline, paroxetine, venlafaxine, fluoxetine and fluvoxamine effective in social phobias and anxiety[53–56].

Side effects

All SSRIs can cause gastrointestinal effects (nausea and diarrhoea), sexual arousal and performance changes, and a decrease in appetite and weight. The nausea and diarrhoea are usually dose dependent and resolve for most patients within the first week of treatment. An increasing concern has been SSRI-associated weight gain seen with extended use. Paroxetine has been noted to have some anticholinergic activity that may be more apparent in elderly, sensitive patients. A significant potential side effect of SSRIs includes a tendency to stimulate patients, causing tremor and jitteriness.

Guidelines for use

SSRIs have now become the first line treatment for most anxiety disorders. Some researchers have found that an initial use of benzodiazepine augmentation improves overall compliance with treatment[31] without an increased risk of falls[6]. Smith and colleagues[57] have recommended that SSRIs which have shorter half-lives and are less activating, such as paroxetine or sertraline, be used preferentially to fluoxetine. However, it should be noted that fluoxetine has been shown to be effective in treating anxiety symptoms associated with depression.

Newer Antidepressants

Venlafaxine, an SNRI (serotonin-norepinephrine re-uptake inhibitor), is approved for the treatment of generalized anxiety disorder in adults. A retrospective analysis of elderly subjects in the phase III studies for venlafaxine ER (extended release) found a 25% greater response rate than placebo (similar to that observed in younger adults)[58]. Older subjects had a lower rate of side effects than younger subjects, though the side effect-related discontinuation rate was the same (15%). Overall, the side effect profile of venlafaxine is similar to the SSRIs. Small elevations in blood pressure may be seen at dosages above 200 mg/day.

Nefazodone may be a useful antidepressant for depressed elderly patients who have concomitant anxiety symptoms[20]. It has an acceptable level of daytime sedation for the elderly[59], but minimal anticholinergic and other side effects. Its more moderate serotonin re-uptake inhibition may make it less likely to create agitation than the SSRIs[60]. Nefazodone does inhibit P-450 isoenzymes and is contraindicated for use with terfenadine, astemizole and cisapride. It will also increase the plasma levels of alprazolam, midazolam and triazolam.

Mirtazapine, a noradrenergic and specific serotonergic antidepressant (NaSSA) has shown beneficial effects on the concomitant symptoms of anxiety and sleep disturbances in depression trials[61]. It has few anticholinergic, adrenergic and serotonin-related adverse effects, but can be very sedating due to the antihistaminergic effects. There are no current data on its effectiveness in the elderly.

BETA-BLOCKERS

The usefulness of beta-blockers for treatment of anxiety in the elderly is unclear since the data for the elderly are restricted to clinical case

reports[30]. Beta-blocking agents have been shown to be specifically beneficial in younger patients with predominantly somatic symptoms associated with generalized anxiety or anxiety related to stressful situations[62]. They may also have potential use in the treatment of aggression and agitation in patients with organic brain disease[63]. Although beta-blockers decrease autonomically mediated symptoms such as diaphoresis, palpitation, tremor and gastrointestinal upset, they usually do not reduce the inner subjective effects[3,7].

Propranolol in small doses (such as 5–10 mg one to four times a day) may be effective in elderly patients[20]. These drugs should not be used in patients with chronic obstructive pulmonary disease, congestive heart failure, heart block, insulin-dependent diabetes, severe renal disease or peripheral vascular disease.

ANTIHISTAMINES

Sedating antihistamines such as hydroxyzine and diphenhydramine hydrochloride are sometimes useful for anxiety or insomnia in the elderly. They have been rarely recommended because they are less effective than benzodiazepines, and their anticholinergic side effects outweigh their weak anxiolytic effects[3]. They may be used in patients with mild symptoms, in severe chronic obstructive pulmonary disease, in patients with substance misuse, or in patients for whom more traditional drugs are not effective[64]. However, physicians must be aware that the elderly patient is much more susceptible to their anticholinergic properties, which may cause blurred vision, tachycardia, dry mouth, urinary urgency, constipation, restlessness, hallucinations and confusion.

GENERAL GUIDELINES

Despite the limited data on treatment of anxiety disorders in the elderly, the clinician can successfully treat patients with a conservative and thoughtful use of medications. The following guidelines have been adapted from Small (1997)[20]:

1. Conduct a complete psychiatric evaluation. Listen specifically for expression of anxiety. Does this patient have anxiety that significantly affects their quality of life or functioning?
2. Consider the full differential diagnosis. Does the pattern of anxiety identify itself as a formal anxiety disorder, or as a symptom of another psychiatric or medical disorder? Geriatric psychiatry has been called the specialty of co-morbidity. There may be several potential aetiologies for anxiety symptoms that should be considered before initiating treatment.
3. Consider non-pharmacologic treatments first. Education and reassurance are invaluable in the treatment of anxiety, and may themselves be adequate treatments. Specifically address social stressors and evaluate the effectiveness of the support systems. Attention to family caregivers may facilitate the positive response to other treatment. Remember, the ability to benefit from therapy is not based on age.
4. Minimize polypharmacy. In the elderly population (especially those in the nursing care facilities), the use of multiple medications is the rule rather than the exception. Most clinicians stress the importance of reviewing the medication list for potential areas of reduction, prior to adding new treatments. Reducing the number of medications may actually treat the anxiety symptoms[20].
5. When selecting an anxiolytic, consider the full presentation rather than just the anxiety when choosing an initial medication. For example, use an antidepressant if depressive symptoms are apparent. Avoid anticholinergic medications in patients with dementia. Avoid benzodiazepines when the patient's ability to ambulate is compromised.
6. Presently, treatment recommendations for elderly with anxiety disorders are similar to those in younger patients. In general, SSRIs and venlafaxine are considered first line pharmacotherapy for anxiety disorders in the elderly[6].
7. As far as possible, make medication changes one at a time in order to clarify whether a complaint results from a medication side effect or an underlying illness.
8. 'Start low and go slow.' Most medications are started at lower doses than those used for younger adults, but it is generally necessary to increase to usual therapeutic doses.

Obsessive-Compulsive Disorder

James Lindesay

Department of Health Sciences, University of Leicester, Leicester, UK

Although obsessive-compulsive disorder (OCD) is known to occur in old age, studies are few and information is limited. This may be because it is often not perceived as a disorder of late life. The mean age of onset of the condition is 20–25 years[1–3] and it is unusual for OCD to have its first onset after the age of 50 years. However, OCD can become a chronic disorder; as a recent 40-year follow-up study has shown, while most patients improve to some extent, less than half show complete or partial recovery[4]. A significant proportion of cases persist into old age, at which point they may present to services for the first time. It is important, therefore, that old age psychiatrists are aware of this disorder and of its management.

CLINICAL FEATURES

Diagnostic Criteria

OCD is characterized by intrusive, persistent obsessive thoughts, images or impulses and/or compulsive behaviours that are a significant source of distress, or interfere with the patient's personal or social functioning. The current diagnostic criteria, as set out in DSM-IV[5] and ICD-10[6], apply to all patients, irrespective of age. The limited evidence available indicates that the clinical features of OCD in elderly patients are very similar to those of younger adults. In their comparative study, Kohn *et al*.[7] found that concerns about symmetry, need-to-know and counting rituals were less common in elderly patients, and hand-washing and fear of having sinned were more common, but otherwise there were few differences in clinical features compared with younger OCD patients. Extreme ego-syntonic religiosity has been proposed as a variant of OCD that may be more common in older patients[8].

Differential Diagnosis

Unpleasant, intrusive thoughts and abnormal stereotyped behaviours occur in other mental disorders, and OCD is not diagnosed if their content is exclusively related to another disorder, for example guilty preoccupations in depression, worries in generalized anxiety, concern with illness in hypochondriasis, weight control in anorexia or avoidance in phobic disorders[5]. It should be borne in mind that conditions such as depression, generalized anxiety and substance abuse may be co-morbid with OCD. In elderly patients, increased anxious orderliness may be a prodrome of dementia; however, this behaviour is not resisted or associated with the tension that occurs in OCD. The compulsive behaviours of OCD resemble the stereotyped behaviours that occur in certain other disorders, such as Tourette's syndrome, Sydenham's chorea, encephalitis and partial complex seizures. Tourette's syndrome and OCD commonly co-occur[9], and patients with OCD may have a history of Sydenham's chorea in childhood[10]. There is currently some debate as to whether conditions such as OCD, body dysmorphic disorder, trichotillomania and hypochondriasis might form an obsessive-compulsive 'spectrum of disorders'.

Despite its similar name, obsessional personality disorder is quite distinct from OCD. It is characterized not by obsessions and compulsions, but by a preoccupation with orderliness, perfection and control dating back to early adulthood[5]. Individuals who are unable to discard personal possessions may present as the so-called 'senile squalor' syndrome after a lifetime of accumulating rubbish. This syndrome overlaps both obsessional personality disorder and OCD[11].

Not all patients with OCD have insight into the irrationality and inappropriateness of their obsessions and compulsions. If the obsessional thoughts are held with delusional intensity, an additional diagnosis of delusional disorder may be warranted. The ruminative delusions and stereotypies of schizophrenia are usually not ego-dystonic, and therefore would not be regarded as OCD[5].

Clinical Assessment

An effective treatment plan for OCD requires a detailed clinical assessment. What exactly are the main problems? What, if anything, exacerbates or improves the symptoms? How long has the condition been present, and how has it evolved since its onset? What treatments, if any, have been tried in the past? What other symptoms or disorders are present? Any concomitant depression, mania, psychosis or alcohol dependency will require specific management before behavioural treatments for OCD can be effective. If the patient is cognitively impaired, this will have implications for the choice of treatment; for example, some behavioural strategies will not work if information cannot be retained or recalled. In elderly patients with OCD of recent onset, it is important to investigate carefully for any underlying cerebral disease. Late-onset cases are associated with frontal dysfunction[12], which may be caused by a variety of focal and generalized disorders, including cerebrovascular disease, tumours and primary neurodegenerative dementias. Late-onset OCD may also be the result of external factors, such as adverse life events and exposure to trauma, that weaken an elderly individual's resistance to long-standing subclinical obsessionality[13].

EPIDEMIOLOGY

Most of our knowledge about the epidemiology of OCD in old age derives from the US National Institute for Mental Health (NIMH) Epidemiologic Catchment Area (ECA) Program. Overall, the one-year prevalence for those aged 65 years and older was 0.85% (men 0.75%, women 0.93%), as opposed to 1.65% for the sample as a whole[14]. A more detailed analysis of the elderly population at the Eastern Baltimore site found prevalence rates of 1.3% for those aged 65–74 years and 0.6% in those aged 75+[15]. Following the second wave of the ECA, annual incidence rates were estimated. In males aged 65+, the incidence rate of OCD was one-third of that for males of all ages, but in females there was a non-significant upturn in the incidence rate after age 65[16]. In common with a number of other psychiatric disorders, the lifetime prevalence of OCD decreased with age in this study. The reason for this is unclear, but it may be the result of cohort effects, differential mortality or age-specific differences in symptom ascertainment and recall. A rather higher overall one-year prevalence rate of 1.5% in over-65-year-olds has been reported in a more recent community study in Quebec, greater than that found for major depression (1.1%)[17].

AETIOLOGY

OCD is familial; it occurs in 40–50% of parents, 19–39% of siblings and 16% of children of probands with the disorder[18]. Just what is inherited is not clear; other anxiety disorders are also more common in the families of OCD probands[19]. At least part of this familiality is due to genes, and most of the studies that have been carried out have focused on candidate genes in the serotonergic and dopaminergic neuronal pathways[20]. However, to date most of these studies have been too small to establish linkage with an acceptable level of significance, and apart from the glutamate transporter gene, there has been no replication of findings. It is not known how the expression of any genetic susceptibility to OCD may vary across the life span.

Most of the evidence from clinical, neuropsychological and neuroimaging studies implicates the basal ganglia and their connections with the thalamus and the cerebral cortex in the aetiology of OCD[21]. Specifically, it has been proposed that there are structural and functional abnormalities in a neuronal circuit involving the orbitofrontal cortex, the basal ganglia, the substantia nigra and the ventrolateral pallidum[22]. Recent developments in imaging, such as voxel-based morphometry and multivoxel analyses have confirmed abnormality of the orbitofrontal-striatal areas in OCD, but indicate that other regions such as the dorsolateral and ventrolateral pre-frontal and parietal areas are also involved[23]. The specific response of OCD to serotonin (5-HT) re-uptake-inhibiting drugs (see below) suggests that serotonergic neuronal systems are involved, directly or indirectly. In the cognitive behavioural model of OCD, obsessions and compulsions result from pathological, anxiety-provoking over-control of normal intrusive cognitions[24].

TREATMENT

There are no randomized, controlled trials of treatment of OCD in elderly patients. Accordingly, the guidelines that follow are based upon case reports and extrapolations from studies in younger adults[25]. The current evidence-based UK NICE Guideline on OCD recommends a stepped care approach, with low-intensity psychological treatment for mildly impaired patients, and more intensive psychological treatment or pharmacotherapy for the more severely impaired, or those who fail to respond to low-intensity treatment[26]. This document also outlines some useful principles underlying the effective care of this group of patients.

Non-Pharmacological Treatments

Behavioural therapy, in the form of exposure and response prevention (ERP), is well described as an effective intervention for OCD in younger adults[27]. This involves exposing the patient to the feared situation, and helping him/her to resist the urge to perform the compulsive behaviours that would normally follow this exposure[28]. ERP is least effective in those who have obsessional thoughts and covert rituals unaccompanied by compulsive behaviour. In these patients, a cognitive approach directed at modifying the misinterpretation of intrusive thoughts is more appropriate[29]. A recent systematic review of randomized trials of psychological treatments for OCD in comparison with treatment as usual has concluded that treatments based on cognitive behavioural models are effective in younger adults, although larger studies with longer periods of follow-up are still needed[30]. Another systematic review has found that group cognitive behaviour therapy for OCD is effective in comparison with several control conditions, although it is not yet clear how this compares with individual treatment formats[31]. There are a number of case reports of effective behavioural interventions in elderly OCD patients[24,32–35], which suggest that it is reasonable to extrapolate the available evidence from randomized, controlled trials involving younger adults. It should be borne in mind, however, that most of the case reports are difficult to interpret because of the concomitant administration of medication, although in the case described by Calamari *et al*.[35], significant improvement following ERP was maintained without medication at eight-month follow-up.

Sigmund Freud originally proposed that obsessional symptoms were a regression to a pre-genital anal–sadistic phase of development. However, despite this and subsequent psychodynamic formulations of the disorder, there is no evidence that psychodynamic psychotherapy is an effective treatment for OCD at any age.

Pharmacological Treatments

Studies in younger adults indicate that 30–60% of patients with OCD show improvement on appropriate medication, and that drug treatments appear to be more effective for obsessional thoughts than for compulsive behaviours. In practice, drug treatment and behavioural therapy are often given in combination, and there is some evidence that this is an effective strategy[36].

The theory that OCD is a disorder of serotoninergic function is based upon the empirical observation that it can be effectively treated by drugs that inhibit serotonin re-uptake. Clomipramine is the most extensively studied drug treatment for OCD, and its effectiveness has been established in a number of double-blind, placebo-controlled trials in younger adults[37]. However, its lack of receptor sensitivity means that it has significant anticholinergic and antihistaminergic side effects that limit its usefulness in elderly patients[38]. In this age group, the current drug of first choice is one of the specific serotonin re-uptake inhibitors (SSRIs). Fluoxetine, paroxetine, fluvoxamine and escitalopram are currently licensed in the UK for the treatment of OCD, although none of the trials supporting this indication specifically involved elderly patients. A systematic review of trials of SSRI drugs for OCD in comparison with placebo has concluded that they

are effective, at least in the short term, and that there are some differences between the different SSRIs with respect to their adverse effects[39]. The effective dose for the treatment of OCD with these drugs tends to be higher than that required to treat depression, and the time taken to respond is typically much longer: 10–18 weeks. Studies suggest that long-term therapy is required, as discontinuation of medication leads to relapse of symptoms[40].

There is little evidence for the effectiveness of other drug treatments in OCD. There are some case reports suggesting that monoamine oxidase inhibitors (MAOIs) may be useful in patients with concomitant panic or severe anxiety. Anxiolytic drugs may also help with the anxiety associated with OCD, but do not appear to have any effect on the core symptoms. A possible exception is buspirone, which may augment the effect of fluoxetine[41,42]. A recent meta-analysis of randomized, controlled trials supports the use of antipsychotic drugs in combination with an SSRI in patients resistant to first-line drug treatment[43]; the best evidence is for haloperidol and risperidone. Several other drugs, including carbamazepine, gabapentin, memantine and mirtazapine have been reported to be effective in combination with SSRIs in small uncontrolled studies. Lithium augmentation of fluoxetine has also been reported as effective in one elderly case[44].

Physical Treatments

There is very little evidence to suggest that ECT is effective in the treatment of OCD in patients who are not also depressed[45]. Similarly, the therapeutic potential of transcranial magnetic stimulation in this disorder has yet to be demonstrated[46]. Some good results have been reported for stereotactic neurosurgical procedures in patients with severe and treatment-refractory illness, including elderly subjects[25], but since negative outcomes are rarely described, this evidence is difficult to interpret.

CONCLUSIONS

OCD may present for the first time in old age, and many elderly patients with chronic illness will not have been exposed to the full range of pharmacological and cognitive behavioural interventions that are now available. It is important that old age psychiatry services are aware of these treatments and develop some experience in their delivery. There is some evidence that they are effective in elderly patients, but further research is needed. Patients with a new onset of OCD in late life need careful assessment to exclude underlying organic brain disease.

Somatoform Disorders and Unexplained Physical Symptoms

Bart Sheehan

Health Sciences Research Institute, Warwick Medical School, Coventry, UK

HISTORY

Mysterious physical symptoms of uncertain origin have been noted as long as medical matters have been written about. Early explanations of mysterious symptoms involved the abnormal movement or function of the womb, hence the origin of the term hysteria from the Greek word *hysterikos*. Such explanations may now seem absurd, but were influential till at least the seventeenth century, when Sydenham first wrote of hypochondriasis (a male condition) and hysteria (a female equivalent). Sydenham described the two conditions as alike 'as one egg is to another'. He recognized that psychological disturbance was primary, that symptoms were changeable and that these conditions cause great diagnostic difficulty. Over the next 200 years, acceptance of a psychological origin for some ill-defined physical symptoms grew, along with the concept of a group of psychological illnesses called neuroses.

Interest in these ill-defined symptoms really accelerated with the popularization of Sigmund Freud's early ideas about unconscious conflicts and psychological disturbance. Freud was struck by Charcot's demonstrations in Paris of hysterical physical symptoms. He developed the idea that unconscious conflicts were manifest as physical symptoms, as a form of defence mechanism. After the First World War, no-one who had seen the victims of 'shell-shock' could doubt the ability of psychological trauma to cause physical symptoms.

Proponents of psychoanalytic ideas developed terms like somatization and psychosomatic illnesses. As the influence of these ideas eventually waned after the Second World War, clinicians became less focused on aetiology and more on careful description of patients with persistent troublesome physical symptoms. By 1980, when DSM-III was published, the term hysteria was dropped. Somatization disorder, in which multiple physical symptoms persist over years, with no organic explanation, and hypochondriasis, in which patients dread a particular disease and cannot be reassured despite investigation, became the prototypical somatoform disorders. Thus, Sydenham's observations from 300 years previously were confirmed in modern medicine.

MODERN TERMINOLOGY

Both DSM-IV and ICD-10 have categories of somatoform disorders. Both include core somatization disorder and hypochondriacal disorder, and a handful of other disorders like conversion disorder and body dysmorphic disorder (DSM-IV), Somatoform autonomic disorder (ICD-10) and persistent pain disorders (both classifications).

Clinicians dealing with older patients are likely to mainly encounter less differentiated admixtures of unexplained symptoms and hypochondriacal beliefs. The diagnostic categories in DSM-IV are unlikely to be especially helpful when faced with a persistently complaining patient who is likely also to have at least one organic illness. The term 'medically unexplained symptoms' is sometimes used to cover the wider range of patient presentations. This term avoids diagnostic confusion and can sometimes be useful in the presence of real physical illness.

CLINICAL PRESENTATIONS

Case 1

Mr W is a 76-year-old man admitted with worsening depression to a psychiatric ward. In the last two weeks he has become increasing preoccupied with his bowels, plaguing his primary care doctor for consultations. He is now convinced that his bowels have stopped working due to 'a blockage ... cancer or something'. He is reluctant to eat or drink and feels that any treatment is futile. Examination and investigation shows mild constipation but no evidence of any other organic lesion. Reassurance is ineffective. He eventually requires intravenous rehydration and ECT. He begins to improve after about a week, initially saying 'I am not so sure', then later 'I suppose I was worrying too much'. He regains much of the weight he had lost and is discharged home after seven weeks in hospital.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

A case of severe depressive disorder with psychotic features (hypochondriacal and nihilistic delusions). Rapid improvement in physical complaints noted with definitive treatment of underlying psychiatric disorder.

Case 2

Mrs K is a 64-year-old woman who is referred to psychiatric services for the fifth time in her life. She is well known to primary care as a frequent attender and for the last three years has seen her general practitioner at least once a week. She complains of multiple symptoms including pain in the head, back and limbs, abdominal discomfort, bloating and frequency of bowel motions, blurred vision, dry mouth, urinary frequency, some shortness of breath and chest pain, and is 'unable to settle at night'. She has had multiple referrals to secondary care over 40 years. Investigations by gynaecology, general surgery, cardiology and gastroenterology have been negative but did not help. She does not feel taken seriously and is 'fed up with doctors ... the whole time they just try to get rid of me'. She has mild depression but is very reluctant to see a psychiatrist or counsellor. The psychiatrist writes 'No sign of formal mental illness' and discharges the patient back to the general practitioner.

A probable case of somatization disorder. Psychiatry is unhelpful here, maintaining the disorder by rejecting the validity of the complaint and offering nothing helpful to the GP.

Case 3

Mrs T, a 76-year-old widow, presents to her GP with abdominal pain. This has come on in the last three weeks. There are no findings on examination and she has no significant medical or surgical history. Her husband died about six years ago. She becomes tearful during the consultation and says she is 'desperately worried' that the marriage of her only daughter is in trouble. This daughter is her main social support. She thinks she may not see her grandchildren again for some time. She agrees that stress makes the pain worse, and agrees that the family situation is stressful. She comes back to see the GP after two weeks. The pain has lessened, though she is still worried. She has told her daughter of her worry, and been reassured that she will not lose contact with any family members.

Illustrates how mild physical symptoms may follow psychological distress, and how watchful waiting and a sympathetic approach may be associated with improvement and no unnecessary referrals.

EPIDEMIOLOGY

While strictly defined somatoform disorders are relatively rare at all ages, somatoform presentations are very common. In all cultures, somatized symptoms are probably the most common way for depressive disorders to present in primary care. In secondary care, psychological distress and outright somatoform disorders have both been consistently linked with frequent attendance, high costs and chronicity of presentations.

Good-quality evidence on the prevalence and incidence of these presentations among older people is lacking. Somatoform presentations are often defined in loose or confusing ways, or highly selected populations may be sampled. Some studies define somatoform presentations as strict classical presentations with a primary hypochondriacal or somatization disorder, others are rates of ill-defined somatic symptoms. Prospective studies which follow somatoform presentations among older people are especially rare.

Community Samples

Surveys among community samples of older people have tended to show very low prevalence (0.0–3.9%) of strictly defined hypochondriacal or somatization disorders. A consistent finding in studies comparing younger with older people is that older people are no more preoccupied with physical health than younger people. This counters a widespread stereotype of older people concentrating introspectively on physical health.

Primary Care Samples

In older UK primary care patients[1], 5% were reported to have hypochondriacal neurosis, but many more had at least a few somatoform symptoms (unexplained symptoms). In the same study, primary care physicians were asked about the likely origins of the older patients' physical symptoms. A third were rated as having physical symptoms that were equally or mainly of psychological origin. A careful Italian primary care study[2] showed a similar figure of 8.1% having a primary somatoform disorder.

General Hospital Samples

Rates of somatoform disorders, or unexplained physical presentations, in secondary care have consistently been shown to be high. The few studies which have included secondary care patients from across the age range have shown very similar rates between young and old. Unsurprisingly, older hypochondriacal patients at general hospital settings do have higher rates of other true organic illnesses.

Psychiatric Samples

Most interest has been in the prevalence of somatoform presentations among older people with depression. Older patients with either anxiety disorders or depressive disorders have been consistently shown to commonly present with somatized physical symptoms, and these presentations are more common than among younger patients with depressive and anxiety disorders. Unexplained physical symptoms among frail older people are more strongly associated with depressed mood than with the burden of 'real' physical illness. This is an important clinical point: the presence of unexplained symptoms should trigger consideration of psychiatric as well as physical illness.

AETIOLOGY

Many theories about the origins of somatoform presentations have been advanced. Some, like the ancient view that such symptoms

arose from uterine causes, are now dismissed due to modern understanding of anatomy and physiology. Others, including the influential psychoanalytic view that somatization arose from the 'conversion' of unacceptable unconscious mental conflicts, have been highly influential but difficult to examine in scientific study. Modern theories on aetiology have three key themes:

1. Somatoform presentations as manifestations of other psychiatric disorders – Somatoform presentations are undoubtedly found most frequently among people with higher rates of psychiatric disorder, especially depressive disorder.
2. Somatoform presentations as reflecting a stable, internal personality style – Research has shown that neurotic personality styles are much more common among somatizers. It is common when dealing with chronic severe somatizers to note the early appearance of unexplained physical symptoms and persistent pattern of medical help-seeking. In some cases this may be related to early maternal loss, abuse or other trauma. People who have a tendency to negative self-evaluation and to somatosensory amplification (a tendency to interpret normal physical symptoms as aversive) are much more likely to report physical symptoms to a health professional.
3. Somatoform presentations reflecting a social construct (i.e. an understandable reaction to the medical system or societal norms that a person lives in). It is widely held that somatoform presentations are more common in non-western cultures. The largest international study of somatization[3] reported rates of somatization in primary care in 14 centres. Somatization was found commonly in all centres and especially so as a means of presentation of psychiatric disorder. Only South American centres showed higher rates; even here, rates of depressive disorder were as common among those presenting somatically. Another possibility is that somatoform presentations are encouraged by the medical or social system people live in. Somatizing patients consume large amounts of resources, and early recognition of the problem, fewer prescriptions and fewer hospital referrals are associated with better outcomes.

Among older people, the strongest aetiological link has been with depressive illness. While some older people are simply chronic somatoform presenters grown old, new somatoform presentations remain common in old age. Depressive disorders are the most common association, with certain symptoms including fatigue, dizziness, weakness, pain and heavy feelings in the limbs among the symptoms most commonly reported. Moreover, the association with depressive illness is independent of that with physical disorder. Among older people, the traditional concept of 'masked depression' has held up better than many other theories of the origins of somatoform presentations.

OUTCOMES

Most studies at any age indicate that somatoform disorders will tend to persist if they are severe and outcomes also depend on the medical response to the initial presentation. The clinical context is important; mild somatoform presentations in primary care may be transient though the style of presentation, that is, the tendency to present with physical symptoms when emotionally distressed, tends to persist. Among patients with clear-cut severe somatoform disorders in secondary care, persistence is part of the diagnostic criteria. Patients have often had a very persistent course with 10–20 years of relentless presentations despite multiple investigations and failed reassurance. Such patients are difficult to treat, but may greatly trouble health professionals.

Among older patients, few studies have followed somatoform presentations prospectively. Among UK older primary care patients, a prospective study[1] found that severe cases of full somatoform disorders tended to remit, but vague or unexplained physical symptoms were highly persistent at nine-month follow-up. The attribution of physical symptoms to a physical cause was also highly stable over time. These findings are somewhat contrary to reports among younger people. Somatized symptoms were prospectively associated with frequent attendance in primary care. Though research is limited, it is fair to assume that among older patients, milder somatoform presentations use significant amounts of primary care time and are likely to persist. More severe somatoform presentations, especially when secondary to depressive disorder, may be likely to respond to treatment.

TREATMENT

Specific Treatment of Somatoform Disorders

Many controlled trials have been carried out among patients with somatoform disorders. The most frequently evaluated interventions have been cognitive behavioural therapy (CBT) and antidepressant medication. These interventions have been subject to systematic review[4]. This review specified the somatoform disorders addressed, including both pure somatization disorder and lower threshold disorders. Of good-quality trials of CBT, 11 of 13 studies showed benefit above control treatment, while among studies of antidepressant medication, 4 of 5 trials showed benefit. Of those trials addressing health care resource use, 10 of 11 studies showed cost reductions for the intervention group. The author concluded that the best evidence was for CBT. The cognitive behavioural model requires highly trained and skilled therapists and represents a challenge among older patients. Problems may include inadequate provision of psychological therapy for older people and the fact that these patients are likely to have admixtures of somatoform symptoms as well as symptoms from organic illness. A further challenge is to find ways to amend CBT to integrate its use into primary care. No intervention studies have been carried out among older patients with somatoform disorders.

Studies among Patients with Psychiatric Disorders

Studying somatoform presentations among older patients being treated for depressive or anxiety disorders tends to show improvement in somatoform presentations over time. Those trials of antidepressant medication that have examined which symptoms predict positive outcomes tend to consistently show that hypochondriacal or somatization symptoms predict a poorer outcome, though those clinicians with experience of treating severe hypochondriasis among people with depression will be aware that severe hypochondriasis does resolve along with other psychotic symptoms.

AN APPROACH TO MANAGEMENT OF MEDICALLY UNEXPLAINED SYMPTOMS IN OLDER PEOPLE

This approach draws on what is known to be effective among younger people with somatization. Older people have a high prevalence of

physical illness so a commonsense approach to management of new or uncharacteristic physical symptoms must be taken. It may be easier for medically qualified staff to tolerate uncertainty with such patients.

Is There a Physical Illness?

Is it being adequately dealt with?

In the majority of cases the patient will be adequately investigated and treated before somatization is considered.

Is There a Psychiatric Illness?

In depressive disorder, the low mood and biological symptoms such as poor sleep, weight loss, poor appetite, poor concentration and retardation/agitation usually precede the physical complaints. Patients usually admit to gloomy introspection and are likely to admit to depression rather than reject such suggestions.

Is it being adequately treated?

Antidepressant medication will usually resolve depression, with resolution of somatized symptoms.

Do Medically Unexplained Symptoms Need Independent Treatment?

If both physical and psychiatric illness is being reasonably dealt with, but unexplained symptoms are persisting and causing distress, then a positive and structured response is needed.

- Stop investigations and hospital referrals. Explain that investigations are not helping but as a clinician you believe the patients' symptoms and will continue to monitor them.
- Schedule regular appointments with the patient. The patient should be seen regularly but not necessarily frequently. This means they do not need to report symptoms in order to be seen and may reduce demands for appointments at short notice.
- Explain that investigations have shown no condition that they cannot recover from. This allows the prospect of recovery to be available, maintaining hope.
- Use cognitive behavioural techniques. Identify dysfunctional beliefs ('headaches usually mean brain tumour', 'muscle aches mean exercise has damaged the muscle fibres') and dysfunctional behaviours ('I will stay in bed all weekend to give my muscles a chance to recover').
- Identify positive thinking and behaviour strategies. For example, demonstrate that holding a book in an outstretched hand causes pain – to show effect of muscle tension. Exercise increases blood flow and fitness of muscle fibres. Schedule increasing levels of activity and record symptoms in fatigue diary.

Other Neurotic Disorders

Jerome J. Schulte, C. Michael Hendricks and David Bienenfeld

Department of Psychiatry Wright State University, Boonshoft School of Medicine, OH, USA

REACTION TO SEVERE STRESS AND ADJUSTMENT DISORDERS

Before the Second World War it was generally held that psychiatric patients were constitutionally different from 'normals'. During the War it was observed that previously asymptomatic individuals experiencing unusual environmental stress sometimes suffered from transient psychiatric difficulties. This observation led to a reclassification of psychiatric disorders to allow for behavioural and emotional symptoms in people who would return to their premorbid state with the removal of the unusual environmental precipitant[1]. DSM-I and ICD-6 classified these transient difficulties as 'gross stress reaction' and 'adult situational reaction'; DSM-II and ICD-8 classified them as 'transient situational disturbances'. ICD-9 introduced the categories of 'acute reaction to stress' and 'adjustment disorder'. ICD-10 defines 'acute stress reaction', 'post-traumatic stress disorder' and 'adjustment disorder'; although DSM-III-R recognized only the latter two of these, DSM-IV-TR recognizes all three[2].

ACUTE STRESS REACTION

Clinical Features

According to ICD-10, acute stress reaction is a transient disturbance occurring in persons without apparent mental disorder, in response to exceptional physical and/or mental stress and subsiding in hours or days. The diagnosis should not be made for an exacerbation of symptoms of a diagnosable psychiatric disorder already present, except for accentuation of personality traits. Previous history of another psychiatric disorder does not invalidate this diagnosis. An immediate, clear connection between the stressor and the onset of symptoms should be seen.

Symptoms of this disorder show a mixed and changing picture, with no one symptom predominating for long. They appear within minutes of the stress and resolve rapidly when the stressor is removed or, if the stress remains, symptoms decrease after 24–48 hours and are minimal after three days. Typical symptoms include an initial state of 'daze', constriction of consciousness, narrowing of attention, decreased comprehension of stimuli and disorientation. Withdrawal, agitation or overactivity may follow. Autonomic signs of panic (tachycardia, sweating, flushing) are common. Amnesia for the traumatic present may also be present. In the elderly, organic factors and life stage events can be predisposing factors to acute stress reaction[3]. The multiple bereavements that are not uncommon in late life can be the precipitants for acute stress reaction. However, recent data do suggest the older population may tolerate acute stress better than the younger and middle-aged[4].

DSM-IV differs somewhat from ICD-10 in its diagnostic classification of acute stress disorder. Unlike ICD-10, which requires that symptoms appear within minutes of the stress and diminish to minimal intensity after three days, DSM-IV requires symptoms to last a minimum of two days and allows for persistence up to four weeks. DSM-IV also includes dissociative symptoms not included under ICD-10: a subjective sense of numbing, detachment or absence of emotional responsiveness; derealization and depersonalization. Another DSM-IV requirement is that the traumatic event is persistently re-experienced in at least one of the following ways: recurrent images, thoughts, dreams, illusions, flashback episodes, or a sense of reliving the experience; or distress on exposure to reminders of the traumatic event. DSM-IV also requires marked avoidance of stimuli that arouse recollections of the trauma[5].

Differential Diagnosis

The differential diagnosis includes post-traumatic stress disorder (PTSD) and adjustment disorder. PTSD (see below) occurs after a latency period of weeks or longer, while the symptoms of acute stress reaction begin immediately after the traumatic event. The repetitive, intrusive imagery characteristic of PTSD is not usually a feature of the ICD-10 diagnosis of acute stress reaction. DSM-IV, however, does include repetitive intrusive imagery among the features of acute stress disorder. If psychotic symptoms follow an extreme stress, acute (brief) psychotic disorder should be considered. Adjustment disorders are less severe, and longer lasting, than acute stress reactions. Events that precipitate adjustment disorders are also less intense than those responsible for acute stress reactions.

Therapy

By definition, the symptoms of acute stress reaction are time-limited and will resolve without specific therapeutic intervention. Treatment may be requested, however, for intolerable tension or insomnia. For tension, short-term use of benzodiazepines with simple metabolic pathways and short half-lives, such as lorazepam or oxazepam, are safest in the elderly. For insomnia, temazepam or

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

the non-benzodiazepine sedative hypnotic zolpidem[6] are justified. Families and patients may be reassured that the acute response does not indicate a psychotic decompensation, and that the prognosis for rapid recovery is favourable. Acutely, and in the aftermath of the traumatic event, it is useful to help the patient gain mastery over the trauma[7] by using a brief treatment model, consisting of fostering abreaction and integration of the event as quickly as possible, with the expectation that the trauma victim will return to full functioning. Abreaction can be fostered through individual or group psychotherapy[8].

POST-TRAUMATIC STRESS DISORDER

Post-traumatic stress disorder (PTSD) first appeared in DSM-III but was based on older concepts tied to the history of warfare. Da Costa wrote of 'irritable heart' following the American Civil War. In the First World War the disorder was known as 'shell shock'. Early twentieth century psychoanalytic theory called it 'traumatic neurosis' and in the Second World War it was known as 'traumatic war neurosis' or 'combat neurosis'.' In DSM-I it was renamed 'gross stress reaction', a reaction to great stress in a normal personality. During the relatively peaceful time between the Second World War and the Vietnam War, the category was omitted from DSM-II[9]. ICD-9 defined catastrophic stress and combat fatigue as two diagnoses under the category of acute reaction to stress. DSM-III defined intrusive re-experience of the trauma, together with emotional numbing, as the central features of PTSD. DSM-III-R placed more emphasis on the avoidance of stimuli associated with the trauma and less on numbing.

DSM-IV changed the definition of the trauma to an event where a person experienced, witnessed or was confronted with threatened death or serious injury or threat to physical integrity of self or others. Here, the response to the trauma involves intense fear, helplessness or horror. Also, where DSM-III-R required either numbing or avoidance behaviour, DSM-IV requires both[5]. ICD-10 criteria more closely resemble those of DSM-III, highlighting the restriction of emotional responsiveness. In ICD-10 the late chronic sequelae of devastating stress (i.e. those manifesting decades after the stressful experience) should be classified under enduring personality change after catastrophic experience[3].

Clinical Features

The prevalence rate of PTSD in the elderly is about 1%[10–12]. The ICD-10 diagnosis of PTSD requires evidence of trauma, or a response to a stressful event or situation of exceptionally threatening or catastrophic nature, likely to cause pervasive distress in anyone. The central symptoms are repetitive and intrusive recollections (flashbacks) or re-enactment of the event in memories, daytime imagery or dreams. The onset follows the trauma with a latency period of a few weeks to months (rarely exceeding six months).

There may also be a sense of 'numbness' and emotional blunting, and avoidance of activities and situations reminiscent of trauma. Anxiety, depression, suicidal ideation and insomnia are also common in many PTSD patients, particularly with advancing age[9]. PTSD is also associated with alcohol and drug abuse, possibly reflecting attempts to cope with PTSD symptoms. Dissociative symptoms, commonly described in younger PTSD victims, become less prevalent with increasing age[13,14]. However, psychotic symptoms tend to be more common in older PTSD patients[15].

It remains a subject of debate what factors, if any, predispose individuals to the development of the post-traumatic stress syndrome. Some traumas, particularly the concentration camp experience, are so severe that symptoms are almost universal in survivors. Because retrospective assessment of function before the traumatic event is always coloured by the response to the event, correlations are difficult to draw and empirical analyses have been inconclusive[16]. Certain personality traits (e.g. compulsive, asthenic), neurotic illness, and a history of adverse events in early childhood[10] may all lower the threshold for manifestation of the disorder[3]. PTSD can also develop from bereavement. One study surveyed surviving spouses two months after their spouses' deaths and found that 10% of those whose spouses died after a chronic illness met criteria for PTSD; 9% of those whose spouses died unexpectedly met PTSD criteria; and 36% of those whose spouses died from 'unnatural' causes (suicide or accident) had PTSD[17]. Other late life events, including falls, stroke, myocardial infarction and breast cancer, have also been shown to put the elderly at increased risk of developing PTSD[18–21].

Although PTSD symptoms can persist for many years, with increased frequency of symptoms towards the end of life[22], the typical course is one of fluctuating symptoms[23]. One study, examining current PTSD symptoms in elderly Second World War and Korean War prisoners of war (POWs), suggested that severity of exposure to trauma and lack of post-military social support were moderately predictive of PTSD. In this study, 53% of POWs met criteria for lifetime PTSD, with 29% meeting criteria for current PTSD, but for those POWs most severely traumatized, the lifetime PTSD rates were 83%, with current PTSD at 59%[24].

There are two types of PTSD to which the elderly seem susceptible: delayed-onset PTSD and chronic PTSD. In delayed-onset PTSD, patients may exhibit signs of the disorder decades after the trauma, and in chronic PTSD symptoms have been persistent since the time of the trauma. Delayed-onset PTSD may be a reactivation of remote PTSD earlier in life. A typical pattern is the onset of symptoms after initial exposure, a gradual decline in symptoms over several decades, followed by a reemergence in late life[25]. In some elderly Second World War veterans, media coverage commemorating the 50th anniversary of the end of the War triggered PTSD symptoms[26]. Commonly, guilt, distorted memory, emotional numbing, estrangement and feelings of detachment are seen[27]. Patients in this group can present with physical symptoms of cardiovascular, gastrointestinal and musculoskeletal diseases[16].

In general, the onset of severe symptoms can be linked to a profound recent life event, such as death of a wife, job retirement or loss of physical integrity from illness[27]. Most often, the contemporary precipitant reawakens emotions and perceptions from the original trauma. Holocaust survivors and POWs have been noted to begin displaying symptoms of PTSD after admission to nursing homes, where they re-experience a loss of freedom and autonomy. Second World War veterans found the loss of physical integrity due to somatic illness particularly upsetting, since it evoked memories of a traumatic period when their physical integrity was in jeopardy[14].

Differential Diagnosis

Although adjustment disorders also occur in response to life events, these events are in the normal range of human experience, unlike the extraordinary traumas responsible for PTSD. Specific features of numbing and flashbacks do not occur, and adjustment disorders, by definition, do not last more than six months. Acute stress reaction

is characterized by a more variable clinical picture that resolves within days. Whether PTSD is predicted by acute stress reactions remains unclear[28]. While anxiety and depression are common features of PTSD, generalized anxiety disorder and phobic disorder have anxiety as a more specific and central symptom. Major depression is marked by deep and persistent mood disturbance, usually with loss of reactivity; dysthymia results in chronic, indolent dysphoria. None of these disorders includes the specific symptom of intrusive recollections.

Therapy

The signs and symptoms of PTSD include distorted expectations and perceptions, mood disturbances, psychophysiological symptoms and social withdrawal. Thus, common sense dictates, and empirical data confirm, that multimodal treatment is most advisable[11,29]. Psychosocial intervention and pharmacotherapy each has its place. Historically, dynamic psychotherapy has been a useful approach, but recent treatment guidelines support exposure-based psychotherapies as the most evidence-based form of treatment for PTSD[29]. Antidepressants can offer symptomatic relief by diminishing dysphoria, intrusive thoughts, insomnia and nightmares[30]. In particular, selective serotonin re-uptake inhibitors (SSRIs) have been shown to be effective pharmacotherapeutic treatment for PTSD, especially in reducing avoidant symptoms[31–37].

Other second-generation antidepressants do show promise in the management of PTSD but sufficient evidence is lacking at this time[35]. Prazosin, an alpha-1 adrenergic receptor antagonist, has been shown to be helpful with the sleep disturbance and nightmares of PTSD, but should be used with caution in the elderly because of the risk of orthostatic hypotension, particularly in combination with other medications that may lower blood pressure[29,38]. Beta-adrenergic blocking agents have been used in younger PTSD patients for relief of symptoms of autonomic arousal, tremors and startle reactions[39]. Older patients, however, are less likely to display a clinical profile of hyperarousal, and are more susceptible to the cardiovascular complications and organic mood disorders associated with adrenergic blockade. There are case reports of positive results using atypical antipsychotics as augmenting agents when added to SSRIs for treatment of refractory PTSD[35,40]. However, this class of medications must be used with caution in the older population given current concerns of increased mortality in older demented patients. Conversely, benzodiazepines do not appear to be a helpful treatment for PTSD[35] and should be avoided as much as possible in ageing individuals since they can cause paradoxical excitation and frequently induce subtle cognitive impairment[41]. Similarly, divalproex (valproate) has been demonstrated to be ineffective as monotherapy for PTSD in older veterans[42].

ADJUSTMENT DISORDER

The diagnosis of adjustment disorder refers to a state of subjective distress or emotional disturbance, interfering with social functioning or performance, arising in a period of adaptation to a significant life change or subsequent to a stressful life event. It is assumed that the condition would not have arisen without the stressor. According to DSM-IV, onset is within three months of the stressor. The duration of symptoms should not exceed six months, except in the case where the stressor is chronic (e.g. a chronic general medical condition) or the stressor has enduring consequences (e.g. the financial and emotional difficulties resulting from a divorce)[5]. ICD-10 describes onset as arising in the period of adaptation to the stressor[3].

Clinical Features

Symptoms of adjustment disorder may include: depressed mood, anxiety, worry, impairment in performance of daily routines and inability to cope or plan ahead. Adjustment disorders can be specified as brief depressive reaction, prolonged depressive reaction, adjustment disorder with predominant disturbance of other emotions, adjustment disorder with predominant disturbance of conduct, or adjustment disorder with mixed disturbance of emotions and conduct. The precipitating events for adjustment disorders can affect social network or values, and may involve the individual, his group or community. Common events causing such symptoms in older patients include physical illness or injury, placement in a nursing home and retirement[43]. The events, while subjectively profoundly meaningful, are of considerably smaller magnitude than those precipitating acute stress reaction and PTSD. Individual predisposition and vulnerability to these stressful life events thus plays a greater role in the occurrence of adjustment disorders. Poor pre-stressor social and co-existing physical problems[44], current dementia[45] and a history of a past psychiatric disorder[46] all increase vulnerability to adjustment disorders. However, while these premorbid risk factors are frequently observed, they do not appear essential. In a recent large study of elderly veterans with no recent psychiatric history admitted to medical/surgical units, adjustment disorder was diagnosed in over 20% of the patients post discharge[47].

Therapy

The cornerstone of treatment for adjustment disorders is focal psychotherapy, although it appears that antidepressants may be of value in the successful management of adjustment disorders in some outpatient settings that often lack ready access to psychotherapy[50]. Based on a psychodynamic understanding of emotions and behaviour, focal therapy identifies the most specific nidus of current distress and views it in the context of the patient's core conflicts or deficits. The therapy is of relatively brief duration, usually 6–20 sessions. The major techniques employed are clarification and confrontation[48]. Quite frequently, the precipitating event can be framed as a narcissistic threat or injury. In psychotherapy, the patient will come to view the therapist as a self-object, looking for restoration of the self-esteem provided by the lost function, role or friend. The therapist helps restore the wholeness of self by allowing the patient to modify his or her expectations of him- or herself and environment[49].

DISSOCIATIVE AND CONVERSION DISORDERS

In the last three decades of the nineteenth century, dissociation was studied extensively by Janet and conversion by Freud. DSM-I incorporated the concepts of dissociation and conversion into its classification scheme. Conversion reaction was assigned to hysterical neurosis, and amnesia was placed in the category of dissociative reaction. In DSM-II they were united under the heading of hysterical neurosis, but divided into conversion type and dissociative type. In DSM-III, DSM-III-R and DSM-IV the two conditions were renamed and separated once again. Hysteria, conversion type, became conversion disorder and was assigned to somatoform disorders. Hysteria,

dissociative type, was expanded into the dissociative disorders[51]. ICD-10, however, continues to contain both under the heading of dissociative disorders.

Dissociative Amnesia

Dissociative amnesia is characterized by loss of memory, usually of important recent events, that is too great to be explained by ordinary forgetfulness or fatigue; and amnesia, either partial or complete, for recent events that are of a traumatic or stressful nature. The amnesia is usually partial and selective. The extent and completeness of the amnesia varies from day to day and between inquirers, but a persistent common core cannot be recalled in the waking state. Complete, generalized amnesia is rare and is usually part of a dissociative fugue. Affective states in amnesia are varied but severe depression is rare.

Perplexity, distress and varying degrees of attention-seeking behaviour may be evident, but calm acceptance is also sometimes striking. Purposeless local wandering may occur, but is rarely accompanied by self-neglect and rarely lasts more than a day or two. Often in dissociative amnesia, new learning is preserved[52]. Disturbing external circumstances causing despair or anxiety may predispose an individual, but a single event is usually at the centre of the syndrome.

As a rule, dissociative amnesia becomes less prominent with age and is uncommon in the elderly[53,54]. However, it has been seen in First World War combat soldiers[55] and soldiers in other conflicts. In most patients the amnesia is short-lived, 75% of cases lasting between 24 hours and 5 days[56]. Its features resemble those of more frequently observed disorders. Organic amnesia is usually anterograde[52]. In postconcussional syndromes there may be a combination of hysterical and organic amnesia that can be difficult to untangle. In dementia, memory loss is seen in the context of global cognitive impairment, which is stable over a period of weeks to months. The syndrome of pseudodementia also features variable memory impairment, but affective disturbance, usually severe depression, is evident[57].

Dissociative Fugue

Fugue exhibits all the features of dissociative amnesia, plus an apparently purposeful journey away from home or place of work during which self-care is maintained. A new identity is assumed and organized travel may be undertaken to places previously known and of possible emotional significance. Although there is retrograde amnesia during the fugue, behaviour during fugue is normal. A severe precipitating stress is almost universal as a precipitant of dissociative fugue. Times of marital discord, financial difficulty, major role change or personal loss may precede the fugue. Depressed mood is frequently present before fugue symptoms are displayed[52]. Fugue is rare in elderly people. Because its features, with the exception of travel, are identical to those of dissociative amnesia, it has been proposed that the two disorders be considered as one.

Treatment

Therapy for dissociative amnesia and that for dissociative fugue are virtually identical. Patients usually seek treatment after the amnesic period has ended. They desire help in recovering memory of events during the fugue. Hypnosis[58], benzodiazepines[59] and short-acting barbiturates have been used to reconstitute repressed memories, although typically they return spontaneously. Psychodynamic psychotherapy has been used to facilitate resolution of conflicts that lead to fugue states. This treatment may decrease the vulnerability of the patient to dissociate in future times of stress[60].

DISSOCIATIVE DISORDERS OF MOVEMENT AND SENSATION (CONVERSION DISORDERS)

In conversion disorder, there is a loss or alteration in movements or sensations (usually cuteneous) in a patient presenting as having a physical disorder. No somatic condition can be found, however, that explains the symptoms. Instead, the symptoms represent the patient's concept of the physical disorder, which may be at variance with physiological or anatomical principles. Here, mental state and social situation suggest that disability resulting from the loss of function is helping the patient to escape an unpleasant conflict, or helps the patient to express dependency or resentment indirectly. Conflicts may be evident to others, but the patient often denies their presence and attributes distress to the physical symptoms or the resulting disability.

In making the diagnosis it is essential that: (i) evidence of a physical disorder is absent and (ii) sufficient knowledge of the psychological and social setting and personal relationships of the patient allows a convincing formulation of the reasons for the disorder.

Predisposing factors to conversion disorder are premorbid abnormalities of personal relationships, childhood sexual abuse[61], and personality disturbance, with histrionic personality being the most common[62]. Also, close relatives or friends may have suffered from physical illness with symptoms resembling the patient's. A few patients establish a repetitive pattern of reaction to stress by production of these disorders, which can continue into middle and old age[3].

The most important differential diagnosis is the group of somatoform disorders (although DSM-IV classifies conversion disorder as a somatoform disorder instead of a dissociative disorder). In the latter, the patient's presentation centers around persistent requests for medical attention and pervasive concern with the perceived medical disorder; patients with conversion disorder are much more likely to take their presumed illnesses in stride. Conversion disorders generally begin in adolescence and young adulthood, and occur in single or recurrent episodes with substantial remission. Somatoform disorders may not increase in prevalence with increasing age, but they tend to assume the quality of a pervasive character style with little remission.

Most conversion disorders remit with non-specific, supportive interventions. Hypnosis[63], anxiolytics and behavioural relaxation exercises may be helpful. Also, psychotherapy aimed at helping the patient recognize and cope with the psychosocial stress that provoked the symptom can be impressively beneficial if the patient can be engaged in a cooperative alliance of therapeutic curiosity. The prognosis of conversion disorder is generally good, since conversion symptoms are of short duration with abrupt onset and resolution. A few become chronic, and some recur, most commonly when the precipitating stress is chronic or recurrent, when there is other psychopathology or when there is marked secondary gain.

NEURASTHENIA (FATIGUE SYNDROME)

Historical Perspective

George Beard introduced the term 'neurasthenia' in 1869. He viewed neurasthenia as a physical illness caused by loss of nerve strength. Janet differentiated psychasthenia from neurasthenia. Freud similarly

separated anxiety neurosis, a 'psychoneurosis', from neurasthenia, an 'actual neurosis' he attributed to misdirected libidinal energy. In the First World War, the syndrome was defined by the term 'shell shock'; in the Second World War, 'operational fatigue'. Although it remains in ICD-10, the diagnosis of neurasthenia was deleted from DSM-III and replaced by dysthymia. In the United States the symptom cluster known as chronic fatigue syndrome is almost identical to the current ICD classification of neurasthenia[64–66].

Clinical Features

Neurasthenia is characterized by persistent, distressing complaints of fatigue after mental effort, or complaints of bodily weakness and exhaustion after minimal physical effort, along with at least two of the following: muscular aches and pains, dizziness, tension headaches, sleep disturbance, inability to relax, irritability or dyspepsia. If autonomic or depressive symptoms are present, they cannot be sufficiently persistent and severe to fulfil the criteria for any more specific disorder[3]. Premorbid fatigue may be the single most reliable predictor of the development of neurasthenia[67].

Differential Diagnosis

Differential diagnosis includes primarily major depression and somatoform disorders. In the elderly it is especially important to rule out depression, since somatic complaints and fatigue are common presentations of depressive disorders in late life. Physical symptoms with no demonstrable organic pathology are the essential features of somatoform disorders. However, these complaints do not include the specific physical symptoms of fatigue or exhaustion found in neurasthenia.

Therapy

Specific treatment for neurasthenia has not been established. Given the high likelihood, particularly in old age, that the neurasthenic picture is a manifestation of a mood disorder, treatment with antidepressant medication and psychotherapy, as for depressive conditions, is generally warranted[68].

Personality Disorders

Personality Disorders: Description, Aetiology, and Epidemiology

Victor Molinari[1] and Daniel L. Segal[2]

[1]*University of South Florida, Tampa, FL, USA*
[2]*University of Colorado at Colorado Springs, Colorado Springs, CO, USA*

According to the Diagnostic and Statistical Manual of Mental Disorders, 4th edition, text revision (DSM-IV-TR)[1], 'A Personality Disorder is an enduring pattern of inner experience and behaviour that deviates markedly from the expectations of the individual's culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment' (p. 685). Also included in the definition of personality disorder is that the traits have to be rigid, maladaptive and pervasive across a broad range of situations rather than expectable reactions to particular life experiences or a normal part of a developmental stage. An important caveat in the DSM-IV-TR is that, although the definition of personality disorder requires an onset no later than early adulthood, it is often the case that a person with a personality disorder may not be diagnosed or treated until later life.

One possible explanation for this caveat is that the individual with personality disorder may have presented clinically with the more obvious signs of an Axis I clinical disorder such as anxiety, depression, disordered eating or substance abuse, whereas the underlying personality disorder features may not have been examined as closely. Another important factor is that in some cases, personality traits can be adaptive at one phase of life but become maladaptive at a later developmental phase. For example, an extremely aloof, reserved and emotionally detached man may have functioned successfully in the occupational sphere by choosing a job requiring little social interaction (e.g. a computer programmer who writes code at home). He managed to live alone and had little use for others during much of his adult life. Imagine the discomfort and distress he would face, however, if in later life he becomes physically frail and debilitated and out of medical necessity is re-located to a nursing home where he is forced to cope with the presence of medical professionals, caregivers and other residents. In this case, it would be only after the person has failed to adjust to his new living situation that his personality traits would be viewed as dysfunctional (and a personality disorder diagnosis given). Thus, the *context* in which personality traits are expressed is an extremely important concept in determining their relative usefulness or hindrance across the lifespan.

Personality disorder in older adults is an important area of study for a number of reasons. First, since personality disorder affects the way an older adult copes with life, individuals with specific personality disorders may be less able to successfully negotiate age-related losses (e.g. a histrionic person who has relied on her physical attractiveness and sexual provocativeness to garner attention for herself may feel neglected as she ages and loses some of her seductiveness; an obsessive–compulsive individual may feel out of control because he feels his medical problems reduce his control over his body; a dependent person may lose his main source of support due to the death of a spouse, siblings, adult children etc.) or the interpersonal compromises necessary for peaceful institutional living (e.g. anger episodes erupt when the interpersonal needs of a borderline or narcissistic person are not immediately met). Second, personality disorder can influence the presentation of Axis I symptomatology, frequently generating complicated diagnostic and assessment dilemmas. For example, disruptive behaviour in the nursing home may camouflage the fact that the person is suffering from a depression that is exacerbating premorbid antisocial personality features. Third, just as for young adults, the presence of personality disorder warrants modification of treatment strategies and prognosis for those with co-morbid Axis I disorders in certain geriatric settings.

In recent years, there has been an ever-expanding body of knowledge about personality disorder in older adults. Notably, there has even been the publication of two books solely devoted to personality disorder in older adults[2,3]. However, as we shall see, there remain many unanswered questions spawned by thorny conceptual and methodological quandaries in this controversial area. This chapter will summarize what is known about the aetiology, diagnosis, epidemiology and prognosis of personality disorder in older adults.

AETIOLOGY

Because personality disorders and personality disorder features begin relatively early in life and have a generally persisting impact across the lifespan, it can be assumed that the aetiology of personality disorders includes psychosocial and biological factors[3]. Concerning personality disorder among older adults, it is helpful to focus on dimensional aspects of personality as well as the categorical diagnosis of personality disorder.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

Psychosocial Factors

Freud noted the importance of Axis II traits in the aetiology of Axis I symptoms. He embedded the idea of personality within his psychosexual schema regarding oral, anal, oedipal, latency and genital stages. Inborn temperamental traits combine with parental influences in these early developmental periods to shape an individual's personality. How early figures react to the growing child's bio-psycho-social needs forges a rigid template that is operative throughout the person's life, and reflects whether the person will satisfy his or her intrapsychic and interpersonal needs in an adaptive manner or in an exaggerated repetitious fashion. Acute symptomatology erupts when current stressors intersect with the psychosocial dynamics and interpersonal sensitivities laid out in early childhood forming this hard bedrock of personality traits. Working from this grand model, Freud erroneously concluded that by the age of 40 personality patterns were invariably set, and advised psychoanalysts to spend their time with younger analysands.

Erik Erikson[4] enhanced the Freudian framework to include three stages of adulthood that were yoked to specific life challenges. Those in young adulthood are faced with the crisis of deciding on a career and achieving intimacy; those in middle adulthood raise their family, maintain a career and hopefully become generative; those in late adulthood are confronted with preparing for death, gaining wisdom and achieving ego integrity. Unfortunately, the heuristic value of these conceptualizations has not been realized because limited research has been conducted to validate these stages.

Coming from a more empirical tradition, Costa and McCrae[5] conducted both cross-sectional and longitudinal research with their well-validated NEO Personality Inventory (which measures five broad lexically derived personality factors of neuroticism, extraversion, openness, agreeableness and conscientiousness) and concluded that there is general continuity of personality across the life span. However, other researchers have argued that Costa and McCrae's five-factor model tends to minimize personality change in adulthood, particularly with respect to environmental factors[6]. Indeed, in his 50-year follow-up study of Harvard undergraduates, Vaillant[7] discovered that significant change can occur for certain individuals, related either to specific negative or positive adult life events (e.g. alcoholism; supportive spouse). Consistent with these formulations, Identity Process Theory[8] postulates that older adults tend first to assimilate and (if assimilation is non-successful) then to accommodate discrepant experiences to maintain self-esteem via a consistent sense of self. Those with rigid understandings of themselves that characterize personality disorders may be less able to employ these more mature coping mechanisms and negotiate the vagaries of ageing. From this conceptual basis, too much or too little stability in personality as we age may become maladaptive.

Finally, a well-researched cognitive model of psychopathology suggests that personality disorders may be characterized by cognitive distortions which are derived from biases in information processing and dysfunctional schema or core beliefs that influence people's perceptions and thoughts at the conscious level[9]. Examples of cognitive distortions include all-or-none thinking (seeing personal qualities or situations in absolutist 'black and white' terms, and failing to see shades of grey), catastrophizing (perceiving negative events as intolerable calamities, commonly referred to as 'making mountains out of molehills'), magnification and minimization (exaggerating the importance of negative characteristics and experiences while discounting the importance of positive characteristics and experiences) and personalization (assuming one is the cause of an event when other factors are also responsible). Schemas are often expressed as unconditional evaluations about the self and others. Some examples include beliefs that: 'I am incompetent', 'I am defective', 'I am unlovable', 'I am special', 'Others are hurtful and not to be trusted', 'Others need to take care of me', and 'Others must love and admire me'. Schemas are generally thought to be formed early in life but to persist if no conscious effort is made to identify, examine and challenge them.

Some examples of cognitive distortions and schema relevant to specific personality disorders include:

- an individual with paranoid personality disorder is prone to habitually and chronically perceive others as deceitful, abusive and threatening;
- an individual with borderline personality disorder is prone to sort people into categories of either 'all good' or 'all bad';
- an individual with obsessive–compulsive personality disorder tends to be a slave to the belief that he or she must be perfect and always in control;
- an individual with dependent personality disorder sees him- or herself as weak, incompetent and inadequate, requiring constant reassurance, nurturance and direction.

Whereas a few studies have attempted to validate the specific relationships between core beliefs and personality disorder pathology[10], notably lacking are studies that specifically examine these relationships in older adult samples.

Genetic Factors

A growing literature base has focused on the genetic factors that contribute to personality disorders. In a study of 483 adult twin pairs, Jang *et al*.[11] found a median heritability of 0.44 for 66 of 69 personality disorder facet traits. Similar data were reported by Coolidge *et al*.[12] who found a median heritability coefficient of 0.75 for 12 specific personality disorders in their sample of 112 child twin pairs. Interestingly, Jang *et al*.[13] found in their cross-sectional twin study that genetic contributions to personality disorder traits actually increase with age. Torgersen *et al*.[14] used a structured interview to diagnose the full range of personality disorders, finding an overall heritability estimate of .60. Finally, a very recent study with a large sample of young adult Norwegian twins found one genetic factor reflecting a broad vulnerability to personality disorder pathology and negative emotionality whereas two other genetic factors more specifically reflected high impulsivity/low agreeableness and introversion[15]. In summary, there is clear evidence of heritability for some personality disorders but much that remains unexamined. Perhaps the best conclusion from this data is that heritable traits play a significant role in the formation of personality disorders but heritability alone does not directly cause an individual to develop a specific personality disorder.

DIAGNOSIS

The diagnosis of personality disorders is known to be particularly challenging across the lifespan. Specifically, in adulthood, it is generally difficult to distinguish one personality disorder from another[16]. Later life adds further complications to diagnosis. There are, for instance, problems in obtaining a reliable diagnosis and, at present, there is no 'gold standard' of diagnosis for personality disorder

in older adults. Molinari *et al*.[17] studied geropsychiatric inpatients with depression, and found general discordance between patient self-report, family informant ratings, social worker evaluations and consensus case conference categorical diagnosis of personality disorder. It appears that there are varied perceptions of an individual's personality, all of which should be taken into account for a comprehensive evaluation of Axis II pathology.

Personality disorder is commonly seen in practice settings yet seldom formally identified. Mental health professionals are loathe to diagnose it, particularly in old age, due to concerns over pejorative bias, pessimistic beliefs about the prospects of therapeutic change for personality disorder pathology, managed care reimbursement biases, and focus on medical or Axis I pathology (particularly cognitive impairment) in old age. Often the patient with personality disorder presents in a demanding, blaming manner with an inappropriate, rigid interpersonal stance and limited insight. Unfortunately these same features are sometimes erroneously interpreted as part of the natural ageing process[18]. Perhaps it is most important to recognize that 'either/or' thinking is often incorrect in the diagnosis of older adults. Comorbidity is the rule rather than the exception, with research consistently finding that older adults with depression also may have longstanding maladaptive personality disorder traits[18–20].

Another factor that impacts identification and diagnosis of personality disorders in later life is that, in some cases, there is an emergence of personality disorder symptoms that were 'hidden' earlier in life[3]. For example, consider a highly dependent woman who was supported by a caring, perhaps dominating, spouse who did not mind making all of the decisions for the couple and essentially took care of his wife throughout much of their adult lives. It would not be until she struggled to take care of herself after becoming a widow that the extent of her 'disorder' would become recognized and perhaps diagnosed. A final diagnostic challenge is that the sets of diagnostic criteria do not fit older adults as well as they do younger adults[3]. In an empirical investigation of potential age-bias using item analysis, Balsis *et al*.[21] found evidence of age-bias in 29% of the criteria for seven personality disorders. In this study, some diagnostic criteria were differentially endorsed by younger and older adults with equivalent personality disorder pathology, suggesting a bias.

EPIDEMIOLOGY

Some early anecdotal reports suggested that personality characteristics become uniformly less harsh with age[22,23]. Other clinicians working with older adults believed that the 'high-energy' personality disorders (e.g. Cluster B) mellow whereas the 'low-energy' personality disorders (e.g. Cluster C) may be aggravated by the ageing process[24–26]. DSM-IV-TR[1] states that 'Some personality disorders tend to become less obvious or remit with age, whereas this appears to be less true for some other types' (p. 688). Early research yielded wide variability in personality disorder prevalence rates due to inadequate definitions of personality disorder, non-standardized measures and different samples of older adults. With the employment of better diagnostic criteria, some consistent findings have emerged. This section on epidemiology will therefore largely focus on studies using standardized measures, and will be divided into community, institutional, outpatient and depression studies.

Community Settings

In community settings, two studies[23,27] compared young and older adults utilizing the Coolidge Axis II Inventory. Coolidge *et al*.[23] found a greater need for organization and more restricted affect in older adults, whereas Segal *et al*.[27] found that older adults were significantly higher on obsessive–compulsive and schizoid personality disorder, but lower on the antisocial, borderline, histrionic, narcissistic and paranoid scales. Ames and Molinari[28] used the Structured Interview for Disorders of Personality scale (SIDP-R) and detected a trend of less personality disorder in older adults, with significantly fewer older adults meeting the criteria for more than one personality disorder. Cohen *et al*.[29] used the Structured Psychiatric Examination and found that individuals 55 years old and older were less likely (6.6% vs. 10.5%) to have personality disorder, due to a threefold decrease of Cluster B personality disorder in older adults. These data documenting personality 'mellowing' in older adult community samples are in stark contrast to the results of a study by Segal *et al*.[30], who found that a high number (63%) of community-dwelling older adults surveyed at a senior center met personality disorder criteria by self-report. However, this study used a measure known to be overly sensitive to personality disorder pathology, and the cognitive status of the participants was also not taken into account.

Institutional Settings

Early personality disorder prevalence rates in nursing home settings were reported to be 12–15%[31,32], whereas for geropsychiatric inpatients, personality disorder estimates were more variable (7–58%). In a large sample of hospitalized male veterans, Molinari *et al*.[33] conducted a cross-sectional investigation of personality changes across different age groups for those clinically diagnosed with personality disorder. Older adults with personality disorder were more responsible and less impulsive, paranoid, energetic and antisocial than young adults diagnosed with personality disorder. Kunik *et al*.[34] studied 547 older psychiatric inpatients, and found that a consensus case conference diagnosis of personality disorder varied widely, depending upon the specific co-morbid Axis I diagnosis (e.g. 6% for patients with an organic mental disorder, but 24% for those with depression). Only a few studies of geropsychiatric institutionalized patients utilized standardized instruments. Molinari *et al*.[35] used the SIDP-R and found that older adults had personality disorder rates similar to those of a young adult comparison sample; however, older adults were less likely to meet criteria for more than one personality disorder, and clinical diagnoses yielded fewer personality disorders than the SIDP-R. Likewise, Coolidge *et al*.[36] used the Coolidge Axis II Inventory and found similarly high personality disorder rates among young (66%) and old (58%) chronically mentally ill patients, but the younger group was more likely to be specifically diagnosed with antisocial, borderline, and schizotypal personality disorder. Finally, among older inpatient veterans, Kenan *et al*.[37] found a 55% personality disorder prevalence rate.

Outpatient Settings

The findings from the lone study conducted with a structured personality disorder scale in a geropsychiatric outpatient setting are consistent with the latter inpatient studies. Molinari and Marmion[38] found that older adults were less likely to meet the criteria for more than one personality disorder than younger adults, and clinical diagnosis again yielded fewer personality disorders than the SIDP-R.

Depression

One area of intense study has been the relationship between personality disorder and depression in older adults. Kunik *et al*.[20] studied 154

depressed older inpatients and identified 24% with co-morbid personality disorder, whereas Molinari and Marmion[39] determined that 63% of depressed geropsychiatric outpatients met personality disorder criteria. Thompson *et al*.[40] found that 33% of depressed older adults who were being treated with psychotherapy in a geropsychiatric outpatient clinic met personality disorder criteria. In a study investigating the relationship between personality disorder and functioning in acutely depressed older psychiatric patients, Axis II pathology was found to be associated with greater disability and more impaired social and interpersonal functioning[41]. In their review of the literature on personality disorder in older adults, Agronin and Maletta[42] posit that personality disorder in late life may be intrinsically related to Axis I pathology, particularly major depressive disorder.

Summary of Epidemiological Studies

In an attempt to lend clarity to the burgeoning literature on personality disorder in older adults, Abrams and Horowitz[43] conducted a meta-analysis of the most methodologically sophisticated epidemiological studies. They inferred a personality disorder prevalence rate of 10% (with a range of 6–33%) for those over the age of 50, and concluded that research neither substantiates nor disconfirms an age effect. However, these authors remark that the bulk of the evidence supports, at least for certain personality disorders, a decline in frequency and intensity with age. The cause for this decline is one of the most controversial and debated topics in the literature on personality disorder in older adults. Four main reasons have been postulated.

First, there is a general mellowing of the 'high-energy' Cluster B personality disorders due to biological (reduced testosterone in males) and developmental changes (those with personality disorder finally master a single interpersonal strategy to manage stresses). This accounts for the consistent result that older adults are less likely to meet the criteria for more than one personality disorder, and is also supported by the study of Segal *et al*.[27], who discovered lower levels of dysfunctional dispositional coping styles among older adults compared with younger adults.

Second, the decline in 'high-energy' personality disorder relates to the greater mortality rates of those with Cluster B personality disorder in their younger years. Older adults with personality disorder are thereby a selective sample of less extreme personality disorder 'survivors'. Third, personality disorder is generally under-diagnosed, particularly in older adults, where cognitive and medical causes are emphasized or personality disturbance (avoidance, dependency, emotional lability) is viewed as normal[44].

Fourth, the decline in personality disorder with age is a methodological artefact, since some DSM criteria are age-insensitive. For example, occupational and vocational impairment are often irrelevant to older adults. From this point of view, there really is no true decline in personality disorder rates with age, just a change in form that is inadequately assessed. These so-called 'geriatric variants'[45] reflect the more subclinical, non-specific or age-relevant personality disorder traits that account for personality disorder NOS (not otherwise specified) to be diagnosed with particular high frequency in older adults. These formulations are consistent with the theory of heterotypic continuity[46] which proposes that core psychological constructs remain constant, but that they are manifested in different ways throughout the life cycle (e.g. failure to conform to social norms may be reflected by repeated fights in younger individuals with antisocial personality disorder, but by repeated rule infractions in long-term care settings by older adults with antisocial personality disorder). The construction of a new geriatric nosology has been proposed to accommodate the late life changes in Axis II pathology[42,43,45]. Such re-classification will need to: (i) reconsider the diagnostic requirement that maladaptive personality disorder behaviour be rooted so early in young adulthood; (ii) routinely address Axis II pathology in the context of more acute Axis I symptomatology; and (iii) integrate age-related developmental, medical (Axis III) and psychosocial/environmental stressors (Axis IV) with Axis II manifestations[42].

PROGNOSIS

Unfortunately, only a few seemingly contradictory studies have investigated the prognosis of personality disorder in late life. In two separate studies of geropsychiatric outpatients, personality disorder was found to be a poor prognostic sign for the psychotherapeutic treatment of depression[40,47]. However, Molinari[48] examined the one-year relapse rates for 100 male geropsychiatric inpatients and found no significant differences for those diagnosed with and without personality disorder. Consistent with the finding of Kunik and colleagues[20] that personality disorder diagnosis had no impact on the acute response of inpatient treatment for depression with older adults, no differences were found in relapse rates for a subgroup of depressed inpatients with and without personality disorder[48]. It appears that in inpatient geropsychiatric settings, Axis I symptomatology overrides Axis II pathology as an outcome predictor, probably related to the complex combination of medical, cognitive and psychiatric symptoms often observed in those older patients needing acute care. More generally, the prognosis for older adults with personality disorder is highly variable and contextualized. Some adults with personality disorder clearly mature with advanced age, some seem to deteriorate in the face of challenges associated with ageing (e.g. loss of prestige, reduced physical stamina and attractiveness, increased need for assistance from others) and yet the third pattern is the unabated continuity of similar levels of dysfunctional behaviours from younger life to later life[3].

SUMMARY

1. There are psychosocial and genetic determinants of personality disorder in older adults.
2. The assessment of personality disorder in older adults is challenging, especially due to the presence of Axis I and Axis III co-morbidities.
3. There are poor concordance rates of personality disorder diagnosis between clinical examination, structured interviews and self-reports, suggesting the need for data collection from a variety of sources.
4. There may be an age-related mellowing of the 'high-energy' personality characteristics of individuals with personality disorder, and/or there are 'geriatric variants' of personality disorder not tapped by DSM.
5. There is a positive association between depression and personality disorder diagnosis.
6. Identifying personality disorder in older adults may be more useful prognostically in outpatient settings, where the Axis I symptomatology is less severe.
7. DSM-V must do a better job of accommodating late life changes in personality disorder presentation.

Although age-related changes in personality disorder expression may be in the less volatile and impulsive direction, novel geriatric manifestations still can create a significant burden in stressful caregiving contexts for family members, friends, health care professionals and administrators of institutions attempting to support a flawed and vulnerable older adult. Future empirical research guided by conceptual advances in psychodynamic, self/identity, cognitive and life span developmental theories of personality that address the interrelationship of genetic, biological, psychological and social variables promises to yield exciting progress in the creation of gero-specific assessment instruments and treatment protocols for personality disorder in older adults.

Diagnostic and Treatment Issues Regarding Personality Disorder in Older Adults

Richard A. Zweig[1] and Dana Scherr Parchi[2]

[1]*Ferkauf Graduate School of Yeshiva University, Bronx, NY, USA*
[2]*The Child and Family Institute at St Luke's and Roosevelt Hospitals, New York, NY, USA*

A growing body of epidemiological and observational studies support the notion that personality disorder is highly prevalent in community and clinical samples of adults and older adults (see Chapter 104) and that personality disorder moderates the presentation, course and outcome of Axis I disorders in both younger[1,2] and older adults[3–5]. The potential import of such findings for prevention and treatment cannot be overstated; recent findings, for example, suggest that personality pathology in the elderly may be a risk factor for coronary heart disease[6] and late-life suicidal behavior[7]. Even normative variations in personality appear to play a salient role, as inter-individual differences in personality have been linked to outcomes such as physical and psychological well-being, functional ability and longevity in older adults[8,9]. Yet, much personality pathology remains undetected and undertreated in clinical settings.

It is likely that efforts to translate these findings to practice settings have been hampered by differing conceptual models and methods (e.g. dimensional versus categorical)[10] as well as myriad obstacles to the assessment of personality pathology in the elderly[11]. Additionally, the lack of appropriate detection and treatment of personality disorder exacts a heavy cost, as personality disorders have been associated with long-term functional impairment[12] and a doubling of treatment expenses[13]. In this chapter, we review methods and measures for assessing personality pathology, describe obstacles to accurate detection, and delineate some common challenges in the differential diagnosis of personality pathology from other late-life disorders. We also discuss the psychotherapeutic and pharmacological management and treatment of these disorders.

DETECTION OF PERSONALITY PATHOLOGY

Methods and measures for detecting personality pathology have advanced considerably in the past four decades, such that an array of structured clinical interviews, multiscale self-report inventories and other measures have been developed and refined for this purpose[14,15]. Most current measures are derived from categorical or dimensional models of personality. Broadly speaking, measures based upon a categorical model tend to adhere closely to the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders, fourth edition, text revision (DSM-IV-TR) constructs of personality disorder[16], and determine presence/absence of personality disorder based upon whether an individual meets or exceeds DSM thresholds for each personality disorder type and manifests significant functional impairment or distress, in a manner analogous to the diagnostic assessment of Axis I syndromes. Measures of this type, such as the Structured Interview for DSM-IV Personality (SIDP-IV)[17] and the International Personality Disorders Examination (IPDE)[18], are more reliable than unstructured interviews, allow for the use of informant data to control for biased reporting of symptoms, and incorporate clinician judgement as to whether personality disorder symptoms are maladaptive, pervasive and inflexible across situations and contexts. Dimensional measures of personality (e.g. NEO-PI-R)[19] are derived from models that view personality disorder typologies as extreme variants of normative personality traits (e.g. neuroticism/emotional stability; introversion/extraversion; compliance/antagonism). Such measures, which typically rely on a patient's self-report of inner experiences and behaviours, allow for a more heterogeneous picture of patients' personality traits, and rely less on clinician inference, but vary in their accordance with DSM criteria for personality disorder.

Recent trends favour a dimensional approach to assessments of personality pathology, as flaws in the current categorical model of personality disorder, including arbitrary diagnostic thresholds with limited empirical support, high co-occurrence of personality disorder typologies, and inadequate coverage of diverse presentations of personality disorder in practice settings, appear insurmountable[10]. Moreover, recent research suggests that select dimensional personality traits (e.g. neuroticism, agreeableness) independently predict remission in adults with borderline personality disorder (BPD)[20], adding incremental validity to efforts to assess for personality pathology.

BARRIERS TO DETECTION OF PERSONALITY DISORDER IN OLDER ADULTS

Avoidance of Disclosure

Personality disorder may be undetected or inaccurately assessed due to difficulties engaging in the personality assessment process on the part of patients and clinicians, and due to limitations in applying current measures and constructs for this purpose. Specifically, many older adults grew up in an age when it was not acceptable

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

to openly talk about discordant feelings or interpersonal conflicts. Perceived stigma may impede inquiry into deviant inner experiences or behaviours, and would also make it unlikely that an older adult would have received a previous personality disorder diagnosis of which they can inform their current physician[21]. In a complementary manner, some clinicians adhere to the erroneous belief that older adults simply do not have personality disorders[14]. In addition, personality disorders may increase risk for developing Axis I disorders and it is often for this subsequent condition that patients seek professional help. Axis I conditions may be easier to recognize and accept, for both the clinician and patient, and are therefore often deemed the focus of diagnoses and treatment.

Assessment Measures

The structured interview is often considered an ideal assessment tool for diagnoses of personality disorder, but is subject to biases and inaccuracies when assessing older adults. As longitudinal evidence is required for a diagnosis of personality disorder, older adults may be asked to recount events and trends from 30–50 years before, and it is often doubtful that such information is valid or reliable[21]. Furthermore, measures of personality disorder cannot fully account for the potential influences of current psychological states, medical or neurological problems, situational or environmental contexts, or sociocultural roles on reporting of current symptoms or behavioural patterns[21]. Self-report inventories face similar vulnerabilities[14,15], and must be supplemented by a practitioner's clinical judgement.

Diagnostic Criteria

DSM-IV criteria for many personality disorders may not be generalizable to experiences and behaviours displayed by older adults. For example, symptoms of personality disorder such as increased dependency, social withdrawal, or rigid and moralistic thinking may be misinterpreted by clinicians as part of the natural ageing process and therefore may not enable discrimination between normal and pathological behaviour. In a large epidemiological survey which compared younger and older adults with equivalent levels of personality disorder pathology, an item analysis found evidence for age bias in two thirds of personality disorder criteria sets[22,23]. Difficulties determining when impairment in social and occupational functioning is significant enough to warrant a diagnosis of personality disorder may also impede diagnosis. In the lives of older adults, where retirement and smaller social circles are common, this may not be an accurate measure of impairment[14,21]. Finally, discrete behaviours upon which inferences as to personality are based may be more fallible in older adulthood. As individuals age, changing physical and developmental capabilities may limit their repertoire of behaviour, and thus the likelihood that behaviours are completely representative of their inner character. In this context it may be dangerous to rely on a solely behavioural framework for diagnoses[11,24].

DOES THE AGEING PROCESS ALTER PERSONALITY PATHOLOGY?

One of the most prominent barriers to accurate detection of personality disorder pathology is uncertainty as to whether and how age-related biopsychosocial changes affect the phenomenology of personality disorder, and a definitive answer remains elusive. Tyrer and Sievewright[25] suggested that personality disorders can be divided into mature and immature types, in which the mature types, such as obsessive–compulsive, paranoid, schizoid and schizotypal, remain stable with age. In contrast, the more dramatic disorders, termed immature (borderline, narcissistic, histrionic), are hypothesized to decrease in intensity with age.

Empirical studies of normal personality find evidence for both stability and change over the life span. Major personality traits, such as those represented in the five-factor model (FFM) of personality (neuroticism, extraversion, openness, agreeableness and conscientiousness) have a prominent genetic basis, appear universal across cultures, and demonstrate substantial stability over the life course[10,26,27]. Hence, one might expect that maladjusted individuals with personality disorder tend to remain so as they age. However, a recent meta-analysis of 92 longitudinal studies of reports of personality traits over the life span found that 'people tend to become more socially dominant, conscientious, and emotionally stable through midlife' (p. 21)[28], suggesting a positive maturational effect for most adults likely linked to age-graded roles (e.g. work, marriage, parenthood). Personality processes, such as emotion regulation, also display favourable age-related changes in cross-sectional studies of younger and older adults[29,30]. Such findings are in accord with case series reports and cross-sectional studies of late life personality disorder[31], and suggest that normative, maturational effects may favourably modify the phenomenology of personality disorder in older adults, especially in areas such as affect regulation and impulsivity.

Longitudinal studies of personality disorder are limited, but extant research provides further insight into stability and change in the phenomenology of personality disorder over the life span. McGlashan[32] performed a longitudinal study on inpatients diagnosed with BPD, unipolar depression, or schizophrenia. He obtained follow-up data for over 288 participants (mean age of 47) at an average of 15 years after discharge (range 2–32 years). Compared to the other groups, the BPD group displayed the highest level of global functioning at follow-up, particularly in those conducted 10–19 years after discharge compared to subsequent follow-ups. Instrumental and global functioning increased for participants with BPD, whereas their interpersonal relationships often remained problematic or non-existent. McGlashan speculated that as patients with personality disorder age and lose employment capabilities, earlier improvements in instrumental functioning become less relevant and the lack of close relationships becomes more significant, potentially resulting in diminished functioning later in the life span. Similarly, a 16- to 45-year longitudinal follow-up of male inpatients diagnosed with antisocial personality disorder (ASPD) found that over half had improved or remitted, but that many also had enduring problems with occupational performance, interpersonal discord and social isolation[33].

Perry[34] reviewed 26 longitudinal studies on personality disorders, with the majority focusing on BPD. At an average follow-up of 8.7 years, only 57% of BPD patients continued to meet diagnostic criteria. This relationship was reportedly linear, with approximately 3.7% of borderline cases remitting each year. A more recent 10-year follow-up study of inpatients with BPD found that 88% achieved remission (many within 2 years), and that symptoms such as impulsivity were likely to resolve, while chronic dysphoria and interpersonal symptoms persisted[20,35].

In sum, investigations into the temporal stability of personality traits, disorders and processes find evidence for substantial continuity, particularly for major traits and for interpersonal functioning, but

also for favourable change in select areas, such as emotion regulation and impulsivity. Although we are unaware of studies that follow personality disorder into older adulthood, such findings suggest shifts in the phenotypic expression of personality disorder, and provide further empirical support for recommendations that clinicians consider possible attenuation and exacerbation of personality disorder traits and symptoms over the life span, apply time course criteria flexibly, and appreciate the salience of subsyndromal presentations of personality disorder in late life[11,24].

CHALLENGES IN THE DIFFERENTIAL DIAGNOSIS OF PERSONALITY DISORDER IN LATE LIFE

In addition to the barriers described above, clinicians who work with older adults face added diagnostic challenges, as personality disorder is often embedded in a complex matrix of age-related changes in cognitive and physical health, functional ability, interpersonal roles, and coping resources and behaviours. Although co-morbidity is the rule rather than the exception in geriatric practice, the DSM-IV-TR 'General Criteria for Personality Disorder'[16] require that manifestations of personality disorder be disentangled from major psychiatric syndromes, medical and neurological disorders, situational behaviours or coping styles, and social/cultural roles. Among the most vexing issues are difficulties differentiating personality disorder from (i) an unremitted Axis I disorder; (ii) context-dependent roles and behaviours; (iii) subtle neurocognitive impairment; or (iv) a difficult doctor–patient relationship.

Personality Disorder Versus Unremitted Axis I Disorder

In practice settings an older person's long-standing and unremitted Axis I pathology, especially if associated with features of irritability, negativism and caregiver exhaustion, is often attributed to personality pathology. Although personality pathology is correlated with poorer treatment outcomes and persisting decreases in functioning in older depressed samples[3–5], it is not a 'diagnosis of exclusion' and such a conclusion may confuse personality disorder with illness duration and/or treatment responsiveness. This challenge may be addressed through careful application of the general diagnostic criteria for personality disorder, supplemented by dimensional personality measures and informant reports, with special attention to temporal relationships between the onset of Axis I and Axis II symptoms. If core features of personality disorder persist following maximal treatment of Axis I syndromes with combination therapies, a definitive diagnosis of personality disorder may be warranted.

Personality Disorder Versus Context-Dependent Roles and Behaviours

Older adults confronted with significant, ongoing life stressors such as serious medical illness (e.g. becoming disabled), interpersonal loss or role transition (e.g. becoming a caregiver), or the need to navigate a novel social environment (e.g. long-term care setting) may exhibit behaviours that mimic aspects of personality pathology. For example, confronted with medical problems or physical limitations, some elderly may express their distress somatically as if to manipulate the responses of caregivers; others may become antagonistic and demanding; still others may regress to a child-like dependency. Although significant psychosocial stressors may lead underlying personality disorder features to emerge[24], it is often the case that such behaviours are context-dependent, or only loosely tied to personality traits rather than disorders. A longitudinal history, supplemented by informant data and dimensional measures of personality, may help clarify whether personality disorder symptoms and behaviours preceded the change in life context, thus meriting a diagnosis of personality disorder.

Personality Disorder Versus Subtle Neurocognitive Impairment

Neurological disorders such as Alzheimer's disease, Parkinson's disease, and vascular and frontotemporal dementias are common in late life, and both their characteristic features and associated behavioural manifestations are well recognized. Recent evidence suggests that personality changes (such as increased egocentricity, emotional lability, rigidity or apathy) may represent early or prodromal manifestations of dementia[36]. Further, neuroscience research affirms that impairment of discrete brain regions often manifests as personality changes: orbital frontal lobe dysfunction is associated with reduced empathy and disinhibition; dorsolateral frontal lobe impairment is related to impaired initiation, planning and social awareness; parietal and temporal lobe insults are associated with misperception of the emotional context of speech[24]. Personality manifestations that are prominent, have insidious onset or long duration, and overshadow evidence of neurocognitive impairment (which may be subtle) may be mistaken for personality disorder. When such personality features are the consequence of a medical condition, result in functional impairment and are not attributable to a diagnosis of dementia, delirium or another Axis I disorder, they are best described in DSM-IV-TR nosology as 'Personality Change Due To ... (a general medical condition)'[16]. A careful historical review of the temporal relationship between medical or neurocognitive and personality symptoms, assisted by a neuropsychological evaluation or diagnostic neuroimaging may clarify this differential diagnosis.

Personality Disorder Versus a Difficult Doctor–Patient Relationship

Patients who are especially challenging to treat due to prominent mood states such as irritability/hostility or fearfulness/mistrust, who deny emotional distress or express this through somatic complaints, or whose interpersonal behaviour violates 'expected rules' of the doctor–patient relationship are often experienced as difficult by their clinicians. Although clinicians' emotional experiences may signal the presence of a patient with personality disorder, difficulty experienced in the doctor–patient relationship can also occur in the context of somatization disorder and other Axis I disorders[37,38]. Hence clinicians' emotional experiences provide important data, but may be non-specific regarding presence/absence of personality disorder. For purposes of differential diagnosis, such data might best be evaluated alongside informant information, clinical history and other assessment approaches described above.

One might expect that the above challenges would result in many false positive diagnoses of personality disorder in late life, but more commonly, behavioural problems that mimic personality disorder are informally and erroneously attributed to 'personality' in much the same way that ambiguous medical problems are ascribed to 'ageing'. Both practices may serve to reduce clinicians' discomfort with diagnostic uncertainty or other dissonant experiences, but can also result in failure to detect or properly manage an underlying, potentially treatable condition.

MANAGEMENT AND TREATMENT OF PERSONALITY DISORDER IN OLDER ADULTS

Progress in the development of strategies to manage and treat personality disorder has been slow, and evidence-based guidelines regarding the treatment of personality disorder in older adults currently do not exist. Hence clinicians engaged in the psychotherapeutic or pharmacological treatment of older adults with personality disorder often extrapolate from treatment models developed for younger adults. Generally, approaches for managing late-life personality disorder are based on the following premises: (i) evidence-based treatments for Axis I disorders require augmentation when personality pathology is present; (ii) standardized psychotherapeutic treatments developed to target aspects of personality disorder in adults are more effective than usual care; (iii) initial studies suggest that older adults may also benefit from these targeted treatments; (iv) guidance regarding the treatment of personality disorder in late life may be derived from common ingredients of effective approaches, extant research and clinical observations.

Studies of depressed younger or older adults provided with standardized brief treatments demonstrate that those with co-morbid personality disorder achieve less favourable outcomes[4,39]. Importantly, these data do not suggest that depressed older adults with co-morbid personality disorder cannot derive some benefit from treatment for Axis I conditions[40], but they underscore that those with personality disorder are at higher risk of slower treatment response or adverse outcomes[5]. The presence of a personality disorder may interfere with the success and efficacy of such treatments in a variety of ways: long-standing maladaptive interpersonal patterns can pose challenges to forming a working therapeutic alliance; patients may be unwittingly invested in their symptoms and reluctant to get better for fear that secondary gains (attention, sympathy, intimacy) of illness may be lost; other aspects of the patient's life may be so chaotic that treatment adherence is difficult; or a patient may act out in offensive or self-destructive ways, causing the clinician to decrease their commitment to and optimism about treatment.

Empirical studies of psychotherapeutic approaches developed for the treatment of personality disorder in adults demonstrate promising findings. Dialectical behaviour therapy (DBT), schema-focused therapy, transference-based psychotherapy, and interpersonal group therapy have displayed efficacy in treating characteristic maladaptive coping styles and behaviours common to BPD in adults[41–43]. Preliminary findings suggest that at least some of these models may have utility in treating depressed elderly with co-morbid personality disorder. In a recent trial, older adults with chronic depression and co-morbid personality disorder demonstrated improved remission rates when antidepressant treatment was combined with an adapted form of DBT. Those offered combined treatment also showed reduced interpersonal sensitivity and aggression, although it is unclear if other components of personality disorder were ameliorated[44].

Since effective approaches to treating personality disorder appear to share common ingredients, Livesley has argued for an integrative, common factors therapeutic approach[1,45]. Such an approach would combine treatment modalities (psychotherapeutic and psychopharmacologic; individual and group psychotherapies) and techniques (behavioural, cognitive and psychodynamic) and maximally draw upon common factors found to be effective across treatments as part of an intensive, long-term intervention. Although this model has yet to be validated for older adults, it is consistent with models, emerging research and clinical reports regarding the treatment of late-life personality disorder[31,44,46–50].

PSYCHOTHERAPEUTIC MANAGEMENT: BASIC PRINCIPLES

Collaborative Multimodal Treatment, Managing Crises and Ensuring Safety

Effective treatment approaches for personality disorder tend to utilize a collaborative multimodal approach, in which clinicians of different disciplines combine treatment interventions to help the patient. Since older adults with personality disorders are likely to experience functional impairment in multiple areas (health, mood, social functioning), a multimodal approach in which the person may receive individual and group therapy, pharmacotherapy, medical attention for health concerns and case management is often ideal.

As with any psychiatric illness, the utmost priority in the treatment of patients with personality disorder is ensuring the patient's safety. Older adults with personality disorder may be prone to act in impulsive and self-destructive ways, arousing clinicians' concerns regarding their potential for self-harm or suicidal behaviour. A collaborative and cohesive treatment approach, often including all treatment team members and enlisting the patient's family or significant others to ensure safety, may assist to defuse such crises. This approach can also help clinicians evaluate the patient's need for hospitalization, closely monitor symptoms, and modify treatment parameters as needed.

Treatment Parameters

Effective psychopharmacological or psychotherapeutic treatment of individuals with personality disorder requires that clinicians attend carefully to treatment parameters such as session frequency and duration, availability of clinicians during non-treatment hours, policies regarding confidentiality and consent, and the respective roles and responsibilities of the patient and team members. Individuals with personality disorders may be more likely to cross boundaries with clinicians, or in some cases, encourage clinicians to cross boundaries for them. When clinicians find themselves stepping outside their normal repertoire of behaviour for a patient, whether in a positive or negative way (avoiding sessions, letting the session go overtime, doing tasks for patients that one would expect other patients to do for themselves, having intrusive thoughts or fears about a patient), this can reflect an enactment of the patient's interpersonal problems. When a clinician conceptualizes such boundary disturbances in a therapeutic manner (i.e. this person crosses boundaries because it is likely that someone crossed boundaries inappropriately with them in the past), it may be easier for the clinician to intervene using a combination of empathic clarification and limit-setting approaches, while maintaining a therapeutic alliance with the patient.

A common clinical occurrence when working with individuals with personality disorder is the propensity for the patient to split the treatment team. Splitting describes a tendency to engage in dichotomous thinking, such as categorizing people or experiences as all good or all bad, often evoking responses that appear to confirm this polarized and distorted perspective. When splitting does happen, it is of utmost importance that the treatment team recognizes it, retains solidarity and acts towards the patient as a unified front, especially in regard to treatment parameters, expectations regarding the patient's responsibilities in the treatment, and consequences regarding a failure to meet these expectations.

Patients with personality disorder may be especially prone to acting out or becoming more symptomatic when there is a transition

regarding the treatment team. Whether prompted by a clinician's departure or the patient's need for a different level of care, such personnel changes may be interpreted implicitly as rejection or abandonment, and it is essential that transitions be handled with sensitivity and increased alertness regarding safety issues. Anticipatory discussions of these transitions permit an exploration of how the patient perceives them, and a respectful and empathic response by the clinician may serve to diminish the chance of exacerbated symptoms or maladaptive behaviours. An interdisciplinary treatment team of providers may also serve to offer some constancy during such times.

Therapeutic Relationship and Treatment Alliance

Some of the most effective treatments for people with personality disorders are those that highlight the importance of the therapeutic relationship. For example, dialectical behaviour therapy, schema-focused therapy, transference-based psychotherapy and interpersonal group therapy all include a focus upon emotion regulation and the recognition of maladaptive interpersonal patterns, with special attention to how these problems may affect the therapeutic alliance. Several of these models, tested primarily in adults with BPD, suggest that clinicians assist patients to recognize and expect the emergence of underlying insecurities that would normally rupture the therapeutic process. For example, when conflicts in therapy arise, the clinician may enquire about past relationships in which the person had a similar experience or felt the same way. Clarifying similarities and differences between experiences of current and past relationships, and recognizing and correcting cognitive distortions about relationships, can be beneficial. During this process, as individuals with personality disorder come to recognize and label their own underlying emotions and experiences, they tend to engage less in acting out unacknowledged affective states, prompting interpersonal relationships to improve.

Since maladaptive interpersonal behaviours are core aspects of personality disorder, clinicians often find it difficult to form and maintain the alliance that is needed as a foundation of treatment. Clinicians challenged by this ongoing struggle may find it helpful to keep the aetiological factors of personality disorder, such as early trauma or aversive psychosocial experiences, in mind. Without understanding the underlying issues which often drive patients with personality disorder to act in offensive or self-destructive ways, clinicians are bound to be put off and frustrated by such patients, and it is likely that a clinician's instinctive defensive or avoidant response may reinforce the patient's pathological beliefs and interpersonal patterns. Thus, clinicians need to draw on their reservoir of knowledge to understand the underlying motivations for such behaviour so as not to contribute to its negative effects. Accordingly, a useful clinical guideline to keep in mind when treating individuals with personality disorders is to respond to underlying anxieties rather than maladaptive coping styles or defences. If one conceptualizes an individual's personality disorder in terms of an underlying vulnerability (e.g. sensitivity to issues of abandonment, loss of control, rejection etc.), one may be better able to respond to these insecurities as opposed to the maladaptive behaviours they can inspire. When the clinician can maintain a therapeutic stance (often putting their own ego and pride aside) and respond to the patient by acknowledging and validating fears, they are more likely to be able to successfully set limits, break interpersonal patterns, and provide patients with a new experience that can lead to real change.

PSYCHOPHARMACOLOGICAL MANAGEMENT

As mentioned above, psychopharmacological intervention is often an important component of a multimodal integrative approach to the treatment of personality disorder, and both theoretical and practical rationales may be presented for pharmacotherapy for late-life personality disorder. First, there is evidence that neurochemical abnormalities (e.g. serotonergic dysfunction) mediate the relationship between adverse genetic or environmental diatheses (e.g. temperament) and manifestations of personality pathology (e.g. impulsive aggression; suicidal and compulsive behaviours)[51]. Similarly, there is some evidence that dimensions of personality pathology (e.g. affective dysregulation, cognitive-perceptual dysfunction, impulse dyscontrol) may share common psychobiological substrates with Axis I disorders, and thus targeted pharmacotherapies might address neurotransmitter systems linked to these underlying substrates[49,52]. A second, practical rationale for adjunctive pharmacotherapy is that personality disorder is often associated with Axis I disorders, brief destabilizing symptoms such as agitation or psychotic-like experiences, and behavioural crises, in which cases pharmacotherapy can be employed to manage acute symptoms, restore emotion regulation and reduce overall functional impairment.

Controlled studies find that psychopharmacological interventions have some effectiveness in treating circumscribed symptoms related to personality disorder, but research has been limited to three personality disorder types (borderline, schizotypal and antisocial personality disorder) and has only been conducted in young adult samples[31]. Studies of patients with BPD have found that atypical antipsychotic, anti-epileptic, and SSRI or SNRI medications effectively treat symptoms of cognitive-perceptual disturbance, mood instability and negative emotionality or aggression, respectively[51]. However, a review of forty randomized controlled trials of pharmacotherapy for adults with personality disorder (borderline, schizotypal and antisocial types) cautioned that although useful, psychotropic medications tend to only induce partial improvement in circumscribed areas[53].

A general framework for psychopharmacologic management of older adults with personality disorder augments general principles of geriatric psychopharmacology with an understanding of both the potential goals and challenges of managing symptoms in the context of late-life personality disorder. Once the best possible diagnostic formulation is reached, clinicians are advised to review with the patient all medications and remedies currently in use, and to attend to possible medication interactions[49]. The presence of comorbid medical illnesses, cognitive impairment and other factors that may affect adherence should be identified. Even when target symptoms and goals are identified and agreed upon, it is important that both clinician and patient recognize that pharmacotherapy will not cure the personality disorder, and so the potential benefits and risks of treatment should be carefully reviewed and documented. In regard to specific agents, recent reviews suggest that SSRIs be used as first-line interventions for low mood as well as suicidal, aggressive or obsessional behaviours, and that mood stabilizers be considered to control affective fluctuations, which may occur in the context of cluster B and C personality disorders. Atypical antipsychotic medications may be helpful when psychotic-like symptoms are present, or in cluster A personality disorders. All reviews emphasize the prescribing clinician's need to carefully attend to the doctor–patient relationship, as a tenuous alliance and medication misuse or non-adherence are common in work with patients with personality disorders[11,31,53,54].

CONCLUSIONS

Personality and personality pathology exert profound effects on psychological well-being in older adults, yet are often underdetected and undertreated. Barriers to effective diagnostic assessment include the limitations of current measures, the differing phenomenology of late-life personality disorder and problems in differential diagnosis. Current findings favour a two-step, multimethod assessment approach in which presence/absence of personality disorder is first identified according to DSM-IV 'General Criteria for Personality Disorder'[16] and then supplemented by collaterally informed semistructured interviews, and dimensionally-based personality self-report measures to characterize personality disorder type[45]. Longitudinal assessment may be required to fully sort out personality disorder from Axis I disorders, subtle neurocognitive impairment, context-dependent behaviours, or other causes of difficult doctor–patient relationships.

Although randomized controlled trials of the treatment of late-life personality disorder are rare, recent findings in young adults suggest that components of personality disorder are amenable to targeted psychotherapies and pharmacotherapies. An integrative approach that combines treatment modalities and the common therapeutic ingredients of efficacious approaches may offer the best hope for the management and treatment of late-life personality disorder.

INTRODUCTION

Alcohol abuse in the elderly involves the persistent and intended use of ethyl alcohol despite problems caused by its use[1,2]. It is often overlooked, as elderly with alcohol abuse may present with non-specific concerns such as confusion, mood lability, depression, anxiety, unusual behaviour, self-neglect, falls, injuries, diarrhoea, malnutrition, myopathy, incontinence, hypothermia[3–5] and motor vehicle accidents[6]. However, as these conditions are evaluated, signs of the characteristic addictive use of ethyl alcohol may be uncovered with: (i) tolerance; (ii) withdrawal symptoms; (iii) loss of control of use; (iv) social decline; and (v) mental and physical decline[2]. Late-life alcoholism is a substantial problem. In a recent population representative study which included 4236 non-institutionalized elderly, at-risk alcohol use was described by 13% of men and 8% of women, and binge drinking was reported by over 14% of men and 3% of women[7]. In another recent study of 24 863 elderly primary clinic patients, 21.5% were moderate drinkers, 4.1% were at-risk drinkers and 4.5% were heavy or binge drinkers[8].

EFFECTS OF ALCOHOL IN THE ELDERLY

Older people are at greater risk and more vulnerable to the toxic effects of alcohol for two main reasons:

1. The elderly have a decreased volume of distribution due to decreased muscle mass, a greater proportion of fat and a smaller water compartment. These all result in a higher blood alcohol level than in a younger adult for the same amount of alcohol consumed[9,10]. In a younger person, larger amounts of alcohol consumption may be necessary before detrimental effects from alcohol abuse become grossly evident. A susceptible elderly person may reach this threshold for hazardous use of alcohol after drinking relatively less.
2. The general decrease in the capacity to withstand stress and maintain homeostasis as well as a higher risk for medical illness and disability in elderly people may hinder adaptation to the noxious effects of alcohol and magnify the consequences of alcohol abuse in the elderly[11].

The interaction of these two main factors places the elderly alcohol-using person at greater risk for multiple impairments resulting from the use of alcohol.

There are many possible detrimental effects from alcohol abuse in the elderly. Among them are the following:

1. Driving ability can be adversely affected with the consumption of minimal amounts of alcohol. In some elderly, relatively small amounts of alcohol can exacerbate or lead to confusion, visuospatial impairment, problem-solving deficits, motor impairment[12] and motor vehicle accidents[6].
2. Cognitive impairments suggesting dementia may be caused by alcohol abuse. Though some cognitive impairment can result from even social drinking, chronic consumption of higher doses of alcohol has been shown to cause marked cognitive deficits with associated cortical atrophy and ventricular dilatation on brain scan[12].
3. Elderly alcoholics have a higher prevalence of alcohol-related medical conditions than the elderly population at large. Such conditions include alcoholic liver disease, alcoholic cardiomyopathy, hypertension, chronic obstructive pulmonary disease, neurological diseases (including cognitive disorders and peripheral neuropathy), malnutrition, osteopenia, psoriasis, peptic ulcer disease and various cancers[3,12,13].
4. Alcohol use can adversely affect the elimination of some drugs and add to the toxicity of others. This places an elderly person with medical illness or disability who is taking prescription medication at great risk for having subtherapeutic or adverse effects from the medication[14,15]. The magnitude of this problem is evident when one considers that the elderly are the largest per capita prescription drug users[16] and the most at risk for medication associated adverse events[17].
5. The depressant effects of alcohol on the central nervous system may mimic or contribute to depression in the elderly. Some elderly with depressed mood may resort to drinking in order to 'self-medicate' themselves. This may alleviate the depressive symptoms initially, but later lead to an increase in depression, anxiety, sleep disturbances and impotence[18,19].

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

6. Alcohol can contribute to malnutrition in the elderly. Malnutrition can result from the interaction of the following factors[20,21]:
   (a) Food intake can be hindered if the elderly alcoholic develops depressed mood, becomes apathetic and experiences loss of appetite. If the elderly alcoholic's impaired ambulation or driving results in a reduced capacity to obtain food, or if limited financial resources are used to purchase alcohol instead of food, dietary intake may be restricted further.
   (b) The effect of alcohol on the gastrointestinal tract is to produce malabsorption of fats, fat-soluble vitamins, calcium, magnesium, iron and zinc. The active transport of B vitamins is also impaired.
   (c) Alcohol can contribute to increased losses of magnesium, phosphate, potassium and zinc through the urine. If vomiting and diarrhoea occur, there may be increased loss of sodium, potassium and chloride.
   (d) Alcohol use increases the requirements for folate and pyridoxine.
7. Alcohol use contributes to accidents and injuries that may lead to fractures or subdural hematomas[3,6,22].
8. Heavy use of alcohol is associated with greater mortality[23–25].
9. Alcoholism can disrupt the elderly alcoholic's family structure and cohesiveness, and may even lead to family violence. This can result in dysfunctional family relationships, with consequent increased difficulty in treatment of the alcohol-related problems.

Despite the many unfavourable effects of alcohol abuse in the elderly, researchers have also reported positive aspects of alcohol use. Light to moderate alcohol consumption has been associated with decreased mortality risk[24,25], reduced risk of substantial functional health decline[26], better cognitive health and well-being[27,28], improved bone mineral density[29] and, in elderly coronary patients, elevated high-density lipoprotein cholesterol[30].

CHARACTERISTICS OF ELDERLY ALCOHOL ABUSERS

Elderly alcohol abusers differ from younger alcohol abusers in a number of ways. Alcohol abuse in the elderly is often associated with clusters of stressors such as job retirement, widowhood, the deaths of close friends and relatives, medical illness and disability in oneself and one's peers, and perceived loss of meaningful roles or functions. Some authors consider late-onset alcoholism to be associated with tension reduction, where alcohol is used to regulate stress. However, the extent to which alcohol abuse in the elderly is precipitated by stress is unclear. Some researchers have found little or unexpected change in alcohol consumption or drinking behaviour due to life stressors[31,32].

The time of onset of alcohol abuse may also significantly differentiate the younger alcoholic from the older one[10,33,34]. The early-onset alcoholics have a greater amount of psychopathology and family history of alcoholism than the late-onset alcoholics. The early-onset alcoholics are characterized by being male relatives of alcoholic men with histories of violence with and without alcohol, legal problems due to alcohol use and illegal substance abuse. The late-onset alcoholics are characterized by having isolated alcohol-induced problems with health, marital relationships, or self-care, and much reduced histories of arrests, violence or other substance abuse. Many elderly with alcohol problems fall into the late-onset alcoholic group. These findings suggest that the aetiology and predisposition of a person to an alcohol use disorder may differ by onset age. If this is so, the treatments and interventions for an alcohol use disorder may also differ with age of onset and need to be individualized accordingly.

Individual feelings towards alcohol use are affected by exposure to cultural and historical attitudes[35]. For example, the experience of the American elderly alcoholic may differ from that of younger alcoholics in that the elderly alcoholic and his peers may have been exposed to the turmoil of the Prohibition era[36]. The moral issues highlighted in this historical period may influence the willingness that some elderly may have in recognizing and accepting a diagnosis of and treatment for alcoholism. In some retirement communities, evening cocktails are a part of the social routine, leading some individuals to increase their prior alcohol consumption.

THE RECOGNITION OF ALCOHOL ABUSE IN THE ELDERLY

Alcohol abuse in the elderly often comes to the attention of health professionals through presentation with a non-specific medical or psychiatric symptom, such as self-neglect, falls, confusion, emotional lability, depression, unusual behaviour, injuries, diarrhoea, malnutrition, myopathy, incontinence or hypothermia. In cases where alcohol abuse is suspected, alcohol dependence must be considered. Alcohol dependence is suggested when there is: (i) tolerance; (ii) withdrawal symptoms; (iii) loss of control of use; (iv) social decline; and (v) mental and physical decline[2,37].

Tolerance to alcohol may be assessed by establishing a reliable history of the patient's drinking pattern. Corroboration from family members and others close to the patient may be crucial. Tolerance is suggested if the patient exhibits a quantity and frequency of drinking which is increased over his baseline pattern of drinking. A patient with tolerance to alcohol will require a greater quantity of alcohol to achieve the same amount of inebriation that a lower quantity had been able to achieve previously. Tolerance is strongly suggested if there has been at least a 50% increase in the amount of alcohol required to attain a given effect[2,37].

Withdrawal symptoms occur when a patient who is physically dependent on alcohol experiences a rapid decrease in blood alcohol concentration. In an older person, the onset of withdrawal may be delayed by days after drinking cessation, and the duration of withdrawal may be prolonged[37,38]. Symptoms of the alcohol withdrawal syndrome stem from autonomic hyperactivity and include tachycardia with a pulse of greater than 110 beats per minute, tachypnea, hypertension, low-grade fever, sweating, nausea, vomiting, hand tremors and increased anxiety. In some cases, the patient may develop seizures or delirium tremens with confusion, agitation and visual or tactile hallucinations. An elderly patient undergoing withdrawal may experience one or all of these symptoms[37,38].

Loss of control means that the patient is no longer able to consistently choose the amount of alcohol consumed in a given situation[37]. The patient may also experience blackouts, and behave and feel in unpredictable ways.

Social decline in the elderly alcoholic is assessed from a baseline of age-appropriate behaviours[2,37,38]. Many elderly people no longer hold a steady job, do not drive or hold a driver's license, and have lost many of their close friends and associates with whom they used to socialize. Thus, it may not be as appropriate to assess for social decline by investigating these areas of the elderly patient's life as it would be in a younger patient. However, it is relevant and revealing to ask elderly people if they are in contact with their children or grandchildren, and to what extent. It is also useful to find out whether

the patient's relatives express any concern about the patient's alcohol use. Investigating the patient's functioning with respect to hobbies or other enjoyed activities can also be useful.

Physical, psychological and laboratory findings may also uncover problems with alcohol use[37–39]. Addictive alcohol use can lead to malnutrition, gastrointestinal upset and bleeding, delirium, falls, depression, hypertension and neglect of self. Recurrent diseases of the stomach, pancreas or liver may also be caused by excessive alcohol abuse. These medical conditions often bring the elderly alcoholic to clinical attention. Laboratory results of macrocytosis, elevated mean corpuscular volume and increased liver enzyme levels, especially gamma glutamyl transpeptidase, may correlate with alcohol abuse in the elderly. Carbohydrate-deficient transferrin is approved by the Food and Drug Administration (FDA) as a clinical diagnostic test for identifying heavy alcohol use[39]. Blood alcohol levels, and urine or breath tests for alcohol, may be used to confirm alcohol intoxication.

Assessment of tolerance, withdrawal, loss of control, social decline and mental and physical decline are useful clinical parameters to recognize and diagnose alcohol addiction. Several screening instruments have been devised to help clinicians recognize alcoholism. These scales typically assess the quantity and frequency of drinking, social and legal problems resulting from alcohol abuse, health problems related to excessive alcohol use, symptoms of addictive drinking and/or self-recognition of alcohol-related problems[40,41]. Three screening instruments that are commonly used with the elderly are the CAGE screen[42], the Short Michigan Alcoholism Screening Test-Geriatric Version (S-MAST-G)[43] and the Alcohol Use Disorders Identification Test (AUDIT)[44].

The CAGE screen is the most widely used. 'CAGE' is a mnemonic for the questions: Have you ever felt a need to Cut down on drinking? Have you ever felt Annoyed by others enquiring about your drinking? Have you ever felt Guilty about drinking? Do you ever use alcohol for an Eye-opener? If two or more of these questions are answered positively, a need for more extensive evaluation for alcohol abuse is indicated. The validity of the CAGE screen for alcoholism in the elderly has been examined empirically[42].

A more detailed screen is the 10-item S-MAST-G[43] or the original 24-item MAST-G[45]. The S-MAST-G was developed for screening older adults in various settings and has excellent psychometric characteristics. Scores of ≥ 2 on the S-MAST-G or of ≥ 5 on the MAST-G are indicative of possible problems with alcohol.

The AUDIT[44] emphasizes the identification of harmful drinking and need for current treatment. It was validated in a sample of non-elderly adults and is composed of two parts: a 10-item AUDIT Core Questionnaire and an 8-item AUDIT Clinical Procedure. The AUDIT Core Questionnaire includes specific questions about the quantity and frequency of drinking and can be incorporated into a general interview or medical history. In the original study sample, all alcoholics scored ≥ 9 on the AUDIT Core Questionnaire. The AUDIT Clinical Procedure complements the AUDIT Core Questionnaire and includes questions about clinical signs associated with harmful drinking, such as fractures, tremors and hepatic abnormalities. The AUDIT Clinical Procedure may be especially helpful in evaluating patients who underestimate their alcohol-related problems. A short version of the AUDIT, the AUDIT-C[46], is a 3-item screen composed of the alcohol consumption questions of the AUDIT. The AUDIT-C has been reported to be a valid primary care screen for heavy drinking and/or current alcohol abuse/dependence. Various versions of the AUDIT have been used widely, but for older adults, the overall accuracy is low and multiple screening methods are recommended[47,48].

THE TREATMENT OF ALCOHOL ABUSE IN THE ELDERLY

In acutely intoxicated patients, a thorough evaluation for and treatment of other co-existing medical or psychiatric problems must be initiated at the same time as the patient is being detoxified. Providing adequate nutrition and hydration is especially important in the elderly alcoholic due to increased nutritional problems and impaired thirst mechanisms in the elderly. Benzodiazepines are generally avoided in most elderly due to their potential for causing delirium. However, if significant withdrawal symptoms occur, benzodiazepines should be administered according to assessments of alcohol withdrawal severity[38,49]. Withdrawal severity may be evaluated using the revised Clinical Institute Withdrawal Assessment Scale for Alcohol (CIWA-Ar)[50] and taking sequential vital sign measurements. Elderly patients may experience a delayed onset of and more severe withdrawal from alcohol and require higher doses of benzodiazepines than younger patients[38]. In general, detoxification using a symptom-triggered regimen with benzodiazepines with a shorter half-life is recommended in the elderly. Longer acting benzodiazepines may allow a smoother course of withdrawal but may cause more sedation in elderly patients[38]. They may also cause ataxia which can lead to falls. Non-benzodiazepine GABAergic medications are considered to be potential agents to treat alcohol withdrawal[51], but their effectiveness in elderly patients is unclear. There is anecdotal experience for trying an anticonvulsant such as divalproex to prevent withdrawal seizures.

Once the elderly alcoholic patient is detoxified, adequate relapse prevention and rehabilitative treatment is crucial for the patient to maintain sobriety. The elderly alcoholic must first come to an acceptance of the alcohol abuse problem. Family members or others who are close to the patient may intervene to help the patient break through the denial regarding alcohol abuse seen in many alcohol abusers. Family members may also be instrumental in motivating the patient to stop drinking. Patient and family education about the effects of alcohol must be provided, and the need to abstain from alcohol must be stressed. Although light-to-moderate drinking has been reported to be health promoting [24–30], abstinence may be the healthiest goal for those who are unable to drink normally, tend to lose control of their drinking, or lose control of themselves when drinking. Early intervention includes brief alcohol counselling (BAC) to patients and family which encompasses expressions of concern, feedback associating the patient's drinking with health issues and explicit advice to reduce drinking[52]. Age-specific relapse prevention and rehabilitative programmes may improve treatment participation and completion[53]. A behavioural and self-management treatment module has resulted in marked success in treating alcohol-use problems in the elderly[53]. This module educates the elderly alcoholic about drinking behaviour, the acquisition of self-management skills and the reestablishment of social networks.

The elderly alcoholic patient's recovery and rehabilitation is an ongoing process. The patient needs to learn to readjust to life without alcohol. The patient's family and close relatives and friends can help him in this endeavour by supporting sobriety in the patient and incorporating the non-drinking patient into their lives without the presence of alcohol. Family members may have been 'enabling' the patient to drink, and they need to be made aware of these patterns of behaviour and change them through family education and family therapy. Sometimes, even when relatives are aware of the harmful effects of alcohol, they still provide alcohol if the patient insists. If the elderly alcohol abuser is a parent and the enablers

are his children, the role reversal that is inherent in the children's setting limits on their parents may make this task especially difficult. Group therapy may help the patient adjust to a non-alcoholic lifestyle. In this setting, he can develop non-alcohol-related social skills and learn to bond with others in safe surroundings, free of the context of alcohol. If elderly alcoholics can be treated in age-specific groups, they may remain in treatment significantly longer and be more likely to complete treatment than those treated in mixed-age groups[53]. Involvement in Alcoholics Anonymous with people with whom the patient feels comfortable and can consider his peers is important, especially if he has no close relatives or friends. The relationships with others that can be formed in these settings can provide a replacement for the alcohol to which he was bonded previously. Family involvement with the patient in Alcoholics Anonymous and in other affiliated groups such as Alanon, Alateen or Alatot is important, as alcoholism adversely affects family members who also need support, education and treatment.

Use of alcohol-deterrent medication such as disulfiram or anti-craving medication such as naltrexone may serve as adjunctive treatments. Disulfiram is infrequently used in the elderly due to concerns about adverse effects. Naltrexone was approved by the FDA for the treatment of alcohol dependence, based on efficacy studies with middle-aged patients with alcohol dependence[54,55]. It seems to be well tolerated in many elderly. A study in older veterans aged 50–70 found that treatment with naltrexone 50 mg/day resulted in decreased rates of relapse to heavy drinking, but no improvement in total abstinence[56]. These drugs may help motivated alcohol abusers reduce the quantity of alcohol used or the number of drinking days. However, these medications generally are not effective unless prescribed and monitored as part of an overall, multidisciplinary treatment and relapse prevention plan. Acamprosate has anti-craving therapeutic effects and also has been FDA approved for the treatment of alcohol dependence. It seems to be well tolerated by elderly, but there are no clinical trials focusing on its use in elderly[52].

The cultural aspects of alcohol abuse intervention are also worthy of consideration. In instituting any type of treatment or intervention, it is important to consider the context of the problem that is being addressed and the context into which the treatment or intervention will be instituted. The consumption of alcohol can take on a variety of cultural meanings. To some groups, ethanol is a food or is associated with religious rituals. For others, it is a means to relax and calm one's nerves. For still others, alcohol is considered to be a sinful intoxicant used by those of weak moral fibre. To intervene most effectively with an aged person for whom alcohol consumption has become a problem, it is important to understand what meaning the use of the alcohol has for him as an individual, a family member and as part of the greater society, including his cultural group. The contextual meaning of the change in alcohol use must likewise be considered. To understand these contextual meanings most effectively, the clinician must be aware of what his inherent assumptions may be about these contextual meanings and try not to confound with his own biases, his understanding of the situation. Members of the patient's contextual and cultural groups may be very helpful in providing meaningful insights into these understandings. Once these cultural factors are understood, interventions to reduce the problematic alcohol consumption to the desired outcome of abstinence or, perhaps, of less harmful alcohol use can be creatively formulated and instituted more effectively and efficiently.

CONCLUSION

In summary, alcohol abuse in the elderly is a significant problem that needs to be addressed aggressively. Recognition and diagnosis of alcohol abuse may be more difficult in the elderly. The biological and psychosocial losses and decline that are often used to identify alcoholism in younger people can occur in many elderly who do not abuse alcohol. The clinical presentation of an elderly alcoholic is often with a medical condition that may be masked by other medical diagnoses. For these reasons, the clinician must be especially alert to the possible presence of alcohol abuse in this age group. If alcohol abuse is identified, the clinician must then be prepared to direct or initiate treatment in a culturally appropriate, sensitive, flexible and creative manner that is geared to the elderly individual and his family and significant others.

Epidemiology of Alcohol Problems and Drinking Patterns

Celia F. Hybels and Dan G. Blazer

Department of Psychiatry and Behavioral Sciences, Center for the Study of Aging and Human Development, Duke University Medical Center, Durham, NC, USA

Alcohol use in excess of recommended limits is an important clinical issue for older adults. This chapter begins by summarizing the epidemiology of alcohol use disorders. Some older adults, however, fail to meet criteria for alcohol abuse or dependence yet engage in heavy drinking. The chapter continues with a discussion of patterns of alcohol use and problem drinking as well as the factors and outcomes associated with alcohol problems in this population. Issues of detection and co-morbidity are also addressed.

PREVALENCE OF ALCOHOL USE DISORDERS

Over the past decade, large community-based epidemiologic studies have provided new information concerning the prevalence of alcohol use disorders in the general population. In the National Comorbidity Survey Replication (NCS-R), conducted in the USA between 2001 and 2003 with a representative sample of 9282 adults, the lifetime prevalence of DSM-IV alcohol abuse disorder was 13.2%, a lifetime prevalence similar to that of major depression, specific phobia and social phobia, and therefore one of the more common lifetime psychiatric disorders. The lifetime prevalence of alcohol abuse disorder among those 60 years or older was 6.2%, lower than that observed for those aged 45–59 years (14.0%), 30–44 years (16.3%) and 18–29 years (14.3%). The lifetime prevalence of alcohol dependence was not as high as that of alcohol abuse, and among those aged 60 or older was 2.2%[1]. Although higher estimates were reported from the 2001–2002 National Epidemiologic Survey of Alcohol and Related Conditions (NESARC) in the USA (the lifetime prevalence of any alcohol use disorder was 16.1% among those aged 65 or older), younger or middle-aged adults were still 2.5 to 3.5-times more likely to have a lifetime alcohol use disorder than those aged 65+[2]. These estimates are similar to those obtained in the landmark Epidemiologic Catchment Area (ECA) surveys where the lifetime prevalence of alcohol abuse/dependence was 13.52% among older males compared to 26–28% among males aged 18–44. The lifetime prevalence among older females was 1.49%[3].

Similar to lifetime estimates, the current prevalence of alcohol use disorders has been shown in cross-sectional studies to decline with age. In the NESARC, the 12-month prevalence of DSM-IV alcohol abuse was 7.0% among those aged 18–29, 6.0% among those 30–44, 3.5% among those 45–64 and 1.2% among those aged 65+. A similar decline was observed for alcohol dependence with a 12-month prevalence of 9.2% among those aged 18–29 and 0.2% among those aged 65+[2]. These estimates are in agreement with the 12-month prevalence of any alcohol use disorder in the ECA among those aged 55+ (2.6–2.8%)[4]. One-month prevalence estimates of any alcohol use disorder among those aged 65+ in the ECA were 1.8% in males and 0.3% in females[5].

The prevalence in clinical samples of older adults can be higher. In one sample of 2405 patients aged 60+ seen in the emergency department, the prevalence of any current alcohol use disorder was 5.3%. The disorders occurred more frequently among men. Compared to older patients without disorders, those with alcohol use disorders were more likely to be homeless, live alone, be divorced or be never married. The most common alcohol-induced disorders were alcohol intoxication and alcohol-induced mood disorders. Falls and delirium were frequent emergency admission circumstances in the elderly drinkers[6].

While the proportion of older adults with defined alcohol use disorders may be low in comparison to younger adults, alcohol consumption at any level may potentially be problematic in this age group due to increased sensitivity to alcohol[7]. Because of decreased lean body mass and smaller volume of distribution, higher peak ethanol concentrations per dose are found in older compared to younger adults[8]. Also, even in small amounts, alcohol may exacerbate or mask symptoms of illness. Finally, many older adults are users of both prescription and over-the-counter medications that may interact with alcohol[7]. In a study of 700 persons aged 75+ from Finland, the prevalence of alcohol consumption was 44%. However, 86.9% of the alcohol drinkers used medications on a daily basis and 87.8% used medications as needed, including medications known to interact with alcohol[9]. In another study, 19% of older adults who used alcohol-interactive drugs also reported concomitant alcohol use[10]. These factors suggest alcohol use in older adults, especially in excess of recommended limits, may have adverse consequences. The number of older adults is projected to increase significantly over the next few decades as the post-Second World War generation ages, bringing

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

a higher lifetime prevalence of alcohol disorders. This could potentially result in higher numbers of older adults with alcohol-related problems[11].

Defining recommended limits given these age-related issues can be difficult. Chermack *et al*. examined the relationship between alcohol consumption patterns and the presence of DSM-III-R alcohol symptoms among 443 current drinkers aged 55+, and found that both average daily consumption and days of heavy drinking in the past year independently predicted symptom status. Consumption levels for men and women were only different for symptomatic drinkers. The authors reported that their results supported the recommendation that moderate consumption levels should be lower for older than for younger adults, and the recommendation not to exceed one drink/day to reduce the risk of symptoms[12].

PREVALENCE OF ALCOHOL USE

Alcohol use declines with age. In the 2001–2002 NESARC, 45.1% of the participants aged 65+ reported that they had consumed one or more drinks in the past year, compared to 64.3% among those 45–64, 72.9% among those 25–44 and 70.8% among those 18–24. Among those aged 65+, 28.5% reported former alcohol use and 26.4% reported lifetime abstinence. Among older adults, the prevalence of current drinkers was 48.3% among Whites, 23.4% among Blacks, 37.9% among American Indians/Alaskan Natives, 32.7% among Asian/Pacific Islanders, and 36.6% among Hispanics. Among current drinkers aged 65+, 64.3% were classified as light drinkers, 20.7% as moderate drinkers and 13.9% as heavy drinkers. A total of 58.0% of older adults with excellent/very good self-perceived health were current drinkers compared to 29.1% of those who rated their health as fair/poor[13].

This decline in alcohol use by age is also observed among the oldest old. Ruchlin examined the prevalence of alcohol consumption in adults aged 55+ and found 46% had consumed alcohol in the past year, with a continuous decline across age groups, from 52.9% of those aged 55–64 categorized as current drinkers compared to 24.7% of those aged 85+. A total of 17% of the sample reported that they had consumed alcohol every day in the past two weeks. In controlled regression analyses, more people aged 65–74 drank every day, compared to those 55–64 (odds ratio = 1.36), but people aged 75+ drank less than those aged 55–64. Males and Whites used alcohol more frequently and were more likely to be heavy drinkers than females and non-Whites. The lower one's perceived health status, the lower the odds of drinking every day. Believing excessive drinking increased the chances of getting cirrhosis of the liver decreased the odds of moderate and heavy drinking[14].

There are various explanations as to why the prevalence of alcohol use is lower in older adults. Selective survival may be a factor, in that persons who drink may be less likely to survive to older ages. Cohort effects are also possible. Persons who grew up before the Second World War may have had lower alcohol use throughout their lives. In the NESARC, the proportion of lifetime abstainers was highest in the 65+ age group (26.4 vs. 13.7% among those aged 25–44 years)[13]. Studies have also shown that some older adults decrease their use as they grow older. Busby *et al*. investigated alcohol use in a community-based sample of adults aged 70+ in New Zealand. Both frequency and quantity of intake decreased with age. A total of 60.1% of the men and 30.3% of the women said they drank less compared to middle age, while 7.4% of the men and 11.1% of the women said they drank more. The main reasons cited for decreased use of alcohol were change in health and fewer social opportunities, with reasons cited for increased intake being more time and money[15].

Adams *et al*. followed a cohort of 270 healthy community-dwelling adults aged 60+ over seven years. At baseline, the investigators found a decline in percentage of drinkers with increasing age. In the seven-year follow-up, there was a 2% per year decline in the percentage of subjects consuming any alcohol, but the mean alcohol intake did not change for those who continued to drink, except among heavy drinkers, suggesting an age-related decline rather than a cohort effect[16]. A study from Denmark of adults aged 50–74 interviewed at five time points between 1987 and 2005 reported that the unadjusted probability of heavy drinking declined with age but increased by calendar year and year of birth for both men and women[17].

Using data from four time points over 20 years, Karlamangla *et al*. found evidence for age and period effects for heavy drinking but not cohort effects across all age groups. The prevalence of heavy drinking decreased with increasing age, an age effect, and also tracked declines in USA per capita alcohol consumption, a period effect. The prevalence of heavy drinking in specified age groups did not differ by birth year[18]. Cohort effects have been noted across all age groups, however, for beverage-specific consumption, with adults born before 1940 more likely to drink spirits than those born after 1940, and elevated beer consumption among those born between 1946 and 1965[19]. In the NESARC, beverage preference among current drinkers aged 65+ was coolers (long drinks with ice, 1.3%), beer (23.6%), wine (31.1%), liquor (14.2%) and no preference (29.7%). Preference for beer was lower and preference for wine and liquor was higher compared to other age groups[13].

While the NESARC reported that less than half of older adults in the USA had consumed any alcohol in the previous year, regional studies have shown much variation. In a sample of 270 healthy men and women aged 65–89 living in the Southwestern USA, 48% of the participants reported in their three-day diet record that they had consumed alcohol, with 66% reporting they had consumed alcohol at least monthly[20]. The prevalence of alcohol use reported from the Established Populations for Epidemiologic Studies of the Elderly (EPESE) studies of persons aged 65+ varied by site. In East Boston, 70.5% of the sample drank alcohol in the past year and 54.7% had used alcohol in the past month. Similar findings were reported from New Haven, where 65.8% had used alcohol in the past year and 51.9% in the past month. The proportions were lower in Iowa and North Carolina. In the Iowa sample, 46.3% had used alcohol in the past year, while 31.2% had done so in the past month. In the North Carolina EPESE, 37.4% had consumed alcohol in the past year and 24.6% in the past month[21,22].

Samples from clinical populations have also found a range of alcohol use among older adults. Saunders *et al*. reported, among men and women aged 65+ randomly selected from patient rosters, that 10.5% admitted to drinking more or less every day (17.7% men and 6.1% women). At the three-year follow-up, one-fifth of the participants were regular drinkers, drinking at least on one occasion per week[23]. In a sample of 539 medical admissions aged 65+, the prevalence of alcohol abuse was 7.8%. An additional 29.7% of the sample who were neither abstainers nor occasional drinkers or alcohol abusers drank regularly: 43% of the men and 16% of the women[24].

PREVALENCE OF HEAVY DRINKING

Heavy drinking in older adults has been documented in research studies in various ways. In the EPESE baseline studies, the percentage of

persons who drank two or more ounces of absolute alcohol per day in the previous month was 8.4% in East Boston, 6.6% in New Haven, 5.4% in Iowa and 7.2% in North Carolina[21,22]. Goodwin *et al*. found in their sample from the Southwestern USA that 17% of the drinkers drank more than 30 g alcohol per day on average[20]. In a study of older Medicare beneficiaries, 9% reported exceeding recommended drinking limits. The prevalence was higher in men (16%) than women (4%). Exceeding limits was defined as monthly use exceeding 30 drinks per typical month, or consuming four or more drinks a day in a typical month[25]. In a report from the 2004 Behavioral Risk Factor Surveillance System (BRFSS), the prevalence of binge drinking decreased with age, from 27.4% among those aged 18–24 to 3.7% among those aged 65+. However, among binge drinkers, those aged 65+ reported the highest average number of binge drinking episodes during the previous month. The number of drinks consumed during the most recent binge episode decreased with age, from 9.8 among those aged 18–24 to 6.4 among those aged 65+[26].

The prevalence of heavy alcohol use among drinkers has also been reported. In the NESARC, daily limits across all age groups were defined as 5+ drinks per day for men and 4+ for women. A total of 3.9% of older drinkers reported excess drinking 1–11 times in the previous year, and 6.1% reported excess consumption 12+ times in the past year. Weekly limits were defined as 14 drinks per week for men and 7 per week for women. A total of 13.9% of the older drinkers exceeded the weekly or both daily and weekly limits during the previous year[13]. Saunders *et al*. found that 19.5% of the men and 19.6% of the women who were regular drinkers were exceeding sensible limits[23].

The prevalence of heavy drinking in clinical samples is similar. Adams *et al*. screened 5065 primary care patients aged 60+ and found that 15% of the men and 12% of the women regularly drank in excess; 9% of the men and 2% of the women reported regularly consuming more than 21 drinks per week[27]. Iliffe *et al*. studied 241 patients aged 75+ from general practice and found that 51% of the men and 22% of the women reported using alcohol in the past three months. Among drinkers, 3.6% of the men admitted consuming more than 21 units and 3.2% of the women more than 14 units of alcohol per week. Weekly alcohol consumption was not associated with age, cognitive impairment, depression, falls or inpatient or outpatient care[28]. Callahan and Tierney found the prevalence of CAGE[29]-defined alcoholism was 10.6% among primary care patients aged 60+. Patients with alcoholism were more likely to be younger, have fewer years of education, and be male, Black, smokers and malnourished[30]. In another sample of adults aged 65–103 years selected from primary care, 70% reported no alcohol consumption during the past year. A total of 21.5% were moderate drinkers, 4.1% were at-risk drinkers and 4.5% were heavy or binge drinkers[31].

Bristow and Clare interviewed 650 medical and geriatric admissions over age 65 and found 9% of the men but few of the women drank in excess of recommended safety limits. Another 10% had drunk heavily over the age of 65 but cut down because of medical, social, financial or other reasons. Compared to the non-drinkers and light drinkers, the heavy drinkers were more likely to smoke, to be unmarried and to have some impairment of mobility[32]. In a similar sample of hospital patients aged 65+, 54% reported no alcohol consumption and 9% screened positive for alcohol problems (17% among male and 2.5% among female patients). Seven percent of the patients were discharged with an alcohol-related diagnosis[33].

IDENTIFICATION OF PROBLEM DRINKING

Clinicians may have difficulty detecting and diagnosing alcohol problems in older adults for a number of reasons. Screening instruments used in younger populations to detect problem drinking may not be as reliable for older adults[34,35]. Adams *et al*. compared responses to a beverage-specific self-administered questionnaire about the quantity and frequency of alcohol use and episodes of binge drinking to the widely used CAGE questionnaire (**C**ut down, **A**nnoyed by criticism, **G**uilty about drinking, **E**ye-opener drinks)[29] in 5065 primary care patients age 60+, and found the CAGE performed poorly in detecting heavy or binge drinkers[27]. Many of the screening instruments enquire about frequency and quantity of alcohol use, but even small amounts may be problematic for older adults with chronic health conditions and in combination with certain medications. Criteria for alcoholism often include problems with social and/or occupational functioning. However, older adults are less likely to be married or employed, and therefore less likely to report marital or job problems. Older drinkers may also be less likely to cause public disturbances resulting in legal problems[36].

Clinicians may be reluctant to enquire about alcohol use out of embarrassment or because the patient doesn't fit the stereotype of an alcoholic. They may also fail to diagnose alcohol problems because symptoms of alcohol misuse may be similar to symptoms of ageing such as cognitive difficulties[37]. Adams *et al*. screened patients 65+ seen in the emergency department for alcoholism. Using their criteria of either CAGE-positive or self-reported drinking problems and alcohol use within the past year, they found the current prevalence of alcohol abuse was 14%, with a high prevalence (22%) among those presenting with gastrointestinal problems. Physicians, however, detected only 21% of current alcohol abusers[38]. In a study from primary care, only 41.6% of older patients who screened positive for alcoholism had a diagnosis of alcoholism recorded in their medical record[30]. In a study where all new admissions to the medical service were screened for alcoholism using the CAGE and the Short Michigan Alcohol Screening Test (SMAST)[39], the prevalence of alcoholism was 27% in patents under 60 and 21% among patients aged 60+. These age differences were not significant. However, 60% of screen-positive younger patients were identified as having alcoholism by their house officers compared to only 37% of those aged 60+. Older patients with alcoholism were less likely to be diagnosed if they were White, female, or had completed high school. Even when diagnosed, older patients with alcoholism were less likely than younger patients to be referred for treatment[40].

Another identification problem is establishing what constitutes excessive drinking in older adults. Moos *et al*. compared several guidelines defining excessive drinking in a sample of 1291 older adults. Depending on the criteria used, 23 to 50% of the women and 29 to 45% of the men engaged in potentially unsafe drinking patterns. The number of drinks per week and per day was associated with alcohol use problems. The authors concluded that safe alcohol consumption levels should not necessarily be higher for men[41]. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the Center for Substance Abuse Treatment Improvement protocol recommends that persons aged 65+ consume no more than one standard drink per day or seven drinks per week. Also, they should not consume more than four standard drinks on a given day[7].

In a study of community-dwelling older adults from New Zealand, the prevalence of hazardous alcohol consumption was 9.9%, and the lifetime prevalence of DSM-IV alcohol dependence was 24.8%. None of the physicians identified by the participants, however, had

diagnosed alcohol problems in the past year, and only 4% reported a history of alcohol problems. The adults with hazardous patterns of alcohol use were twice as likely to be hospitalized but less likely to have seen their physician in the past year[42].

FACTORS ASSOCIATED WITH ALCOHOL USE

In general, older adults who consume alcohol are more likely to be male, be married, and have higher income and years of education, have a good social life and have fewer health conditions[13,20,43]. Older drinkers are also more likely to be current or former smokers[13]. Goodwin *et al*. found no differences in social support between elderly drinkers and non-drinkers, and no relationship between alcohol intake and emotional status. They also reported that those older adults who consumed alcohol performed better on cognitive functioning tests, but no relationship was found between past alcohol consumption and present cognitive performance[20].

A somewhat different profile emerges for older adults with drinking problems. Heavy drinking has been shown to be associated with male gender, younger age, being unmarried, fewer years of education, smoking, depressive symptoms, impairment in cognitive functioning and poor self-rated health[25,30,32,44,45]. While some studies have shown an association between alcoholism and functional limitations[32,45], Mangion *et al*. found that men aged 65+ classified as alcohol abusers were more independently mobile than those not abusing alcohol, suggesting greater physical fitness[24]. As another example of conflicting results, in a sample of Medicare beneficiaries, unhealthy drinking patterns were associated with higher education and income and better health status[25].

In a study of 209 patients selected from a geriatric inpatient ward in France, 54.5% of the patients had consumed alcohol in the past month and 52% consumed at least once per week. A total of 9% of the patients (3% of the women and 18% of the men) met criteria for DSM-IV alcohol dependence. In a comparison between those with and without alcohol dependence, those with the disorder were more likely to be younger, male, to consume alcohol at least one day a week, consume alcohol alone, to begin to drink in the morning, to have more drinking days per week, to more often consume >5 drinks on one occasion, be treated with benzodiazepines, and be dependent on nicotine[46].

In a study of adults aged 70–75 in Italy, higher self-reported alcohol consumption was associated with: male gender; better mood, daily function and somatic health; not living alone and being married; while CAGE-detected alcoholism was associated with male gender, poorer cognitive function and income dissatisfaction. There was not much overlap between the groups[47]. Mirand and Welte studied the relationship between health-oriented lifestyle and heavy drinking among older adults in Erie County, New York, and reported that the prevalence of heavy drinking was 6%. Heavy drinking was positively associated with being male, having suburban residency and currently smoking, and negatively associated with socioeconomic status, rural residency and degree of health orientation. Age and level of active lifestyle were not related to drinking[48].

Changes in alcohol use have also been studied. Moos *et al*. followed a cohort of adults aged 55–65 for 10 years and found overall that health-related problems increased and alcohol consumption and drinking problems declined over the follow-up interval. Medical conditions, physical symptoms, medication use and acute health events predicted a higher likelihood of abstinence and less frequent and lower alcohol consumption. Increased health problems predicted reduced alcohol consumption but more drinking problems[49]. Perreira and Sloan examined the relationship between the experience of life events and changes in alcohol consumption using four waves of the Health and Retirement Study. Alcohol consumption did not change for the majority of older adults (68%) over the six years. Hospitalization and onset of a chronic illness were associated with a decrease in consumption, while widowhood was associated with a short-term increase in drinking. Onset of retirement was associated with increased drinking. Getting married or divorced was associated with both increases and decreases in drinking[50].

ONSET OF PROBLEM DRINKING

In research focusing on the age of onset among elderly problem drinkers, two groups have emerged. There are older adults who have had problems with alcohol for most of their adult life and have survived to old age, generally referred to as 'early-onset' problem drinkers. There are also older adults who may or may not have consumed alcohol earlier in their lives, but who do not become problem drinkers until later in their adult life, a group referred to as 'late-onset' problem drinkers.

Atkinson *et al*. studied the age of onset among 132 men aged 60+ admitted into an outpatient treatment programme and found onset after age 60 in 15% of the sample and in 29% of the sample aged 65+. Later-onset alcohol problems were milder, associated with less family alcoholism and associated with greater psychological stability. Treatment variables were better predictors of outcome than age of onset[51]. In a similar sample of patients admitted to an alcoholism treatment programme, late-onset alcoholism was present in 39% of the men and 46% of the women. Few differences were noted between the two groups[52].

Symptom presentation may differ by age of onset. In a study of 268 patients on an alcohol detoxification ward in Germany, alcohol dependence was diagnosed in 94.1% of those with an earlier onset but in only 62.2% among those with a later onset. Those with late onset were less likely than those with a younger onset to report a strong desire to drink alcohol, impaired capacity to control drinking, and preoccupation with drinking[53].

Brennan and Moos reported that late-middle-aged problem drinkers reported more negative life events, chronic stressors and social resource deficits than did non-problem drinkers. Among problem drinkers, those with late onset consumed less alcohol, reported fewer alcohol-related problems, functioned better and had fewer stressors than early-onset problem drinkers[54,55].

Age of onset may differ by gender. Brennan *et al*. found that women with drinking problems consumed less alcohol, had fewer drinking problems, and reported more recent onset of drinking problems than did male problem drinkers. The female problem drinkers also used more psychoactive medications, were more depressed and were less likely to seek treatment[56]. Osterling and Berglund examined gender differences in age of onset among older first-time admitted alcoholics in Sweden across two time periods. During the period 1978–1982, they found that age of onset of problem drinking occurred significantly later in females compared to males. One decade later, during the period 1988–1992, sex ratios indicated a significant convergence in age of onset for female patients to that of males[57].

Moos *et al*. followed a cohort of problem drinkers aged 55–65 for one year. Remitted problem drinkers were those who did not experience any problems in the follow-up period. Late-onset drinkers were

more likely to remit during the year. At baseline, the to-be remitted problem drinkers consumed less alcohol, reported fewer drinking problems, had friends who approved less of their drinking, and were likely to seek help from a mental health practitioner[58].

OUTCOMES ASSOCIATED WITH ALCOHOL USE

The relationship between alcohol use and physical health is not straightforward. In cross-sectional studies, patients with alcoholism have an increased likelihood of some chronic diseases and decreased likelihood of others. Callahan and Tierney reported that patients with alcoholism were less likely to have a diagnosis of hypertension, arthritis or diabetes, and more likely to have obstructive lung diseases, injuries and gout[30]. Hurt *et al*. described 216 older inpatients treated for alcoholism. The frequency of serious medical disorders among this group was higher than what would be expected for the overall population aged 65+. Hypertension was less frequent among these patients, but alcoholic liver disease, chronic obstructive pulmonary disease, peptic ulcer disease and psoriasis were more prevalent among the alcoholic group compared to the population at large. The frequencies of ischaemic heart disease, cerebrovascular disease and diabetes were about the same as what would be found in an older population[52].

In longitudinal studies, moderate alcohol use in older adults has been shown to decrease the risk of stroke[59], heart failure[60–62] and incident diabetes[63]. It is not clear whether there is a true protective effect of alcohol or whether older adults who consume alcohol are already in better health. In the Framingham Study, alcohol consumption was not associated with stroke across all age groups, but alcohol intake among those aged 60–69 was associated with a lower risk of stroke. In addition, former drinking of 12 or more grams of alcohol per day was associated with 2.4-times higher risk of stroke among men[64]. Drinking in excess has been associated with adverse health outcomes as well as protective effects. For example, heavy consumption of alcohol may be associated with an increased risk of stroke[59]. In the Cardiovascular Health Study, however, consumption of 14 or more drinks per week was associated with a reduced risk of coronary heart disease[65]. In the NESARC, women aged 65 or older who consumed alcohol had better self-perceived health, improved cardiovascular health and lower rates of hospitalizations. No associations for men were significant[66]. Older adults, particularly those with pre-existing drinking problems may use alcohol to manage pain. Older men with drinking problems who used alcohol to manage pain had more health problems and injuries while female problem drinkers who used alcohol for pain had more drinking problems three years later[67].

Studies have also shown that alcohol problems in older adults are associated with psychiatric co-morbidity. Saunders *et al*. reported that 44% of men aged 65 or older with a history of heavy drinking were given current psychiatric diagnoses, compared with 12% of the men without a history of heavy drinking. The most common diagnoses were depression and dementia. The association between drinking history and current psychiatric morbidity was not explained by current drinking habits[68]. The prevalence of alcohol use is three- to four-times greater among depressed older adults compared to those who are non-depressed. Among older adults with major depression, the prevalence of an alcohol use disorder is 15–30%. Depression can put the older adult at risk for alcohol problems, and alcohol use disorders can be a risk factor for late-life depression[69].

Increased hospitalizations have also been linked with alcohol use in the elderly. Callahan and Tierney reported that older patients with alcoholism were more likely to be hospitalized within the year following the interview, compared to those without alcoholism (21.5% vs. 16.9%)[30]. Using 1989 hospital claims data, the prevalence of alcohol-related hospitalizations among persons age 65+ in the USA was 54.7 per 10 000 population for men and 14.8 per 10 000 for women, a proportion similar to that seen for myocardial infarction[70].

The relationship between alcohol use and mortality is also complex. In a study from Finland, drinking had an independent protective effect on 10-year mortality among older adults. Mortality was lowest among frequent and occasional drinkers, second lowest among abstainers, and highest among ex-drinkers. In analyses controlling for variables such as chronic disease and smoking, frequent drinkers had a reduced risk compared with abstainers[71]. Paganini-Hill *et al*. studied changes in alcohol intake over 23 years in a sample of residents of a California retirement community. Those who drank 2+ drinks per day had a 15% reduced risk of death. Stable drinkers also had a reduced risk compared to non-stable drinkers. Women who quit drinking had an increased risk of death, suggesting persons who quit may do so for reasons that affect mortality[72]. In a community-based longitudinal Australian study of women 70–75 years old at baseline, women who did not consume alcohol or drank rarely were more likely to die compared to women in the low-intake category[73].

In contrast to moderate drinking, alcoholism has been linked to increased mortality. In a sample of elderly male veterans from primary care clinics at Veteran Administration medical centres, where the prevalence of alcohol use can be higher than in the general older population, 48% of the veterans reported drinking in the past year. Half of the drinkers and non-drinkers screened positive for problem drinking. Overall health status and survival were better in drinkers compared to non-drinkers, but worse in those who screened positive for problem drinking compared to those who screened negative[74]. Callahan and Tierney found that patients with alcoholism were more likely to die within two years than those without evidence of alcoholism; 10.6% compared to 6.3%, controlling for age, gender, race, education and smoking history[30]. Hurt *et al*. followed a sample of inpatients treated for alcoholism for an average of 5.2 years. A total of 32% had died by follow-up. Of those who died, 47% of the deaths could be attributed to the patient's alcoholism[52]. In the Canadian Study of Health and Aging, alcohol abuse was associated with short-term mortality[75]. In a retrospective case control study of 1735 older people that died of falls, motor vehicle crashes or death by suicide and 13 381 controls, having 12+ drinks in the past year was associated with an increased risk of fatal injury[76]. Finally, at-risk drinking was associated with increased 20-year mortality in men when 'at-risk' was determined by the amount of alcohol consumed in the presence of relevant co-morbidities (e.g. an illness or medication use)[77].

Heavy drinking has also been shown to be associated with impairments in physical function. In a study of 161 primary care patients aged 60+, 16% of the patients consumed 8–14 drinks, and 22% had more than 14 drinks per week. Forty two percent of the sample (33% of the men and 51% of the women) reported binge drinking (four or more drinks on one occasion for men and three or more for women) in the past year. Compared to those having fewer than 7 drinks per week, those consuming more than 14 drinks per week were more likely to have impairments in instrumental activities of daily living (IADLs) and advanced activities of daily living (ADLs). Those having 7–14 drinks per week were more likely to have impairments in IADLs but not ADLs. Binge drinkers were more likely to have impairments in IADLs[78].

Other studies have reported different findings. Using data from the Health and Retirement Study in the United States and the English

Longitudinal Study of Ageing, samples of adults aged 65+ followed from four to five years, Lang *et al*. reported that 10.8% of US men, 28.6% of English men, 2.9% of US women and 10.3% of English women drank above USA recommended limits for this age group. Functional outcomes did not differ between those who drank >0–1 drink per day and those who drank >1–2 drinks per day[79]. Karlamangla *et al*. found that light to moderate drinking was associated with a decreased risk of incident disability compared with abstention. Disability risk decreased with light to moderate drinking among men and women with good or better self-reported health, but not among those with fair or worse self-rated health[80]. La Croix *et al*. found, by following three of the EPESE cohorts for four years, that older adults who did not consume alcohol had an increased risk of losing mobility, defined as the ability to climb up and down stairs and walk half a mile, compared to those with small to moderate amounts of alcohol consumption[81].

The relationship between alcohol consumption and cognitive performance has received considerable attention in this population. In the Honolulu-Asia Aging Study, non-drinkers and heavy drinkers had poorer scores on cognitive functioning tests compared to those who consumed 1–60 ounces (28.4–1701 g) of alcohol per month[82]. A protective effect has also been reported from longitudinal studies. In the Cardiovascular Health Study, older adults who consumed one to six drinks weekly had a lower risk of incident dementia compared to those who abstained[83]. In a study of adults aged 75+ from Sweden, light to moderate drinking was associated with a decreased risk of six-year incident dementia and Alzheimer's disease compared with non-drinking[84]. In a two-year study of older adults in China, light to moderate drinking was associated with a lower risk of dementia compared to non-drinking, while excessive drinking was associated with a higher risk of dementia[85]. In the Canadian Study of Health and Aging, the occurrence of all types of dementia except probable Alzheimer's disease was higher in those older adults with definite or questionable alcohol abuse[75]. Other studies have not found an association between drinking and incident cognitive impairment[86]. A study from China reported among older adults with mild cognitive impairment that those with light to moderate alcohol consumption had a decreased risk of transition to dementia over two years when compared to abstainers or heavy drinkers. Heavy drinkers with mild cognitive impairment had a higher risk compared to those with light to moderate use and abstainers[87]. Researchers from the Italian Longitudinal Study on Aging reported that older adults with mild cognitive impairment who were moderate drinkers had a lower rate of progression to dementia than abstainers. Older adults with mild cognitive impairment and higher levels of drinking, however, did not have a higher rate of progression to dementia compared to abstainers. Incidence of mild cognitive impairment was not associated with any level of drinking compared to abstainers[88].

In the NESARC, only 3.54% of current drinkers aged 65+ with an alcohol use disorder in the past year and 1% of older adults classified as heavy drinkers received any alcohol treatment in the past year[13]. Long-term remission among older untreated problem drinkers followed for 10 years was predicted by being female, having a recent onset of drinking problems, having fewer and less severe drinking problems, having friends who approved less of drinking, and drinking less and less frequently at baseline. Long-term remitted problem drinkers attained levels of functioning and life context similar to those of lifetime non-problem drinkers, but remitted problem drinkers continued to report more incipient drinking problems, depressive symptoms, health and financial stressors, psychoactive medication use, less social support and dependence on avoidance coping strategies compared to lifetime non-problem drinkers[89].

SUMMARY

Alcohol use, including drinking in excess, among older adults is prevalent, particularly among males. Because of interactions with chronic disease and prescribed medications, the use of alcohol among older adults is an important health concern. Given the higher prevalence of alcohol use disorders among middle-aged adults, the numbers of older adults with alcohol-related problems is expected to increase in future generations. Screening and questioning for alcohol problems should be routine. Drinking within recommended guidelines could potentially decrease the proportion of alcohol-related illness, hospitalizations and mortality seen in this population.

Drug Misuse in the Elderly

Martin M. Schmidt and Mohammed T. Abou-Saleh

Division of Mental Health, St George's University of London, London, UK

Substance misuse occurs mainly in young adults, with most research focusing on this group. Several factors, however, suggest a growing trend towards substance misuse in the elderly. Increasing age is associated with chronic illnesses and multiple medications, with the attendant risk of dependence. There is also evidence to support a growing trend to increased alcohol consumption in the over-65s, while a generation of lifetime drug users are now entering old age[1]. Along with the increase in ageing of European and North American populations, the number of older adults requiring treatment for substance misuse is predicted to double between 2001 and 2020[2]. The need for age-appropriate treatment interventions has never been greater.

USE, ABUSE AND HARMFUL USE

When considering drug use among the elderly it is helpful to consider substances of misuse in three broad categories: medications, both prescribed and non-prescribed; socially sanctioned psychoactive substances; and illicit substances. Self-evidently this will differ between countries due to religious, cultural and legal differences[3]. Some of the consequences of drug misuse are determined by the status of the drug rather than its physical effects. Difficulties in obtaining a drug supply and financing that use may account for as much harm as the physical effects of the drugs themselves in younger adults. Among the elderly, drugs from the medicines category are overrepresented in cases of misuse when compared to other age groups[4]. This reflects the increased access to medicines among this group, allied to the physical and social barriers that make accessing other drugs harder for this group. This chapter will focus on drug misusers who display 'harmful use'. This is defined as 'a pattern of psychoactive drug use that causes damage to health, either mental or physical'[5]. This definition allows consideration of individuals suffering damage as a result of drug use, irrespective of the nature or the source of the drug of abuse. It excludes cases where omission of a psychoactive medication may be harmful, e.g. in cases of underuse of antidepressants.

Harmful use may be related to a single episode of drug misuse resulting in harm, such as a fall while intoxicated. More often it is a chronic condition associated with a dependence syndrome. 'Dependence syndrome' describes the cluster of cognitive, behavioural and physical phenomena that are observed when use of a substance becomes a greater priority for the individual than other previously more valued activities. It is characterized by:

- a compulsion to take the substance;
- difficulties in controlling the substance use in terms of timing and levels of use;
- withdrawal symptoms on discontinuation of the substance, with relief of these symptoms on reinstatement of use;
- tolerance or neuroadaptation, where increasing amounts of the substance are required to achieve effects previously possible at lower doses;
- progressive neglect of alternative activities, due to prioritization of drug-related behaviour;
- persistent use of the substance in spite of evidence of harmful consequences.

Presence of three or more of the above features simultaneously in the past year supports a definite diagnosis of dependence syndrome, using World Health Organization criteria[6].

PHARMACOKINETICS

Ageing is associated with a series of physiological changes that significantly alter the fraction of an ingested drug available for a psychoactive effect. Drug absorption shows little variation with age, despite changes in gastrointestinal motility and acidity, reduced absorption surface and slowed gastric emptying. However, once absorbed, the volume of distribution in an elderly subject is likely to have changed.

Ageing results in an increase in percentage body fat and a fall in total body water. Hydrophilic drugs, such as alcohol, are distributed in body water, such that with increasing age the volume of distribution falls and the peak concentration for a given dose may rise by 20%[7], resulting in lower levels of intake giving the same intoxicant effect. Conversely, lipophilic drugs, such as benzodiazepines and other psychotropics, that are stored in fatty tissue will remain in the body for longer but at lower peak concentrations. A fall in plasma albumin in old age results in increased bioavailability of protein-bound drugs, such as warfarin and diazepam.

Drug elimination occurs primarily through direct excretion or metabolism. Both routes are reduced in the elderly. Glomerular filtration rates fall steadily in old age, leading to the accumulation of renally excreted drugs. This may be compounded by renal damage due to drug misuse, e.g. analgesic abuse[8]. Hepatic metabolism is impaired due to a loss of liver mass and a reduced blood flow, which may also be compounded by toxic drug effects. The efficiency

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

of microsomal oxidation also falls with age, leading to reduced drug excretion of hepatically metabolized drugs[9]. The combination of these effects may greatly alter pharmacokinetics in the elderly. For example the half-life of diazepam in the very elderly has been shown to be over 3 days, compared with 20 h in a younger subject[10].

Multiple drug use complicates the pharmacokinetics of a substance, due to competition for binding sites and metabolic pathways. Polypharmacy may have different effects, depending on whether it is acute or chronic. Alcohol will inhibit microsomal enzyme activity in acute use, while prolonged administration will induce the same enzymes. Hence, alcohol will acutely raise concentrations of benzodiazepines, while lowering them if used chronically[11].

Pharmacodynamics also alter in the elderly. Sensitivity to drugs, particularly those acting on the central nervous system, tends to increase, while drug receptor populations also change with increased age. The particular effects of age-related brain changes on the reward effects of abused substances is currently difficult to predict[12].

As a consequence of all these variables, the extrapolation of a drug's effects in the elderly, based on observation in younger adults, is foolhardy.

CONCLUSION

The terms 'old age' and 'substance misuse' are both terms that have a wide range of meaning to different readers. The current literature is based primarily upon chronological age banding of individuals, as opposed to banding by overall health, possibly a more valid measure. Definitions of substance misuse are similarly varied. Often in transgenerational studies, definitions of caseness are set at a level to prevent false-positive reports for younger adults. In older age groups, where less of a substance may have a greater effect, there is the possibility of missing cases if such standards are applied.

PREVALENCE AND CORRELATES

The elderly may display harmful use of any psychoactive substance. However, access to a potential substance of abuse is key to determining what an individual may misuse. Alcohol is obtainable with ease in most industrialized nations and is a socially acceptable and accessible psychoactive drug. Sedatives, hypnotics and analgesics are easily accessible through prescription and consequently, along with alcohol, are responsible for the majority of cases of harmful use. Over-the-counter medication is also easily obtained and may be misused. Illicit drugs are usually only available in potentially dangerous environments from individuals who may pose a significant risk to vulnerable older adults. Illicit drug use is therefore not commonly observed in the elderly, but numbers are on the rise[13]. Shah and Fountain identified the following as factors associated with illicit drug use in the elderly: male gender, 'young old' age group, belonging to the post-war cohort, African American ethnicity, prior convictions, diagnosis of mental illness or alcohol misuse, serious medical illness and past history of substance misuse with onset before age of 30[14].

BENZODIAZEPINES

Benzodiazepines replaced barbiturates as the mainstay of pharmacological interventions in both anxiety and sleep disturbance. Benzodiazepines accumulate more readily in the elderly due to changes in body composition, leading to a greater volume of distribution for lipophilic drugs[10]. Chronic use may contribute to toxic effects, including cognitive impairment, poor attention and anterograde amnesia, cerebellar signs such as ataxia, dysarthria, tremor, impaired coordination and drowsiness[15]. Increased falls and hip fractures are associated with benzodiazepine use in the elderly[16] while withdrawal may be accompanied by rebound insomnia, agitation, convulsions and an acute confusional state. If benzodiazepines are required for the elderly then short-acting drugs (i.e. with half-life less than 24 hours) at the lowest effective dose may be used for a short duration[17]. There is no 'safe' period of use but tolerance and dependence levels increase with prolonged use[18].

Prevalence of Benzodiazepine Use

Establishing levels of benzodiazepine among the elderly is problematic. National prescription audits can reflect trends in use but are unhelpful when considering particular population subgroups.

Following the publication of guidance for the appropriate use of benzodiazepines by the UK Committee on Safety of Medicines (CSM) in 1988[19], prescribing of benzodiazepines has fallen dramatically. In England and Wales prescriptions have fallen by 32% from 1987 to 1996[20], while prescribing of benzodiazepines by general practitioners in England has fallen from 15.8 million prescriptions in 1992 to 12.7 million in 2002[21]. Of concern, however, is that 30% of prescriptions were for long-term treatment and 56% of prescriptions for the three most commonly prescribed benzodiazepines were issued to patients over the age of 65[21]. More recent trends for England show a relatively stable annual prescription rate of 10 million items for hypnotics; however, Z drugs (zopiclone, zolpidem, zaleplon) appear to be responsible for a larger proportion of prescriptions, rising from 33% in 2001 to 44% in 2004[22].

A community follow-up study of 5 000 over-65s in Liverpool[23] revealed that 10% were using benzodiazepines on first assessment and that of these some 70% were taking a benzodiazepine two years later. A further four-year follow-up revealed that 69% of these were still on benzodiazepines. Women were twice as likely to be taking a benzodiazepine as men at any stage in the study. In the USA, a study found 6.3% of a large sample of over-65s used a hypnotic, one third of these daily and nine tenths for at least a year[24]. Five-year follow-up found 46.6% still using hypnotics, but with a switch away from barbiturates and longer-acting benzodiazepines towards short-acting ones[25].

Use of benzodiazepines in institutional samples has traditionally been higher and associated with female gender, greater age, bereavement and poor health[26]. Chronic benzodiazepine use in older adults' nursing homes has been associated with depression, sleep disturbances and demand for medication[27]. In the USA a study found that one quarter of nursing home residents were prescribed a benzodiazepine and nearly 10% of all residents had chronic benzodiazepine use[27]. Studies from other countries reveal similarly high levels of benzodiazepine use among institutionalized older adults[28].

The level of morbidity among institutional residents is likely to be higher than community-dwelling elders. While chronic pain may require treatment with dependence-inducing medication, there are few indications for long-term benzodiazepine use. It has been argued that the regular use of benzodiazepines in institutions is a form of behavioural control, used more for the benefit of staff and others than these users. In many cases, the individual may be incapable of giving valid consent to taking such medication. The use of medication in

such circumstances may be considered benzodiazepine misuse by some and as elder abuse by others[29].

Correlates

Psychiatric morbidity

Significantly high rates of psychiatric disorder have been described among elderly benzodiazepine users[30]. Among elders using short-acting benzodiazepines as hypnotics, one third reach caseness for depression, while a further third have a diagnosable anxiety disorder. Among users of anxiolytic benzodiazepines, half are depressed and one fifth are anxious in spite of treatment. As with alcohol misusers, one third of elders requiring inpatient treatment for benzodiazepine misuse are of late onset, while two thirds have graduated from misusing benzodiazepines or other drugs while younger[31]. The incidence of co-morbid alcohol abuse has not been consistently shown to be significantly greater among benzodiazepine misusers[31]. However, more recent research suggests that a prior history of alcoholism may predispose to later benzodiazepine misuse in the elderly[32]. An all-age study found that DSM-III-R Axis I co-morbidity existed in all cases of a sample of benzodiazepine-dependent users in Spain[33]. The commonest diagnoses were insomnia, anxiety disorders and affective disorders. Obsessive–compulsive, histrionic and dependent personality disorders were found in half of the cases and physical problems in one third of the cases.

Gender and age

Benzodiazepine use is over-represented among women of all ages. The likelihood of use of a benzodiazepine increases with age. There is little evidence that this gender divide narrows on reaching old age. Legislative approaches and prescribing guidelines have made some inroads into the over-representation of prescribing to the elderly[34]. Increasing public awareness of the side effects of benzodiazepines and an increase in advocacy services for the elderly are likely to have a similar effect.

OTHER PRESCRIBED AND OVER-THE-COUNTER MEDICATION

The elderly routinely receive a wide variety of medications, the majority of which may be misused. One quarter of prescription drugs sold in the United States are used by the elderly often for conditions such as chronic pain, insomnia and anxiety[35]. Ten per cent of over-64s are on prescribed analgesics at any one time, with at least an equal number using over-the-counter medication. Edwards and Salib[36] found 3% of a community sample of over-65s to have been using mild opiate analgesics for a period of at least a year; 40% of this group were deemed to fulfil the criteria for dependence. In addition to the dependence caused by these drugs, physical harm may also result, e.g. nephropathy may be caused by the use of paracetamol, salicylates and pyrazole derivatives, while renal impairment occurs with non-steroidal anti-inflammatory drug use[37]. Chronic nephropathy may also be caused by the excessive ingestion of analgesic mixtures combining two or more antipyretic analgesics, along with codeine or caffeine (both independently capable of causing addiction). Such acute and chronic effects are more likely among the elderly, where relative drug levels are higher and less biological reserve exists. Similar physical complications may arise from the misuse of other medications, the commonest being laxatives and cough mixtures.

ILLICIT DRUG MISUSE

Little is known about levels of illicit drug use among the over-65s, although the general perception is that it has been less of a problem than the misuse of prescribed medication. Overall the prevalence of illicit drug use in the elderly is low compared to younger people[14].

In the Epidemiological Catchment Area Study (ECA), only 0.1% of elders met the criteria for drug abuse for an illicit substance in the previous month. Lifetime prevalence was 1.6% for over-65s[38]. Figures from the 2005 and 2006 National Survey on Drug Use and Health found similar low rates in the elderly along with higher rates in the middle aged, lending further evidence to the suggestion that prevalence rates may rise in the elderly as the younger cohort ages[39]. Current predictions are that the number of older adults requiring substance abuse treatment in the USA will increase from 1.2 million in 2000 to 4.4 million in 2020[13].

The 2007/8 British crime survey reported the following in 55–59 year olds: 17.9% had used illicit drugs at some point in the past, 1.7% had used in the last year, and 0.9%, in the last month[40]. No figures were available for older age groups because respondents over 59 were not asked about illicit drug use. The decision to omit drug use questions in this age group was based on previous surveys which showed a lifetime prevalence of less than 1% for people aged 60 and over[14].

In the UK, few cases of illicit drug use among the over-65s have found their way into the literature; one exception is a series of seven elderly reported to have initiated injecting heroin in later life. They attributed their behaviour to a combination of loneliness and depression[41].

In the USA, in a study of a Veterans Administration old age psychiatry inpatient facility, 3% of the patients were found to have a primary drug misuse disorder involving prescribed medication, while 1% were addicted to illicit substances[32]. Also in the USA, attendance at methadone maintenance clinics by the elderly is reported to be rising, although over-60s still form 2% of those attending[4]. Similarly, a number of elders are reported to continue their use of cannabis into late life[42]. Anecdotal evidence also points to some individuals initiating the use of cannabis in later life in a search for its reputed therapeutic benefit in conditions such as multiple sclerosis.

On balance, it appears that illicit drug use is less of a problem in the elderly than the abuse of legally sanctioned drugs.

POLYSUBSTANCE MISUSE

The elderly have access to a variety of drugs of misuse. In many cases they may misuse one drug without misusing others. This is often the case with prescribed medication, where one medication is overused while compliance with the prescription is maintained for the others. Where non-prescribed substances become involved, the possibility of abuse of more than one substance is elevated. Finlayson and Davis[30] found 15% of over-65s requiring inpatient detoxification from alcohol were also dependent upon a second substance, usually a hypnotic, anxiolytic or analgesic. The phenomenon of cross-tolerance must also be considered. Psychoactive substances may have a cumulative effect, due to either a shared outcome effect or to different drugs acting as interchangeable substitutes for one another (cross-tolerance). Cross-tolerance exists within each class

of drug, such that the clinician should always consider the total benzodiazepine or opioid dose, using class-specific equivalence charts[43]. Cross-tolerance for some drugs may also occur outside of the class, most notably for alcohol and benzodiazepines. While this phenomenon is widely exploited for detoxification, failure to consider the clinical possibility may lead to overlooking cases of dependence.

CONCLUSION

Alcohol and prescribed medication remain the most prevalent substances misused by the elderly. There is little clear evidence of great changes in individuals' addictive behaviour patterns with increasing age. However, a convincing body of evidence points towards a relative and absolute increase in older adults requiring specialist treatment for illicit drug use in the future.

TREATMENT

Treatment of substance misuse is a multistage process involving the integrated use of physical, psychological and social interventions. These interventions should, where possible, run concurrently as opposed to consecutively and must be provided in a form that is acceptable to the individual and sensitive to the specific needs of the elderly[44]. Among this client group, individuals rarely present complaining directly of a substance misuse disorder but may present with associated physical problems. The first step of treatment is the identification of cases. This requires clinical observation allied to sensitive yet persistent enquiry. The routine use of standardized screening tools may help to focus clinical impression more accurately. Once potential candidates for treatment have been identified, their attitude towards their substance misuse requires examination. Exploration of the risks and a discussion of potential avenues for change may help to establish or reinforce the motivation to change. Drugs that cause significant physical dependence may necessitate detoxification regimens, while co-morbid conditions such as depression that perpetuate the disorder need to be adequately treated. Social issues, such as housing and a social network that is comprised mainly of substance misusers, may perpetuate the problem and need to be examined for opportunities to change. The individual requires psychological rehabilitation to address the issues that may have contributed to the uncontrolled use of substances and to provide future coping strategies to prevent a relapse into substance misuse.

DETECTION

Self-presentation by elders may be limited by a number of factors[45,46]. Practical issues, such as accessibility of treatment centres to disabled individuals, large-print information sources for the visually impaired and the availability of domiciliary treatment, are fundamental. Elders may not realize that they are ill, or may not realize that the medical profession identifies substance misuse as an illness and will offer help. Traditional forms of service promotion may fail to reach the elderly, while a service staffed by young professionals may seem intimidating or inappropriate for someone much older, particularly if his/her substance misuse is associated with a high degree of shame. If self-presentation is unlikely, then the number of professional caregiver contacts that the elderly have provides a further opportunity for education about the problem and potential sources of help. This resource appears underdeveloped at present, with a need for better training for carers in identification of at-risk individuals and in appropriate actions once misusers are identified[47].

Currently, evidence suggests that carers are often unaware of sources of help and frequently are in collusion with alcohol misuse, citing reasons such as the elder 'has not got long to live' or that 'it's his only pleasure'[47]. Studies have found that many agencies providing care for the elderly have no written policy to guide their employees when encountering a client with an alcohol problem. Greenwood[48] argues that substance misusers, and the elderly in particular, suffer as the result of stigmatization, as their disorder is perceived as self-inflicted. This stigma may be reflected in a clinician's reluctance to become involved by acknowledging the problem. For other carers, their own previous experiences with elderly substance misusers, both professional and personal, may lead to attempts to justify the behaviour, resulting in a similar loss of objectivity.

BENZODIAZEPINE USE DETECTION

Prevention and early recognition form the basis of management of benzodiazepine misuse. Appropriate prescribing of sedatives for time-limited periods should be accompanied with vigilance for drug-seeking behaviour. Such behaviour includes early requests for repeat prescriptions or requests for increased doses. The elderly may also receive medication from multiple sources, particularly where they are under the care of prescribing hospital specialists as well as their primary prescribers. Careful exchange of clinical information is vital in such settings. For those abusing over-the-counter medication, chance presentation or the intervention of a pharmacist presents the best hope of detection. The Severity of Dependence Scale has been validated as a screening tool for benzodiazepine dependence[49]. It consists of five questions, referring to the past month:

1. Did you think your use of tranquillizers was out of control?
2. Did the prospect of missing a dose make you anxious or worried?
3. Did you worry about your use of tranquillizers?
4. Did you wish you could stop?
5. How difficult would you find it to stop or go without your tranquillizers?

Each of the items is scored on a four-point scale (Items 1–4: 0 = never/almost never, 1 = sometimes, 2 = often, 3 = always/nearly always. Item 5: 0 = not difficult, 1 = quite difficult, 2 = very difficult, 3 = impossible). A total score of 6 or more indicates problematic use, with a specificity of 94.2% and sensitivity of 97.9%[49].

Urine screening provides a reliable means of establishing the presence or absence of drug metabolites, but its clinical utility can be limited by the unacceptability of the test to many who may be offended by the suggestion that they have a substance misuse problem. In addition, urine screening is usually qualitative rather than quantitative. For those abusing a prescribed drug, the mere presence or absence of the drug is clinically uninformative. With these considerations in mind, the need for dependence-inducing drug prescriptions should be regularly reviewed and co-morbid contributory conditions, such as depression, should be actively treated. Changes in legislation on prescribing practice may reduce the opportunity for drug misuse[34].

INITIATING TREATMENT

There is no published data about the level of uptake of offers of help once elders abusing substances are identified. However, elders do achieve equivalent or better results than younger adults when they do enter treatment[2]. Motivational interviewing and education as to the risks of alcohol use, along with the benefits of even a small reduction in levels of alcohol intake, may persuade some elders to change. Unfortunately, the pessimistic attitudes held by many professionals and carers towards the likelihood of successful resolution of the problem are frequently also held by the individual too. A fatalistic resignation to a life of substance misuse is often reported, particularly by long-term users, while more recent-onset users may express greater motivation for treatment[50].

Once long-term use of benzodiazepines is established, dose reduction can be difficult to achieve. Withdrawal insomnia and rebound anxiety make patient motivation difficult to achieve. Where abstinence is desired, a conversion to a longer-acting benzodiazepine and a gradual reduction in dosage over the course of months is advisable[43]. Rapid detoxification is associated with breakthrough withdrawal symptoms and may be complicated by convulsions. If a rapid withdrawal is necessary, it is best conducted in an inpatient setting if severe dependency is suspected. As with alcohol, the withdrawal period for the elderly is more likely to be complicated by confusion than in younger adults. Longer term prescribing of benzodiazepines should adhere to the following general principles: clear indication of benzodiazepine dependence, clear intermediate treatment goals, regular review and methods to prevent diversion[51].

Psychological techniques, such as relaxation training and educative initiatives in the areas of sleep hygiene and correct medication use, may also prove valuable. Cormack *et al*.[52] demonstrated that writing to benzodiazepine users in primary care urging them to reduce their medication use resulted in a fall in total use by one third over the next six months. Treatment of other forms of drug misuse in the elderly is under-researched. Misuse of analgesics may require formal detoxification if opioids are involved or physical dependence has developed. More often the patient requires information to allow him/her to make an informed choice about drug use and an alternative form of treatment for his/her condition. Still less information is available on the treatment of illicit drug use in the elderly although several key publications argue for age-appropriate services to be formed[2,44]. These services should pay particular attention to co-morbid health problems and should provide basic-level medical services[2]. Severe or complex health problems should be identified and referred to appropriate specialist services.

PSYCHOLOGICAL INTERVENTIONS

Once a patient is detoxified, rehabilitation is necessary to address the issues behind his/her substance use and to foster coping strategies for the future. Few studies have examined the particular needs of the elderly in a rehabilitation setting and have mostly focused on alcohol. Janik and Dunham report on comparative outcomes for over 3 000 over-60-year-olds and younger entrants into alcohol treatment programmes[53]. Outcomes after six months showed no differences between the groups.

Psychological programmes designed specifically with the elderly in mind may be more appropriate for consideration. Some success has been claimed for models encouraging the development of social networks with self-management skills[54]. Kofoed *et al*.[55], in a small study, reported that retention in outpatient treatment of older adults was greater in an age-specific treatment group that focused on socialization and minimal confrontation (a mainstay of many programmes), compared with older patients in a mixed-age treatment group. At one-year follow-up the effect was lost.

Variations of the Alcoholics Anonymous 12-step model tailored to the needs of elders have been reported in the USA, with varying degrees of success[56]. Models low on confrontation, traditionally regarded as fundamental to overcoming denial on the part of the patient, appear to be supported by the work of Kashner *et al*.[57], who found that one-year follow-up of elders in a confrontational programme revealed half the levels of abstinence as compared with a group in a programme where self-esteem, tolerance and peer relationships were promoted.

Behavioural approaches, including cue identification and avoidance, have also been reported to be of clinical benefit[54]. A programme focusing on cognitive techniques, such as cognitive restructuring, assertion training and self-monitoring of drinking, resulted in 75% of those completing the programme sticking to their treatment goals at one-year follow-up.

The evidence suggests that a range of therapeutic techniques may be beneficial for the elderly and that local provision may depend upon the skills available to the treating agency. It is suggested that even if an elders-only therapeutic programme is not available, a better therapeutic outcome may occur from a more homogeneous group, where the opportunity for identification and vicarious learning is enhanced.

Even fewer age-specific studies are available to guide the clinician in the provision of aftercare to the elderly non-alcoholic drug user. An avoidance of drugs that have a dependence potential is advisable if practical. Adequate rehabilitation and continuing support of the individual are indicated. This may be provided through generic old age psychiatry services or through specialist drug services, depending upon which service appears best able to cater for the specific needs of the user. The choice of service provider should reflect the lifestyle of the patient, as opposed to being a decision based solely on chronological as opposed to biological age. Further services may also be available in the form of mutual support groups similar to those available for alcohol. The adoption of a cognitively based programme low on confrontation and designed to foster strong social support appears optimal, as shown in work in the field of alcohol.

CONCLUSION

Substance misuse and old age psychiatry have long been unpopular choices for specialization. Both fields are known for providing challenging patients with differing priorities to those of the clinician. Research in either field is hampered by the difficulty in obtaining reliable clinical data on conditions for which few empirical measures exist. The field of old age substance misuse has suffered to some extent in clinical practice, where patients do not fit neatly into either service and are welcomed by neither. It is, however, clear that there exists a significant morbidity due to drug use in the elderly. The problem may be iatrogenic and autogenic in origin. Increased life expectancy and the cohort effect of generations of recreational drug users reaching old age are likely to intensify the problem. Adequate research to identify at-risk individuals and the provision of appropriate and accessible treatment services for the elderly drug misuser remain the major challenges to health care providers.

Learning and Behavioural Studies

Old Age and Learning Disability

Oyepeju Raji and Asim Naeem
St George's University of London, London, UK

INTRODUCTION

In England and Wales approximately 2.5% of the population have learning disabilities, of which 1.2 million are at the mild end of the spectrum[1]. While the mortality rate for people with learning disabilities is higher compared with the general population[2], improved standards of care, more positive lifestyles and attitudes to treatment for serious illnesses have contributed to increased longevity. Mean life expectancy is estimated to be 74 years, 67 years and 58 years for those with mild, moderate and severe learning disabilities, respectively[3]. This has made the issue of age-related illnesses within this population group highly relevant.

MENTAL ILLNESS IN OLDER ADULTS WITH LEARNING DISABILITIES

Mental illness is common among adults with learning disabilities. Cooper's epidemiological study[4] comparing the prevalence rates of psychiatric disorder among older (≥65 years) and younger (20–65 years) adults with learning disabilities found significantly higher rates among the elderly cohort (68.7% compared with 47.9%). This was mainly accounted for by the higher point prevalence rates for dementia, generalized anxiety disorder and depression in the older cohort groups. While the ageing process can bring about a similar increased vulnerability to mental illness as seen in the general population, additional risk factors apply for people with learning disabilities. These include: the detrimental effect of pre-existing brain damage; co-morbid physical illnesses like epilepsy; specific psychiatric or behaviour disorders associated with genetic risk factors; low self-esteem which may be related to frequent placement breakdowns, past exploitation, neglect or abuse; and the complications of learned maladaptive behaviours such as self-injurious head injury.

Mental illness may go unrecognized due to a number of barriers in the pathways to health care. Service barriers can include the lack of specialist services or the lack of expertise in mainstream services, complex appointment systems that largely presume reading ability, and inaccessible health-care delivery. Problems with the doctor–user interface include communication difficulties, 'power imbalance' exacerbating the suggestibility of the person with learning disability, capacity issues and the complexities of atypical clinical presentations. Diagnostic overshadowing (assuming that any changes in behaviour or presentation are due to the learning disability, rather than a co-morbid illness) remains one of the major barriers preventing people with learning disabilities from accessing adequate health care[5]. User–carer barriers include pre-existing cognitive impairments making it difficult to obtain an accurate timeline of symptoms, the effects of past negative experiences of health-care delivery and the failure of carers to recognize symptoms. Older people with learning disabilities from ethnic minority groups may have particular problems accessing appropriate services[6].

DEMENTIA IN OLDER ADULTS WITH LEARNING DISABILITIES

The rates of dementia in older people with learning disabilities are four times higher than in the general population[7]. However, these high rates cannot be attributed just to those with Down syndrome and Alzheimer's disease. Strydom *et al.*'s epidemiological survey[8] of dementia in older adults (aged ≥60 years) with learning disabilities, but without Down syndrome, has confirmed this. Alzheimer's disease was found to be the most common sub-type, but the prevalence rates (8.6%) were almost three times higher than expected. While vascular dementia is the second commonest sub-type in the general population, Lewy body and frontotemporal dementias were found to be commoner in the older learning disabled population. Vascular dementia had a prevalence rate of 2.7%. Explanations for these increased prevalence rates include the effects of poorly controlled epilepsy or other physical illnesses, the detrimental effects of brain damage during birth and early life, and genetic risk factors[8].

Diagnosing dementia in people with learning disabilities can be difficult due to the wide range of pre-existing baseline cognitive, functional and behavioural impairments. Individuals are more likely to present with the behavioural and psychological symptoms of dementia, or with atypical symptoms such as unexplained seizures. Greater emphasis should be placed on personality and behavioural changes, in association with functional change, as diagnostic indicators[9]. Diagnostic difficulties can also result from altered social or communication skills making it difficult to identify subjective symptoms (psychosocial masking/intellectual distortion), and from diagnostic overshadowing[10].

Good collateral information from the person's carers is essential. The exacerbation of pre-existing deficits ('baseline exaggeration') may only be detected in day-care environments, where the person has more demands placed upon them.

Table 109.1 Differential diagnoses of dementia: what are the causes of cognitive, behavioural or psychological decline in an older person with learning disability?

Causes	*Examples*
Medical	*Physical*
	Hypothyroidism
	Recurrent urinary/respiratory tract infections
	Deteriorating epilepsy
	Anaemia
	Persistent or intermittent constipation
	Visual impairments (e.g. cataracts)
	Hearing impairments (including ear wax)
	Medication side effects (e.g. beta-blockers, anticonvulsants)
	Psychiatric
	Dementia
	Normal age-related decline
	Depression
	Anxiety-related disorders (e.g. worsening obsessive-compulsive disorder or phobias)
	Psychotropic medication side effects
Psychological	Bereavement-like response to loss events (e.g. death of a family member/carer/friend; care staff/friends moving; day centre closure)
	Environmental re-triggering of past traumatic events
Social	Changes in staffing/layout/structure/routine at home/day activities, within the context of autism
	Physical/sexual/other abuse

A detailed history and clinical examination, incorporating the 'medical-psychological-social model' can help exclude 'pseudo-dementia' symptoms (Table 109.1). While the clinical domains affected in Alzheimer's disease in older adults with learning disabilities are similar to those in the general elderly population, their presentation can be different (Table 109.2).

The Mini Mental State Examination is not valid for use in people with learning disabilities, but there are a number of alternative observer-rated scales available. Examples include the Dementia Scale for Down Syndrome (DSDS), the Dementia Questionnaire for Persons with Mental Retardation (DMR), and the Modified Cambridge Examination for Mental Disorders of the Elderly informant interview[11].

Medical investigations should be focused on excluding the differential diagnoses of dementia. A full blood count, B12/folate levels, ESR or CRP, urea/electrolytes, blood glucose/calcium levels, liver function/thyroid function tests and urinalysis should be done. A baseline ECG (to exclude bradycardic conduction deficits) can be helpful if anticholinesterase treatment is being considered. Neuroimaging should be used to help support a clinical diagnosis, as people with learning disabilities can have baseline frontotemporal abnormalities. Within the context of dementia, people with Down syndrome may develop more significant atrophy in the frontal and temporal lobes[12], hippocampus and amygdala[13].

Management should be based upon pharmacological and non-pharmacological interventions within the context of broad, multidisciplinary 'bio-psycho-social' approaches. Affected individuals can often be maintained in their existing environment[10] with additional support or adaptations. If the person needs to be moved into residential care, significant issues arise as to the suitability of mainstream dementia homes with significantly older people[6].

A number of studies have reported on the efficacy and safety of using acetylcholinesterase inhibitors (especially donepezil) in older people with learning disabilities[14,15]. Antidementia drug treatment can be initiated by the learning disabilities psychiatrist[16]. Associated behavioural and psychological symptoms that fail to respond to non-pharmacological measures may require treatment with an antidepressant, anxiolytic or antipsychotic medication. Persistent seizures may require anticonvulsant treatment. Non-pharmacological interventions such as reality orientation using a life-story photo book, art/music therapies and aromatherapy are of most use in people with learning disabilities.

As with the general population, the prognosis for dementia is generally poor, and the average duration of dementia is generally shorter.

ALZHEIMER'S DISEASE IN OLDER ADULTS WITH DOWN SYNDROME

While neuropathological studies have consistently revealed the evidence of neuritic plaques and intracellular neurofibrillary tangles in nearly all adults with Down syndrome over the age of 40 years[17], not all develop Alzheimer's disease. However, there is a marked exponential rise of Alzheimer's disease in adults with Down syndrome from 30 to 59 years of age, with prevalence rates rising from 2.0% (30–39 years age) to 36.1% (50–59 years age)[18]. For adults with Down syndrome living beyond 60 years of age, approximately three in four will have Alzheimer's disease. The mean age range of onset of the clinical manifestations of Alzheimer's disease is 50–55 years, with the rate of deterioration increasing with age. There are no clear relationships between the level of learning disability and risk of dementia or age of onset of dementia[19].

Neuropathological factors that may explain the increased risk of dementia include the over-expression of the amyloid precursor protein gene, the influence of apolipoprotein E alleles, genetic risk factors, the detrimental oxidative effect of increased superoxide dimutase activity in the brain, the earlier loss of the neuroprotective effects of oestrogen in women, and the effects of atypical karyotypes.

Compared to the general population, executive dysfunction (frontal lobe) symptoms such as social withdrawal, diminished initiative and pervasive slowness are common at an early stage of dementia in people with Down syndrome[20]. Isolated impairments in verbal/long-term memory and visuospatial construction deficits, without significant impairment in other areas of functioning, are more likely to indicate normal age-related decline.

The Dementia Screening Questionnaire for Individuals with Intellectual Disabilities (DSQIID)[21] is a reliable, observer-rated screening questionnaire for use in older people with Down syndrome. It allows the screening out of pre-morbid behaviours, with only changes in behaviour (or new behaviours) positively scored.

PHYSICAL ILLNESS IN OLDER ADULTS WITH LEARNING DISABILITIES

Older people with learning disabilities have health-care needs associated with ageing, and higher rates of respiratory disorders, arthritis, hypertension, urinary incontinence, immobility, hearing impairment and cerebrovascular disease[22].

Table 109.2 Clinical presentation of Alzheimer's disease in older people with learning disabilities

Clinical domain	*Examples of symptoms and signs*
Memory	Forgetfulness of recent events, e.g. content of meals/day activities (episodic memory impairment)
	Forgetfulness of future planned outings/activities
	Forgetting location of recently placed objects (spatial memory impairment)
	Geographical disorientation (e.g. unable to find their way around their own home/neighbourhood)
	Forgetting names of/failing to recognize familiar people (semantic memory impairment)
	Loss of previously learned skills, e.g. making a cup of tea or dialling a phone (procedural memory impairment)
Abstract reasoning skills (judgement, planning and organization)	No longer selecting appropriate clothing for planned activities/routines, or putting on clothes back to front
	Decline in shopping skills
	Difficulty following more than one instruction at a time
	Decline in ability to dress/feed self, or brush teeth (apraxia)
	Decline in reading (alexia), writing (agraphia) or language skills (aphasia)
	Using common everyday objects inappropriately (agnosia), e.g. combing hair with toothbrush
	Being unable to distinguish between day and night
Mood	Low mood/decreased energy/loss of interest/apathy
	Emotional lability (e.g. unexplained tearfulness)
	Overactivity/restlessness/poor concentration
	Irritability/anxiety
	Sleep changes (insomnia or hypersomnia)
Social behaviours	Increased dependence on others
	Personality changes, e.g. aggression/disinhibition, pervasive slowness
	Obsessional slowness/repetitiveness in completing tasks
	Social isolation
	Fear of stairs, kerbs or uneven surfaces
	'Covering up' of memory loss (e.g. saying 'sorry' to tasks they cannot do)
Perceptions	Auditory, visual or tactile hallucinations
Neurological	Gait disturbance/decreased mobility/falls
	Bradykinesia-like slowness in movements
	Seizures (early in Down syndrome)
	Dysphasia
	Dystonia/myoclonus/pathological reflexes
	Urinary incontinence

Hearing problems might further compound already poor communication skills and can be caused by structural abnormalities, neural damage or impacted earwax. People with learning disabilities also have a higher prevalence of sight problems, which may be acquired as they get older, or be as a result of brain damage or cerebral visual impairment[22]. The prevalence of ocular health problems ranges from 25% (in the mildly disabled) to 60% (in the profoundly disabled)[23].

Prevalence rates of epilepsy are considerably higher in people with learning disabilities compared to the general population (16.1% vs. 0.4–1%)[2]. Individuals often have complex seizure types and patterns.

People with learning disabilities have higher levels of oesophageal, stomach and gall-bladder cancers, but lower rates of lung, prostate, breast and cervical cancers.

An increased risk of respiratory tract infections in people with learning disabilities can be caused by aspiration or reflux due to swallowing difficulties. Levels of obesity are higher in people with learning disabilities because of poor diet, lack of physical exercise and difficulty understanding health promotion information, which can increase the likelihood of heart disease, stroke and type II diabetes mellitus. Many people with learning disabilities have high levels of *Helicobacter pylori* which may require testing and treatment throughout life[22].

Certain syndromes that cause learning disabilities are particularly associated with an increased risk of specific morbidity. Down syndrome is associated with increased risks of congenital heart problems, respiratory disease, a poor immune system, eye disorders, lymphoblastic leukaemia, coeliac disease and hypothyroidism. People with fragile-X syndrome have increased connective tissue disease and cardiac abnormalities. Prader–Willi syndrome has an associated risk of obesity-related pathology.

AGEING AND SOCIAL NEEDS OF PEOPLE WITH LEARNING DISABILITIES

Most long-stay hospitals have now closed, with individuals moving to community residential provision motivated by the philosophy of

'normalization'. In England, national policy requires local authorities to offer person-centred planning to all people with learning disabilities, alongside regularly updated health action plans[1]. Staff roles and training now focus on social inclusion, choice, independence and rights.

People with learning disabilities experience low employment and fewer meaningful relationships, as daily activities are usually only provided as part of a package of care. Placements often experience a high staff turnover resulting in carers having an incomplete knowledge of the individual. Many older adults may have been raised in institutions. Younger adults are more likely to have been raised within caring families in the wider community, with better lifestyles and opportunities that may have been denied to their seniors[4].

With good planning, people may stay in their own home funded through the personalization agenda. Accommodation and support varies from minimal to total. People with milder learning disabilities might live by themselves or semi-independently with some structured support each day. Those who need greater levels of support may live in housing managed by private or voluntary organizations, or by health and social services.

SERVICES FOR OLDER ADULTS WITH LEARNING DISABILITIES

Being elderly and having learning disabilities can make people vulnerable to 'double discrimination', as services for both groups tend to be underfunded. Debate exists whether to use mainstream older people's psychiatric services (which may lack neurodevelopmental expertise), to continue with existing learning disability services, or to develop specific specialist services. National policies advocate that people with learning disabilities should be able to access mainstream health services where appropriate, and specialist community learning disability teams (CLDTs) can promote this by providing specialist advice and support to their mainstream colleagues. Some CLDTs operate a life-span approach, but the majority work with people from age 16 or 18 with no exit age. However, such teams need to develop additional skills with regard to age-associated disorders.

Older people with learning disabilities face additional difficulties in primary care settings. Primary care physicians list lack of awareness of conditions specific to learning disabilities as among the top five barriers to care[24]. Strategic health facilitator posts tackle some of these issues by ensuring that people with learning disabilities are offered health screening, and that health promotion materials are accessible to them.

PALLIATIVE CARE ISSUES FOR PEOPLE WITH LEARNING DISABILITIES

Mainstream palliative care services need to be responsive to the needs of people with learning disabilities, as the combination of problems identifying symptoms and diagnostic overshadowing can result in the late presentation of illness at a stage when there is already advanced disease and severe symptomatology[25]. Many people with learning disabilities can be surrounded by a 'conspiracy of silence', where information about the illness and impending death is not shared with them[26]. Carers of people with learning disabilities may equate palliative care with hospice care, triggering unpleasant memories of largely institutional care. Educating well-meaning care staff and family members of the positive role of services in supporting the dying person in the community (within their home) can help alleviate these fears.

Effective end-of-life care requires close collaboration between learning disability services, palliative care teams, carers (including family members, who may highlight important religious or cultural issues) and other medical services.

CONCLUSION

People with learning disabilities share the general experiences and difficulties of becoming old with the rest of the population. Their increasing life span brings about important challenges in view of additional risk factors, increased prevalence rates, co-morbidity and atypical presentations of mental and physical illnesses. There is need for more research, education and training, alongside collaboration between services, to inform service developments. Person-centred approaches take into account an individual's life experiences, clinical needs and the support mechanisms needed for their immediate carers and family. Psychiatrists can act as drivers of positive health outcomes by facilitating access to appropriate pathways to care. Commissioners of older people's and learning disability services need to take these factors into account for future planning.

The Elderly Offender

Graeme A. Yorston

St Andrew's Hospital, Northampton, UK

The elderly are far more likely to be the victims of crime than the perpetrators, but a small number of older people do commit crimes, and this group is important for a number of reasons. First, the mental disorders of late life may lead previously law abiding people to act out of character and behave in a dangerous and distressing manner. Second, the criminal justice system is less sensitive to the ways in which mental disorders can present in older adults, with the result that they may go undetected, and, third, the needs of older mentally disordered offenders are often difficult to meet in existing prisons and secure hospitals, leaving them vulnerable, an easy target for physical aggression and with little chance of moving on because of inadequately developed risk management strategies and care pathways.

A question which most researchers in this field have posed is the age at which an offender should be deemed 'elderly'. Prison studies, particularly in the US, often include everyone over the age of 40! Others have used 45, 50 or 60 but relatively few the more traditional 65 cut-off. People who have had hard lives, no stable employment or relationships, several terms in prison, a history of drug or alcohol use, and patchy health care often appear much older than their peers who have led more conventionally prosocial lives, with the result that many are starting to look and feel old in their forties and fifties. There is a strong case, therefore, for using a lower age limit for research purposes, but all figures based on chronological age are arbitrary, and what is more important in the clinical assessment of an individual is *biological age*, as it is this that will largely determine their needs.

OFFENCE TYPES

Despite an ageing population, statistical data from the UK and US show the number of convictions of people over the age of 60 has been remarkably stable over the past 12 years[1,2]. Broadly speaking, the elderly account for around 1% of recorded crime, though this figure varies considerably for the type of crime.

Sexual Offences

Sexually inappropriate behaviour in dementia is a familiar problem to all old age psychiatrists. Most of this behaviour is mild in severity and does not reach the attention of the police or criminal justice system. Older adults can and do commit more serious sex crimes, however, and account for approximately 1% of convictions for these offences in the UK, with broadly comparable figures from other countries. The proportion of older adults is rather higher for those convicted of sexual offences against children, and a number of possible explanations for this have been proposed, including the greater ease by which children may be dominated by someone of declining physical strength, the degree of trust afforded grandparental figures, ready access to grandchildren, and regression to childhood fantasy objects. The proportion of older sex offenders with suspected or proven organic psychiatric diagnoses varies in published case series from 0% to 60%[3–5]. Other diagnoses reported in the literature include antisocial personality disorder, alcoholism, learning disability, depression and schizophrenia. Though research has consistently shown that older adults are capable of committing the most serious violent penetrative offences, there has been a tendency to minimize the seriousness of offending by this group in the past[6]. Several studies have shown lower rates of recidivism for older offenders[7–9], but some of these failed to account for the reduced time at risk of re-offending of elderly men, and the fact that, as a group, older sex offenders tend to commit less serious offences which have lower recidivism rates. It should also be borne in mind that the lower recidivism rate is of little help in assessing risk in individual cases, which should be approached in a structured manner. The potential for serious harm should never be underestimated on the basis of age alone.

Homicide

There have been few psychiatric studies of elderly homicide offenders, though the individual case study literature is much richer. Rollin[10] described a typical case of a 71-year-old man with a history of depressive illness who battered his wife to death after becoming convinced that she was beginning to fail in health and was too proud to allow herself to be looked after by anyone else should anything happen to him. Large homicide case series often include a small number of elderly cases: in Gillies' classic series of 400 homicides in Scotland[11], there were only three men over the age of 65 and the oldest woman was 54. Unlike the majority of people accused of homicide, who were considered mentally normal (82%), all three of the over-65s were psychotic at the time of the offence.

In a comparison of older and younger homicide and attempted homicide suspects in Canada[12], much lower rates of previous convictions and past hospitalization for mental illness were found in the elderly group. Half of the elderly group had psychotic diagnoses, with none found in those under the age of 30; 19% of the elderly group had an organic mental disorder, with none in the younger group;

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

50% had alcohol problems (31% in the younger group); and only 13% had antisocial personality disorder (compared to 68% of the younger group). Surprisingly, though, fewer of the elderly group were found not guilty by reason of insanity (19% compared to 30%). This finding contrasts with sentencing data from Scotland in the 1990s, which showed that elderly homicides were more likely to be given hospital disposals than younger offenders and far less likely to be given life sentences (F. Thorne, personal communication).

Forensic pathologist Bernard Knight[13] coined the term *Darby and Joan syndrome* for elderly couple homicides which occurred in apparently close, loving relationships, in contrast to younger partner homicides which typically occurred against a background of infidelity, jealousy and money disputes, fuelled by alcohol or drugs. He cited the case of a woman in her seventies who killed her husband with repeated brutal blows to the back of his head with a heavy metal object while he was sitting watching television. No rational explanation for the act could be obtained. Knight commented on the extreme brutality used in elderly couple homicides and cited two cases of octogenarian men who killed their elderly wives with hammers – one of whom rained down 37 blows on his wife's head, resulting in multiple compound fractures of her skull. He also commented on the presence of *bizarre postmortem bondage* in many of the cases he was involved with, describing how a man trussed his wife up in a chair with twine and cord after killing her and then bound her face with towels and cloths secured by more twine.

Though the psychiatric literature emphasizes the differences between elderly homicide offenders and younger homicides, criminological data from US studies show that though elderly homicide rates vary between different US states, they are correlated with the non-elderly rates, which are themselves strongly correlated with urbanization and poverty, suggesting that the same societal pressures influence young and old alike[14]. Other US studies have shown that the elderly are more likely to kill family members, to use firearms and to carry out the offence in the home[15,16]. The majority of elderly homicides are committed by men, but in a study of coroner's office and county prosecutor files of 179 homicides by the over-60s in Cincinnati and Detroit[17] it was found that women accounted for 18% of cases. There have been no systematic studies of elderly women homicides, however, though there are a number of brief case descriptions[18,19].

Homicide–Suicide

A number of studies have demonstrated that homicide followed by suicide is commoner in older adults[20]. It usually occurs in a spousal relationship, and depression and alcohol problems are common. One study showed a mean age difference of 18 years between perpetrators and victims along with prominent histories of discord, violence and separation. There are published case studies of homicide–suicides that have no history of conflict, however: for example, an 82-year-old man who shot his frail 84-year-old wife and then himself after becoming unable to provide care for her after he suffered a myocardial infarction[21]. In such cases it can be difficult to distinguish between homicide–suicide cases and suicide pacts.

Non-Fatal Violence

Minor aggression in elderly dementia sufferers is common, with up to 90% displaying some sort of aggression during the course of the illness[22]. Most is not serious and relatively easily managed, in contrast to the type of behaviour described in an Australian case series of fourteen older adults accused of attempted homicide[23,24]. The only one who succeeded in killing his victim in this series was a 68-year-old man who shot his neighbour with a shotgun.

Arson

There is no published literature on arson by the elderly. Clinical experience suggests that pyromaniacs, fascinated by fire and fire services, do not typically present in old age, but such individuals, many of whom have spent years in secure hospital or prison, may live on to old age and develop a neurodegenerative disorder. Such cases present extraordinary difficulties for psychiatric and social services, and the criminal justice system, which often struggle to balance the risk to others and individual vulnerability issues. It is not clear how risk to others from arson, or indeed sexual or violent offending, changes with the progression of a dementing illness, and so care generally has to be provided in an environment where risks can be managed through relational and procedural security measures. What appears to be more common in old age is the emergence of a pattern of setting small fires, often within residential homes. Though many of these fires cause little actual damage, because of the potentially devastating consequences, all fires in elderly care settings have to be taken seriously. As few old age psychiatrists have much experience of assessing fire setters, referral for a forensic psychiatric assessment is recommended. Arson in the elderly has been linked with personality disorder, psychosis, dementia and previously unrecognized learning disability.

Acquisitive Offending

Shoplifting is the commonest offence of late life, but most cases of acquisitive offending never come to the attention of old age psychiatrists. Anecdotally there is said to be an association with depressive illness, but there have been few studies on this topic. The shame of being arrested for shoplifting can have disastrous consequences for individuals with no previous criminal history, and the case of Lady Isobel Barnett, a British television personality who committed suicide four days after being convicted of stealing a can of tuna and carton of cream in 1980, is well known[25].

Drug- and Alcohol-Related Crime

For people born in the 1940s or before, drug use was uncommon when they were going through their period of highest risk; however, this is not the case for those born in the following decade, and old age psychiatry services are now beginning to see people with active drug problems, something that was almost unheard of previously. At present drugs do not present major problems in UK older adult secure hospital services, unlike services for younger patients, but this is likely to change over the coming years. Alcohol is being increasingly recognized as a problem in older adults[26] and alcohol problems are common among older men in prison in the US[27]. When this is linked to offending behaviour it has serious implications for risk management. The assessment of older offenders with a history of alcohol abuse is further complicated by the possibility of alcohol-related cognitive impairment.

DIAGNOSTIC CONSIDERATIONS

All of the mental disorders that occur in late life can lead to criminal behaviour; for the overwhelming majority of individuals, changes in

behaviour as a result of mental disorder are recognized as such and dealt with by medical services. Sometimes, however, the behaviour can be so sudden and so severe that health services are not involved until after an offence has been committed. In these circumstances it is important that the individual receives an assessment by a clinician familiar with the psychiatry of old age.

Delirium

Metabolic and other causes of delirium, superimposed on the early stages of dementia or a pre-existing depressive illness, can lead to fatal aggression. Some of the bizarre, apparently motiveless homicides described above and many from my own experience have been the result of delirium, often occurring as a side effect of medication, including steroids, anti-parkinsonian medication and the anticholinergic effects of first-generation antidepressants.

Dementia

There are isolated case reports of crime associated with dementia, but given that it is so common, it is surprising that there are not more and that it has not been more systematically studied. Experience suggests that individuals with more than a mild degree of dementia are easily identified as such and not dealt with by the criminal justice system. This is not the case for those with very early dementia, or in cases of frontotemporal dementia with a well-preserved social façade. Dementia can present with a change in behaviour: either the emergence of new behaviours that were not present at all previously, or a change in the type, frequency and character of existing behaviour. Old age psychiatrists are familiar with the evaluation of such issues by taking careful histories from carers and relatives, but forensic psychiatrists are generally more used to assessing individuals through detailed mental state examinations, which may reveal little in early dementia. In a study of referrals to a regional medium secure unit in England, it was found that forensic psychiatrists did not routinely use standardized rating scales for the assessment of cognitive functioning[28]. For these reasons individuals presenting with offending behaviour for the first time in old age ideally need assessment by clinicians with experience of both specialties, or if none are available, by clinicians from each specialty working closely together.

Psychosis

Unlike the psychosis of younger adults in which schizophrenia is the diagnosis most commonly associated with serious aggression and homicide[29], homicidal psychosis in the elderly is more commonly depressive in nature and characterized by nihilistic delusions, and it is often the spouse of the perpetrator who is the victim. The mindset is often that one or both of the couple are ill, leading to worries of how one would cope without the other, and the conclusion that they would both be better off dead. In such cases, the depression can be relatively mild on the surface and be missed by those looking for the entire gamut of symptoms, but careful enquiry about worries and preoccupations and changes in habit can be revealing. In a study of elderly men in English prisons in the 1990s[30], it was estimated that there were up to 50 older men in the UK prison system at any one time suffering from a depressive illness with psychotic symptoms severe enough to be in need of urgent transfer to hospital.

Developmental Disability

Asperger's syndrome, previously unrecognized, can present for the first time in late life and be associated with serious offending. This is commonly due to decompensation because of a change in routine by going into a residential home or through the loss of a supportive relationship, often a very old parent. Making developmental disability diagnoses in the absence of a reliable informant is difficult, however, and can be complicated further if a neurodegenerative disorder is suspected as well.

Personality Disorder

By definition, personality disorders cannot begin in old age, but what may happen is that a change in circumstances reveals a personality that has been disordered throughout life but compensated for by some means, often a spouse or other significant relationship. At retirement of one party or the other, or at the death of a partner, or entry into a care home, personality issues previously hidden within the family can emerge. These may simply cause annoyance or minor distress or be associated with criminal damage, fire setting or violence.

THE ELDERLY IN THE CRIMINAL JUSTICE SYSTEM

Arrest

Anecdotal evidence suggests the police may be reluctant to get involved in offences committed by elderly people with obvious mental health difficulties. This is particularly noticeable if either the perpetrator or victim suffers from dementia, presumably because of difficulties in obtaining evidence. This can lead to very serious offences being inadequately investigated, which then makes risk assessment almost impossible. A study of a special police project in one region in England in 1990[31] showed that of 367 consecutive arrestees aged 60 or over, less than 10% were prosecuted. The remainder were cautioned if they admitted guilt, or were subject to no further action. Nearly two thirds of the arrests had been for shoplifting, in most cases of grocery items of small value. There were 15 arrests for violence, most of which was not serious, and 11 arrests for indecent assault. Police referred the arrestees to their primary care physician or to the police doctor more often than to any other agency. Though only 50 arrestees agreed to have research interviews, nearly one third of these were identified as 'psychiatric cases'.

Trial

All jurisdictions have rules on fitness to plead and fitness to stand trial. For older adults mental health issues must be considered along with physical health and perceptual issues. Is the defendant able to see and hear adequately? Do they need shorter court sessions because of fatigability? Do they need extra toilet breaks or different seating? All these questions need to be addressed when assessing an older adult. However, the main question to be answered in determining fitness to plead in the majority of cases is whether the defendant is able to follow the course of the proceedings in court. The answer to this can be very obvious for someone with severe dementia, or in someone with relatively mild or well-managed mental health problems, but in many cases of mild to moderate dementia, the issue is far from clear. Standard cognitive testing in such cases can be helpful but in serious cases fuller neuropsychological evaluation is recommended, which should include tests of malingering and suggestibility.

Prison

The number of older people in prison has risen sharply over the past 20 years: in England and Wales, there were 365 sentenced prisoners aged 60 and over in 1990[32]. By 2007, this figure had increased sixfold to 2 192, and older prisoners now make up 2.9% of the total prison population[33]. In the US the number of older inmates showed a similar increase, tripling between 1990 and 2001, and their proportion in the total prison population doubled (from 4.0% to 8.2%)[34]. These increases appear to be due largely to changes in sentencing by the courts. 'Three strikes and out' sentences were first introduced in the US in 1993, and in the UK in 1998, with the result that recidivist violent offenders in particular remain in prison well into old age, such that many US states have been obliged to develop nursing home wings for older prisoners and the UK prison service is having to take seriously the needs of older inmates.

In the UK, much of the prison estate is old and difficult to adapt to meet the needs of older adults. Prison regimes can appear harsh and inflexible, as they are primarily concerned with the maintenance of security and discipline, and not with meeting health care needs. The result is that older prisoners can be extremely vulnerable and they are not uncommonly on the receiving end of serious aggression, despite the often very caring attitude of the majority of younger prisoners. Special units for older prisoners began to appear in the US in the 1970s, and a body of qualitative research showed that older prisoners, generally, though not always, preferred being in these units away from the noise and aggression of younger inmates[35]. In a study of sentenced older male prisoners in England and Wales high levels of psychiatric and physical morbidity were found[30,36]. In total, 53% had a psychiatric diagnosis, most commonly personality disorder and depressive neurosis, but 5% had a psychotic illness. In contrast to studies of younger prisoners, in which schizophrenia is the commonest psychotic illness, depressive psychosis was found to be the most common in older prisoners, yet only 12% of those diagnosed with depression were on antidepressants. Somewhat surprisingly, only two cases of dementia were found, but the sample of prisons included in the study contained few lifer units, in which cases of dementia are more common.

It is known that younger prisoners have worse physical health than age-matched controls. There is also evidence that such ill health continues into old age, with the elderly having more physical health problems than younger inmates and age-matched community living elders. A recent US study[28] highlighted the importance of thorough physical evaluation of older men coming in to prison to ensure they benefited from secondary preventive treatment for cerebrovascular disease and other common physical health problems. The study also showed that sexually transmitted disease (STD) is common among older prisoners. Clinicians unfamiliar with working with the elderly often assume that older people are sexually inactive, and do not ask about the possibility of STDs. Older prisoners should have access to primary and secondary care physicians who are familiar with the latest research and guidance on health promotion in this age group.

Women

The number of older women in prison has risen sharply over the past ten years. Many of these are long-term prisoners, though there are some who have committed serious offences for the first time in late life. It is likely that they have at least the same prevalence of mental health problems, if not greater, than their younger peers. But as numbers are small, little formal research has been carried out. In a sociological study of older women prisoners in the UK, it was found that there were a number of older women from ethnic minorities who suffered the double isolation of being different because of their age and different because of their culture[37].

Psychiatric Services

In the past it was very difficult for older patients to access specialist secure psychiatric services, particularly in the UK. Only 1% of those newly admitted to high and medium secure beds in England and Wales between 1988 and 1994 were over 60[38]. The conclusion drawn was that this was because people of such age were regarded as unsuitable for existing UK forensic services, mainly because of concerns about their potential vulnerability to aggression from younger patients. A number of studies have shown that older adults make up between 1% and 3% of referrals to forensic mental health services in the UK and Sweden[39–41]. There have been several descriptive studies of the elderly in high security, but these mainly focused on diagnostic issues[42–44]. In a more recent study at Broadmoor high security hospital in England the heterogeneity of older mentally disordered offenders in terms of diagnosis, assessed needs and expressed preferences was highlighted[45]. Despite there being a ward specifically for older vulnerable patients, the 16 patients over the age of 65 identified in the study were spread across 9 different wards in the hospital. Some authors have proposed 'streamlining' older offenders to make their care more cost-effective[27], but if the findings of the Broadmoor study are replicated then it would appear that streamlining will be very difficult. Older patients have some similarities one with another, because of their age, but the range of problems they present and their needs appear to be just as diverse as those of younger patients. It would be wrong to confine them all together solely on grounds of chronological age. This important issue emerged in some of the earlier qualitative work in prisons when it was found that not all older inmates wanted to be housed together; some liked the hustle and bustle and felt they enjoyed a high status in mixed age units because of their age and life experience[46].

Care homes for older adults often cope with high levels of minor physical aggression and sexually disinhibited behaviour[47]. However, they are not equipped to deal with more serious aggression or predatory sexual behaviour. The understanding of risk issues and how to assess and manage them is often highly sophisticated for the common behavioural problems of dementia, but for behaviour driven by antisocial personality traits it is usually lacking. This means there is a lack of suitable facilities for older offenders who have been assessed and require ongoing nursing care in an environment that is also able to manage their risky behaviour. In the UK specialist hospital units have been set up for those who require inpatient assessment and treatment, but a lack of suitable places to discharge patients to once they have been stabilized, though not necessarily to a state where the risks they pose to others have been substantially reduced, means that many remain in hospital for longer than would otherwise be necessary. Most offenders with established dementia will be unfit to plead or stand trial, and, if violence has been serious, will require further care and supervision in a hospital unit specially designed to meet their mental and physical health care needs with just sufficient security to ensure public protection.

TREATMENT ISSUES

The most important consideration in the treatment of the mental health problems of elderly offenders is location. For less serious offenders, normal treatment by their community mental health team in conjunction with their general practitioner is appropriate. For those in custody, treatment by a visiting psychiatrist and prison in-reach team may be sufficient, but for others assessment and treatment in hospital will be required. For some of these it may be appropriate for an old age psychiatrist to manage the case within their own service with advice from the local forensic psychiatric team, but in some cases the individual may need treatment in secure hospital. The ethos and treatment philosophy of specialist secure units for older adults should ideally be a synthesis of older adult and forensic psychiatric service models, modified and adapted to ensure that security is maintained without unnecessary levels of physical security. They should aim to be comfortable and homely without compromising safety. Staff training is paramount: a well-intentioned but infantilizing approach is likely to be robustly rejected by patients unused to *fluffy nurses* – a pejorative term used by patients to describe staff who are unfamiliar with forensic issues. Equally, a harsh and emotionless approach with an over-reliance on physical restraint is unlikely to meet the needs of individuals who may spend the rest of their lives on a particular ward and have no social contacts outside the ward team and co-patients. Pharmacological treatments are no different for elderly offenders with mental health problems than for their community peers, but the risk/benefit balance is tilted more towards drug treatment than would be the case in standard old age psychiatric practice. Despite all the safety concerns about using antipsychotic medication in dementia[48], there would be few who would argue against a trial of medication in an individual displaying thousands of aggressive acts per month in whom all other treatments have proved ineffective. Antipsychotics in schizophrenia tend to be used at doses more typical of working age adult services than old age services and occasionally there is justification for a trial of high dose antipsychotic medication providing safety guidelines are followed. Anti-libidinal medication can be useful in the treatment of sexual offenders with personality disorders and organic mental health problems though the evidence base for this is still very limited.

RISK ASSESSMENT

The unstructured clinical assessment that was the cornerstone of forensic psychiatric practice a generation ago has been largely replaced by a range of actuarial and structured clinical assessment tools backed up by a substantial body of research. The problem of using these tools is that none has been validated in the elderly, and many tend to focus on past behaviour or negative characteristics. There is a potential for misuse of actuarial tools that predict future risk as their positive predictive value depends on the base rate of offending in the population, which is of course much lower in the elderly than in younger adults on whom the instruments were developed. In the absence of instruments designed for the elderly, the use of structured clinical risk assessment tools such as the HCR-20[49] for physical violence and Risk of Sexual Violence Protocol (RSVP)[50] for sexual violence is recommended to ensure a systematic approach to the gathering of risk information.

PREVENTION

A number of studies in the US have shown that the elderly, being less physically able, make greater use of firearms than younger violent offenders[15,16,27]. Access to guns is much more restricted in the UK, yet older homicide offenders still manage to find weapons of sufficient lethality without too much difficulty. The weapon of choice for such incidents is usually a blunt object, and I have dealt with homicide cases by older adults involving repeated blows to the head with a ceramic fruit bowl, a club hammer, a walking stick, a pair of long handled garden loppers, an antique flat iron, a stone in a sock and decapitation with a saw. Restricting access to conventional weapons is unlikely to affect the rate of these domestic homicides in the UK because the victims are generally of similar age and may be quite frail, and almost any household implement can be made into a lethal weapon given sufficient will and a little physical strength. A far better preventive strategy would be to focus efforts on delivering good quality psychiatric care to all older people with mental health problems, and increasing the skills of primary care physicians for early identification of depression. Other priorities will include persisting with efforts to help those with alcohol problems and routinely asking patients and carers about physical aggression and sexually inappropriate behaviour.

Sleep and Ageing: Disorders and Management

Helen Chiu[1] and Joshua Tsoh[2]

INTRODUCTION

Sleep changes significantly across the human lifespan, and sleep disturbances are particularly prevalent in older populations[1–12]. Epidemiological studies around the world have reported that the prevalence of insomnia symptoms increases with age and reaches around 50% in the elderly (readers can refer to Ohayon, 2002[9], for a review). A representative study by Foley *et al*. on over 9000 participants aged 65 or older in three US communities reveals that over 54% of the subjects had one or more sleep complaints most of the time; the number of complaints rises with age, and the odds for women to have difficulty falling asleep are almost 50% higher than for men[5]. Upon longitudinal examination, insomnia emerges with an annual incidence rate of at least 5% among the seniors who did not have insomnia at baseline[6].

Apart from being a major source of vexation to the elderly and their caregivers, persistent sleep disruptions are associated with poorer mental and physical health, elevated fall incidents, worse cognitive and functional performance, lower quality of life, earlier institutionalization and greater mortality over time[12].

To formulate evidence-based solutions to meet this public health challenge, clinicians should examine and understand the interplay of clinical factors, which include physiological changes in sleep architecture with ageing, sleep disorders that are more prevalent among the elderly (e.g. sleep disordered breathing (SDB), restless legs syndrome (RLS), rapid eye movement sleep behavioural disorder (RSBD)), and sleep modulating effects from physical and mental disorders, medications, undesirable sleep habits and environmental factors that are more common in later life.

INSOMNIA

Insomnia is the most common clinical sleep complaint; it can refer to difficulties initiating or maintaining sleep, waking up too early or an inability to obtain sleep that is of adequate duration or perceived as restorative. However, not all individuals with symptoms of insomnia are dissatisfied with their sleep or face daytime consequences[9]. A diagnosis of insomnia as a disorder according to the International Classification of Sleep Disorders (ICSD) criteria[13] would require the concomitant presence of persistent sleep difficulty, daytime impairment and adequate sleep opportunity.

In a review of 13 representative epidemiological studies from around the world (involving 33 000 non-institutionalized elderly)[9], Ohayon finds that the prevalence of insomnia symptoms varied vastly (9 to 65%) according to criteria differences, but the figures are consistently higher in females. Two studies have examined insomnia as a disorder (Chiu *et al*., 1999[14]; Ohayon and Vecchierini, 2002[15]), in which cases the prevalence is comparable, and significantly more female than male elders suffer from insomnia (around 16 to 18% and 9 to 12%, respectively).

The high rate of insomnia in the elderly might be related to physiological ageing of the structures involved in homeostatic and circadian rhythm mechanisms, secondary to medical and psychosocial conditions that abound in late life, or a combination of these factors[1–4,8–12].

Sleep Architectural Changes with Physiological Ageing

The suprachiasmatic nucleus (SCN) in the hypothalamus is the biological 'master clock' that controls the circadian rhythms of physiological processes including sleep, body temperature and endocrine output in a roughly 24-hour cycle[16]. Its endogenous periodicity is entrained by external *zeitgebers* ('time-givers'), most notably environmental light, through the retinohypothalamic tract (RHT)[16]. Its rhythmicity is also affected by a number of interlocking feedback mechanisms, including pineal secretion of melatonin (a hormone causing drowsiness and lower body temperature), which peaks in the middle of the night[16]. Current evidence shows that sleep is initiated upon reciprocal inhibition of cholinergic, noradrenergic and serotonergic arousal systems in the brain stem by the ventral lateral preoptic (VLPO) area of the anterior hypothalamus, which is in turn influenced by circadian signals from the SCN. Once sleep begins, an ultradian oscillator in the mesopontine junction of the brain stem controls the regular alternation of non-rapid eye movement (NREM) and REM phases of sleep, which usually occur four to five times per night[16]. NREM sleep is divided into four progressively deeper stages (I, II, III and IV), is characterized by slow waves on an electroencephalogram (EEG), and predominates in the early part of sleep. REM sleep, on the other hand, is characterized by an active EEG pattern, REM clusters on the electrooculography (EOG), and muscle atonia. REM sleep is more pronounced in the latter cycles of sleep as NREM sleep becomes concomitantly shallower.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

With ageing there is a physiological change in the circadian cycle at all levels; it has been observed that reduction in SCN cell numbers/neuronal activity[3] and melatonin secretion occurs with advancing age[17]. The responsiveness of the circadian clock and pineal melatonin secretion to zeitgebers also diminishes, along with age-related decline in sensitivity to light in the visual structures[3]. The aged circadian system is also less adaptive to changes; difficulty adjusting to shift-work and jet lag are more common in middle-aged persons than in their younger counterparts[3]. Furthermore, along with other circadian physiological processes, phase-advances in sleep have consistently been observed[3]. Circadian amplitudes might also become less pronounced; the sleep of older individuals is often punctuated by periods of wakefulness, and they are also more easily aroused from sleep by environmental stimuli[2,3,18]. Napping is generally more common; recent studies show that naps do not necessarily have a negative impact on the nocturnal sleep architecture[1–3,18–20].

In terms of sleep polysomnographical findings, Ohayon *et al*. reported, in a meta-analysis on 2400 healthy, non-institutionalized individuals aged 19 to 102 years from the US and Europe[8], that there is a decrease in total sleep time (TST), sleep efficiency (SE), percentage of slow wave sleep (SWS; stages III and IV of NREM sleep) and REM sleep across the adult life span; on the other hand, an increase in stages I and II sleep, and wake after sleep onset (WASO) take place. Age-related differences in sleep and REM latencies are not pronounced; gender differences are modest.

It is, however, noteworthy that most of the stated age-related changes have taken place *already* in younger adulthood. When the sleep of older adults (aged 60 or older) in particular is examined, apart from the SE, which declines mildly, no clear changes in the sleep macroarchitecture are found with advancing age[8].

These polysomnographical findings suggested that the normal sleep macrostructural changes with physiological ageing in later life are (probably with the exception of advanced sleep phase disorder) largely not accountable for the prevailing epidemiological findings of a rising rate of insomnia with age in the elderly, especially among older women.

Other Causes for Insomnia with Ageing

The Foley *et al*. cohort study of 9000 community-dwelling elders in the US found that advancing age was not associated with insomnia after adjusting for differences in health status[5]. Upon follow-up three years later, 93% of persons with incident insomnia in this interval were found to have risk factors including chronic physical disease, depressed mood, physical disability, poor perceived health, widowhood and use of sedatives, while improved self-perceived health was associated with remission of the 2000 survivors with chronic insomnia at baseline. The authors concluded that the incidence of insomnia in the elderly is not related to the ageing process *per se* but to other risk factors, a finding echoed by epidemiological studies on insomnia disorder subsequently conducted in populations from China and from France[9,14,15].

Recent studies have confirmed that incidences of secondary insomnia far outnumber those of primary insomnia disorder in the older population[9,12,21]. Particularly common clinical conditions leading to secondary insomnia in late life include neuropsychiatric degeneration (e.g. Alzheimer's disease or Parkinson's disease), a number of age-related sleep disorders (SDB, RLS and RSBD), psychiatric illnesses (especially depressive and anxiety disorders, alcohol dependence) and other medical disorders (particularly those affecting the musculoskeletal, cardiovascular, gastrointestinal, pulmonary and genitourinary systems, malignancies, painful conditions, and the drugs used to treat them)[9,12,21].

Interested readers can refer to Barczi and Juergens, 2006[21] and Garcia, 2008[22] for two extensive reviews on the relations between prevalent medical disorders and insomnia in the elderly. It should be noted that 'co-morbid insomnia' is the term currently preferred over 'secondary insomnia' when the causative relationships are not clearly proven[23]. The specific conditions of SDB, RLS, RSBD and sleep disorders related to dementia will be discussed in separate sections in this chapter.

Evaluation of Insomnia Disorder

A carefully taken sleep history is important; Lichstein *et al*. recommend a multidimensional approach to exploring contributory factors to insomnia in the (i) circadian; (ii) psychiatric; (iii) pharmacologic; (iv) medical or neurological; and (v) psychophysiological reactivity (like subclinical anxiety and physiological tension) and negative conditioning (e.g. from poor sleep hygiene, or performance anxiety related to frequent insomnia) domains[4]. Along with a relevant physical examination, the primary condition(s) leading to insomnia should first be elucidated and treated where present. Routine investigation with polysomnography (PSG) is not recommended for insomnia disorder by the American Academy of Sleep Medicine except when there is diagnostic uncertainty (covert cases of RLS, SDB or RSBD are more common with advanced age) or prior treatment failure[4,24].

Non-Pharmacological Treatment of Insomnia Disorder

Psychological and behavioural interventions are effective in the treatment of insomnia in older adults, and in the treatment of insomnia among chronic hypnotic users[25]. They are most commonly cognitive behavioural therapies that comprise a combination of relaxation exercises, stimulus control (e.g. limiting bedroom use for sleep), sleep restriction, sleep compression (gradual reduction of time in bed) and cognitive therapy that counters excessive worries about sleep, and education on sleep hygiene. The positive effects are most pronounced on measures of SE, WASO and sleep onset latency (SOL)[4]. Interested readers can refer to Lichstein *et al*.[4] for a detailed review on the results from clinical trials of each cognitive behavioural therapy (CBT) technique. The role of light therapy in insomnia disorder needs to be further elucidated[26].

Pharmacological Treatment of Insomnia Disorder

In general, agents with a short half-life (thus less hangover/daytime sedation), a low dependence potential and a low propensity for disrupting normal sleep architecture are preferred. The newer benzodiazepine agonists including zolpidem, zopiclone, eszopiclone and zaleplon have all been found to be generally safe for short-term use in older adults. Zopiclone might be associated with a mild increase in SWS. For a comprehensive review, readers can refer to Salzman[27].

Complementary and Alternative Medicine for Insomnia Disorder

The use of complementary and alternative medicine approaches for sleep disturbances in older adults is widespread. Thus far there is

evidence of the efficacy of melatonin in treatment of circadian rhythm disorders, but its effect is less conclusive in primary and secondary insomnias. Mind–body exercises like meditation, yoga, and Tai Chi showed promising results in open trials; their roles require further evaluation[28].

RAPID EYE MOVEMENT SLEEP BEHAVIOUR DISORDER (RSBD OR RBD)

First described by Schenck *et al*. in 1986[29], RSBD is now understood to be a parasomnia characterized by abnormal behaviours during REM sleep that cause sleep disruption and/or injury. It is a male-predominant disorder that usually emerges after the fifth decade, although any age group can be affected[13]. The data concerning its prevalence are scant; it was estimated to be 0.5% among the UK general population by a phone survey[30] and determined to be around 0.4% in a two-phase study on community-dwelling Chinese elders[31]. It could take an acute form upon REM rebound state (like withdrawal from alcohol or hypnotics) or be precipitated by intake of different antidepressants (except bupropion)[29]. More commonly, RSBD takes an idiopathic, chronic form which follows a progressively worsening course[29].

Patients with RSBD have dream-enactment behaviours during the REM stage of their sleep; they might talk, shout aloud, walk, kick or punch their bed partners, or fall out of bed[13,32–35]; in clinical series studying US and Chinese populations, about 30 to 50% of patients injure themselves; about 60% hurt their bed partners[32,34]. The patients often can recall their dreams, which are vivid and contain a high degree of violent/aggressive content that is usually out of keeping with the patient's normal behavioural patterns[36].

Moreover, features suggestive of early synucleinopathy including deficit pattern in brain perfusion scans[37] and abnormal cardiac autonomic regulation (likely from a loss of cardiac sympathetic terminals) on cardiac ^{123}I-metaiodobenzylguanidine (MIBG) scintigraphy[38–40] have been reported in patients with idiopathic RSBD. In fact, RSBD also occurs with disproportionately greater frequency in synucleinopathies like multiple system atrophy, Parkinson's disease and dementia with Lewy bodies compared to other neurodegenerative disorders. RSBD has been conceptualized as a manifestation of evolving synucleinopathies[41].

Diagnosis of RSBD is by clinical history, supplemented by video-polysomnographic study[42]. Electromyogram (EMG) during REM sleep reveals an excess of muscle tone or phasic EMG twitch activities[13]. Differential diagnoses include sleep-walking, night terrors, nightmares, nocturnal seizures, obstructive sleep apnoea, posttraumatic stress disorder, dissociative states and nocturnal confusional states[33].

High treatment efficacy (close to 90%) with clonazepam has been found in international studies. Protective measures against injuries during sleep might also be necessary, indicating the importance of the early recognition and management of RSBD[32–35].

SLEEP-RELATED MOVEMENT DISORDERS

Sleep-related movement disorders are characterized by stereotyped movements that disturb the sleep of the affected individual and, not uncommonly, their bed partners as well.

Restless legs syndrome (RLS) involves complex movements in the lower limbs to relieve the unpleasant local dysaesthesia (usually a deep-seated sensation described as 'creeping, crawling', 'pins and needles', 'tearing' and even 'burning' or 'electric-current-like'), which usually take place at night, begin or worsen when the patient is restful and relaxed and are not better explained by another medical disorder[12,13,43,44]. Low awareness and misdiagnosis of RLS are very common[44], which add to already significant distress and impairment from sleep disruption. Differential diagnoses include neuropathy, arthritic conditions, or vascular insufficiency in lower limbs, and leg cramps; RLS is distinguished by its high circadian rhythmicity (peak symptoms from midnight to 3 a.m.) and absence of local signs related to the mentioned disorder. Akathisia from antipsychotics is another differential diagnosis; apart from the drug history, features of akathisia are less focal than RLS[44].

The patho-mechanism for primary RLS is largely unknown. Subnormal dopamine neurotransmission has been implicated. Currently the only FDA-approved medication for RLS is the dopamine agonist ropinirole[43] (although, in suitable cases, other dopamine agonists might be considered, according to the practice guidelines of the American Academy of Sleep Medicine[45]). Low ferritin levels in adult RLS patients have also been reported in a number of studies involving blood tests, neuroimaging and cerebrospinal fluid examination, although the relationship in older individuals appeared less consistent[43]. Secondary RLS has been recognized in uraemia and pregnancy[13]. Some argued that wandering behaviours in demented individuals might be related to unrecognized RLS[46]. Therefore, drugs used to treat neuropsychiatric symptoms of dementia (e.g. antipsychotics and some antidepressants) might potentially aggravate the condition.

A related condition is *periodic limb movements in sleep (PLMS)* which involves clusters of stereotyped, repeated, non-epileptiform leg jerks (typically involving dorsiflexion of the anterior tibilis muscle, although the movement might involve the hip, or be confined to the toe) taking place at 20–40 second intervals over the course of sleep, with each jerk causing a brief awakening that could be captured on PSG; a diagnosis is made when there are at least five kicks per hour of sleep[12,43]. The prevalence of PLMS in the elderly is estimated to be relatively high, at 45%[12]. It is found in 80–90% of patients with RLS, and is also very common in other primary sleep disorders[13,43].

PLMS usually occurs in NREM sleep[13]. Typically, the patient is unaware of the limb movement or the frequent arousals, and might not report sleep dissatisfaction. Usually no treatment is required in such cases. The ICSD criteria require PLMS features occurring in conjunction with clinical sleep disturbance and/or complaint of daytime fatigue for a diagnosis of *periodic limb movement disorder (PLMD)* to be made[13]. Drug treatment with dopamine agonists might also be considered in such cases[45], along with judicious elimination of drugs (serotonin-specific re-uptake inhibitors (SSRIs), antipsychotics etc.) that might worsen the condition in applicable cases[43].

An epidemiological study involving 18 980 adult subjects who were 15 to 100 years old (representative of the general population of five European countries) revealed that the prevalence of RLS, but not PLMD, significantly increased with age. The prevalence of ICSD-based diagnoses of PLMD in older age groups (60 or over) was 3–4% and that of RLS was 8–9%. Risk factors for both disorders include female sex, musculoskeletal disease, heart disease, SDB, cataplexy, intense physical activity close to bedtime and the presence of a mental disorder. Factors solely associated with RLS are advanced age, obesity, hypertension, drinking at least three alcoholic beverages per day, smoking more than 20 cigarettes per day and the use of SSRIs. Factors specific to PLMD include shift-work, coffee intake, use of hypnotics and the presence of stress[47].

SLEEP-RELATED BREATHING DISORDERS

Sleep-disordered breathing (SDB) is characterized by apnoeas (complete cessation of airflow lasting 10 seconds or more), hypopnoeas (reduction of airflow of 10 seconds or longer, accompanied by an oxygen saturation decreased by 3–4% or more) on sleep PSG[48]. The number of apnoeas and hypopnoeas per hour of sleep is called the *apnoea-hypopnoea index (AHI)*. Apnoeas and hypopnoeas during sleep leads to repeated arousals and hypoxaemia during sleep, and the *respiratory disturbance index (RDI)* refers to the number of apnoeas, hypopnoeas and the respiratory effort-related arousals per hour of sleep[49]. In general, an AHI from 5 to 19 is referred to as mild obstructive sleep apnoea (OSA), an AHI from 20 to 29 as moderate, and 30 and above as severe OSA. When the AHI is 5 or greater and coupled with excessive daytime sleepiness (EDS) the patient is considered to have the OSA syndrome (OSAS)[49].

Symptomatically, OSAS manifests as loud snoring and daytime somnolence; associated features include headache, insomnia, apnoea and excessive movements observed during sleep, and nocturia and dry mouth on waking. In addition to sleep fragmentation, patients show decreased SWS and SE on PSG[11]. Complications including elevated cardiovascular morbidities (hypertension, strokes, worsened cardiac functions) and mortalities, and cognitive impairments, especially in the domains of attention and vigilance, executive function, visuospatial learning and motor performance[49]. There are two main types of sleep apnoea: obstructive and central; the former is more common.

The prevalence of SDB rises with age: in middle-aged adults (aged 30–60), the figures for OSA (with AHI 5 or over) are 9% for females and 24% for males; and those for OSAS are 2% and 4%, respectively. In adults aged over 60, the prevalence of OSA is reported to be around 38–62%; there is also a stepwise increase in the prevalence of SDB with each decade of life in old age, which might be due to an increase in central events (readers can refer to Norman and Loredo, 2008[49] for a review).

It remains unresolved, however, as to whether the clinical significance of SDB in the elderly diminishes as compared to that in their younger counterparts. The association between SDB and body mass index (BMI) and reports of snoring also decrease with ageing[11,12]. Before further studies are available to cast light on the issue, elderly patients with symptomatic apnoeas or possible cardiovascular and cognitive complications should be treated as younger individuals would be treated. The mainstay of treatment is continuous positive airway pressure (CPAP) during sleep, which provides continuous air pressure, acting as a pneumatic splint to maintain patency of the upper airway. There is evidence that SDB complications might also reverse with this treatment[49]. General measures including weight reduction, and the avoidance of alcohol and sedative medications should also be undertaken.

Compliance to CPAP could be a problem. Alternative options include oral appliance therapy (in elderly persons with full or nearly full dentition), and an array of surgeries designed to improve airflow in the upper airway. There is, however, scant evidence to support the clinical efficacy of these two alternatives in older adults[49].

SLEEP DISTURBANCES IN DEMENTIA

Sleep disturbances are common in patients with dementia[12]; among patients with Alzheimer's disease (AD) in clinic- and community-based samples, the prevalence varies between 24 and 44%[50–52], and is a major cause of caregiver distress and institutionalization[12,53]. Characteristic changes include significant sleep fragmentation, reduced SWS and REM sleep, decreased SE and TST, reversal of circadian rhythm, EDS and daytime napping, and 'sundowning' (a nocturnal exacerbation of disruptive behaviour or agitation)[12,53]. Poor sleep in AD might, in turn, worsen cognitive function[53].

Causes of sleep disturbances in AD occur at multiple levels. Intrinsically, accelerated degeneration of the SCN and decreased pineal melatonin secretion might cause circadian rhythm disruptions. Degeneration of the cholinergic neurons in the nucleus basalis of Meynert and pedunculopontine tegmental and laterodorsal tegmental nuclei and noradrenergic neurons of the brainstem may account for decreased REM sleep in AD patients, and predispose them to RSBD[12,52–54]. Degeneration of the brainstem respiratory neurons and those in the supramedullary respiratory pathways may heighten risk for SDB in AD; in fact, the *APOE*4* genotype might be a predisposing factor for SDB in the general population[53].

Extrinsic factors might include reduced bright light, diminished daytime activities and increased noise in the environment, especially in group residential facilities. General medical conditions affecting the cardiovascular and respiratory systems and medications might also have negative effects on sleep; for example, cholinesterase inhibitors for dementia might cause vivid dreams and insomnia[12,52–54].

Treatment for sleep problems in dementia should likewise be multimodal. Techniques to counter circadian rhythm disturbances may include structured daytime social and physical activities, restriction of time in bed, and bright light, especially in the morning and evening[12,52–55]. Hypnotics and antipsychotics are often used, although they are more commonly associated with adverse effects like sedation, parkinsonism or orthostatic hypotension and, for a number of antipsychotics, an elevated risk for stroke[56]. Results from randomized controlled trials of melatonin are thus far conflicting[57]. On the other hand, proper identification and treatment of SDB and depression in AD might improve sleep quality and reduce agitation[53,58].

CONCLUSIONS AND FUTURE DIRECTIONS

The management of sleep disorders in the elderly is a major public health challenge, given the rapid growth of the older population in most nations, the high prevalence of sleep complaints and variety of sleep disorders in this phase of life, the plethora of co-morbid clinical conditions and environmental factors that are associated with insomnia in seniors, and their greater susceptibility to the side effects of sedative medications in general.

As reviewed in this chapter, current evidence suggests that insomnia is not an inevitable effect of physiological ageing and the corresponding changes in sleep architecture. Given the fact that sleep disturbances are common in the elderly and that many of the underlying causes are reversible, sleep assessment should be a habitual part of their comprehensive clinical evaluation, with the sleep symptoms compared against a carefully taken history of physical and psychiatric conditions, medications, sleep habits and activity schedules, lifestyle changes and residential conditions. Standard sleep questionnaires in indicated cases (e.g. the Pittsburgh Sleep Quality Index) might facilitate the multidimensional evaluation of sleep quality and disturbances. Investigations should be arranged to rule out co-morbid medical conditions, and sleep polysomnography is indicated for cases in which specific sleep disorders like RLS, SDB, or RSBD are suspected (readers can refer to Misra and Malow, 2008[59] for a review).

Future directions for sleep research on the elderly may include longitudinal outcome of insomnia and specific sleep disorders, and further elucidation of the roles of light therapy, enriched activity schedules, complementary medicine and other measures that might potentially enhance the quality of sleep.

Sexual Disorders

Walter Pierre Bouman

Mental Health Services for Older People, University Hospital, Nottingham, UK

INTRODUCTION

Sexuality is an essential part of any person and expressing it is a basic human need and right of all individuals, including older people. Although sexual functioning and frequency decrease with age[1–3], a significant proportion of older people remain sexually active well into advanced old age and many older people continue to enjoy their sex lives. In fact, several cross-sectional studies have shown that sexual satisfaction does not decline with age[4,5], and the role and value of sexual activity and intimacy remain important quality of life issues to older people[5,6].

Older people can experience sexual problems for all the same reasons as their younger counterparts. Sex research in older women and men emphasizes the widespread prevalence of sexual difficulties[7–9], which are strongly correlated with physical and mental health and with satisfaction in the intimate relationship[10–12].

Should a person or a couple wish to continue but experience sexual difficulties they deserve the same access to treatment as younger people. Furthermore, prevention of sexual difficulties in older people should be encouraged, including appropriate counselling before genital surgery[13], during chronic medical care and after acute medical events such as a myocardial infarction or cerebrovascular accident[14] and the provision of advice on safe sex practices.

HORMONAL CHANGES AND AGEING

In healthy men, testosterone production remains relatively stable until the fifth decade and then decreases slowly over the remainder of the man's life at a rate of about 1.0% per year[15]. It is probably mainly a result of testicular ageing, although a rise in sex hormone-binding globulin (SHBG) and testosterone-binding, a relative failure of the hypothalamo-pituitary axis to drive the testes, and a decline in the level of sensitivity of testosterone receptors in the brain also contribute. The decline in circulating testosterone occurring in older men is responsible for the decrease in desire, but not erectile function, although clinically it may be difficult to distinguish reliably between the two complaints[16].

In women, the most prominent biochemical markers of sexual maturation and senescence are the age-related changes in the level of oestrogen and testosterone. The structural integrity of the female genitalia is predominantly maintained by oestrogen. Vaginal dryness and atrophy, dyspareunia and urinary tract symptoms suggest a lack of oestrogen which is more prevalent following the menopause[17]. In healthy women testosterone levels decline markedly until the fourth decade with stable levels during the menopause transition. Testosterone levels then increase slowly over the rest of the life span[18].

AGE-RELATED CHANGES AND SEXUAL RESPONSE

Master and Johnson's[19] landmark research in the physiology of sexual responses have provided important information regarding sexuality and ageing, although their sample size was small. In both sexes, as one ages, the speed and intensity of the various vasocongestive responses to sexual stimulation tend to be reduced. In men all responses are slower and less intense from nipple and penile erection to rectal orgasmic contractions. An erection takes longer to develop and usually requires more direct tactile stimulation. The period of sustaining an erection gets shorter.

Ejaculation becomes less powerful with fewer contractions and seminal fluid volume is reduced. The point of ejaculatory inevitability becomes more difficult to recognize. Resolution following orgasm is rapid, with loss of erection occurring within seconds and the refractory period is markedly longer in comparison to younger men, sometimes extending to more than a day. In women the responses parallel those of the male. Increased time is required to become sexually aroused and vaginal lubrication is slower and less marked. Orgasms tend to be less intense and there is an increased need for stimulation to become orgasmic. There is no change in the ability to have orgasms, although multiple orgasms are less likely to occur. Resolution is more rapid.

Many older people are unaware of the normal age-related changes in sexual response that accompany ageing and are perplexed or put off by changes in their own or their partner's sexual response. If not appreciated, these changes are easily misinterpreted as sexual dysfunction. Explicit information about changes in sexual physiology with ageing can help eliminate false expectations and can permit modification in longstanding sexual practices that may have become counterproductive. Couples can be advised, for example, not to delay sexual exchange until late at night when tiredness or sleepiness may be great but, rather, to schedule their sexual encounters at a time of greater energy and alertness.

Similarly, increased manual or oral stimulation of the penis may be necessary to achieve an adequate erection for intercourse and may augment the effects of pharmacological therapy[20]. The female

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

partner is often unaware of this important physiological change in her partner, and may misattribute his lack of erection to sexual disinterest or her loss of sexual attractiveness to her partner[21].

Many older couples indicate they would enjoy greater sexual experimentation in their relationship, even though many have minimal experience of foreplay or non-intercourse forms of sexual stimulation[22]. While the overall decline of the sexual responses may seem gloomy and unpleasant, this process tends to develop extremely gradually, allowing an individual or a couple to adjust to a less intense, but not necessarily less enjoyable form of sexual activity.

EFFECTS OF ILLNESS AND MEDICATION ON SEXUALITY

One of the most frequent reasons given by older people for stopping sexual activity is the onset of illness; this may operate through a number of different mechanisms. Physical illness may generate unfounded anxieties about the risks of sexual activity (as in heart disease or stroke); it may make intercourse difficult, exhausting or painful (as in respiratory disease, arthritis and (sexually transmitted) infection); or it may impair responsiveness of the sexual organs (as in diabetes mellitus or peripheral vascular disease).

Illness may further undermine self-confidence and the feeling of attractiveness (as in mutilating operations such as mastectomy or colostomy), and it may have a direct effect in reducing sexual desire (as in depression, chronic renal or hepatic failure, and Parkinson's disease). Older people in general are more likely to suffer from a variety of chronic diseases which may impact on their sexual function[23]. They also commonly undergo surgery, which may influence sexual function, either because of psychological sequelae or as a result of organic damage[16].

If illness has reduced the capacity to respond to sexual stimulation, and this is something a couple cannot understand or discuss, then they cannot resolve this difficulty. In a relationship where the assumption was that the man always takes the active role in sexual exchange, his partner may be quite unused to stroking his penis as part of their preparation for intercourse, and may find it difficult to help him if this is what he requires. Similarly, if there is a transition from an equal partnership to one of caregiver and patient due to severe illness the latter may lose the self-esteem which reassures him that he is still contributing to the relationship; or the caring partner may think it unkind and selfish to make demands on the sexual responsiveness of the one who is ill. Particularly if there is a lack of communication around sexual issues, sexual relationship changes may never be adequately worked out. But even simple actions can have far-reaching effects, such as when a couple decide they should sleep apart so as to give the ill partner a better night's rest, resulting in a potential reduction of closeness and intimacy.

Furthermore, a substantial proportion of older people take medication, and often there is considerable polypharmacy. The list of drugs that can interfere with sexual function is extensive and the most widely prescribed drugs are mentioned[24,25] (Table 112.1).

Where drug-induced sexual dysfunction is suspected, discontinuing the suspected medication or substituting with a different agent can usually resolve the question.

Occasionally medication can enhance (or overstimulate) sexual function, which has been described with trazodone[26,27] and L-dopa[28].

Table 112.1 Drugs associated with sexual dysfunction[24,25]

Anticonvulsants
Antidepressants
Antihypertensives
Antipsychotics
Benzodiazepines
Chemotherapeutic agents
Digoxin
Diuretics
H_2 recepter blockers
Illegal substances ('street' drugs)
Lipid-lowering agents
Lithium
Opioids

SEXUAL PROBLEMS AND AGEING

Generally, the complaints in older people differ little from those of younger people who seek help for their sexual problems; they may have psychological or physical origins, or both. Fear of poor performance, lack of, or diminished sexual desire, difficulty becoming sexually aroused either physically or psychologically, difficulty maintaining an erection, difficulty achieving orgasm, and pain or discomfort with sexual activity, especially during intercourse, as well as a lack of opportunities for sexual encounters are among the most common of the complaints that older people present with[21,29,30].

Sexual dysfunction may also arise simply from a lack of information about the normal age-related changes in sexual physiology. A slower onset of erectile function, or a reduced need to ejaculate, may be interpreted by the man as the onset of impotence, or by the woman as a sign of declining interest in her; and their fearful or offended reactions may then aggravate the difficulty. Similarly, a reduced vaginal lubrication response may cause pain and discomfort during intercourse, leading the woman to avoid further sexual intimacy, which may be interpreted by the man as a rejection of the love he wants to express.

In addition to these problems, older people may mourn or regret changes in their body – its size, shape and firmness may differ significantly from the past. They may complain, as well, about the changing body of their partner, the reduction in, or loss of, passion and attention given to emotional and sexual intimacy, sexual boredom, jealousy of younger potential rivals and changes in sexual urgency or intensity. Menopause, surgery and various losses, both psychological and physical, can exacerbate these complaints.

Despite prevailing preconceptions, many older people are willing and open to address their sexual difficulties. Research suggests that if sex was a source of pleasure and gratification during early and middle adulthood, it will probably continue to be an important source of life satisfaction as one grows older[31]. On the other hand, it must be acknowledged that there remain many older people who grew up in fundamental and traditional households in which sexually proscriptive values and beliefs persist. For these individuals, sex is sanctioned primarily for procreation; sexual behaviours other than intercourse, such as oral–genital sex, are considered unnatural; sexual relations outside marriage are forbidden; and masturbation is sinful. For such individuals, the opportunity to 'retire' from an active sexual life may be ardently anticipated and easily accepted.

SEXUAL DISORDER IN OLDER MEN

Erectile Dysfunction

Erectile dysfunction is the persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate erection. It is the most common sexual disorder in older men and may be the first harbinger of cardiovascular disease[32]. The increase in the prevalence of erectile dysfunction in ageing men is well documented. The Massachusetts Male Aging Study surveyed 1290 men ranging in age from 40 to 70 years from the Boston area[28]. A definite relationship was found between age and the probability of erectile dysfunction, such that the probability of severe erectile dysfunction tripled from 5.1% to 15% in men between 40 and 70 years, and the probability of moderate erectile dysfunction doubled from 17% to 34%.

The oral phosphodiesterase type 5 (PDE5) inhibitors, which include sildenafil (Viagra), tadalafil (Cialis) and vardenafil (Levitra), have significantly improved the treatment of erectile dysfunction[33]. A concomitant essential part of first-line treatment for erectile dysfunction is the modification of risk factors, which include ischaemic heart disease, hypertension, diabetes mellitus, dyslipidaemia, depression, cigarette smoking, use of recreational or medically indicated drugs and alcohol misuse; this is vital in order to improve erectile function and the patient's response to treatment.

Despite the safety, efficacy and tolerability of PDE5 inhibitors, 30–35% of patients fail to respond[34]. Educating patients on the correct use of these drugs can increase efficacy[35]. Other treatment options include a vacuum constriction device[36], intracavernosal[37] and intraurethral[38] administration of alprostadil, psychosexual counselling, androgen replacement and penile prosthesis implantation. Despite the growing clinical evidence that combination treatment may be successful in men for whom monotherapy fails, research is lacking to establish the benefits, optimal dosage, possible adverse effects and acceptability to patients of these treatments.

Hypoactive Sexual Desire

Hypoactive sexual desire is described as a deficiency or absence of sexual fantasies and desire for sexual activity and can be caused by organic and psychosocial factors. It is considered a disorder if it causes significant distress or relationship problems. It is not an uncommon condition in older men although objective epidemiological data are lacking.

Schiavi[16] found a prevalence as high as 17% in a highly selected sample of 236 men with a mean age of 65.7 years although the vast majority also had a diagnosis of erectile dysfunction. As sexual desire is androgen-dependent its loss can be caused by deficient androgenic stimulation. This may result from decreased testosterone secretion or increased production of sex hormone-binding proteins, causing decreased circulating free testosterone. The diagnosis of hypogonadism in older men can be difficult where there is a discrepancy between symptoms and endocrine assay results[39], so specialist advice is usually required.

Any therapeutic trial of androgen treatment must be preceded by exclusion of prostate cancer. A common psychosocial cause for loss of sexual desire in a long-term relationship is habituation and routine[11]. Couples should be encouraged to bring variety into their sexual script to prevent or overcome this problem. Depression should also be considered as a cause for loss of sexual desire.

Ejaculation Disorders

Premature ejaculation can prompt an older man to seek treatment, but it is a rare presentation at this age compared to younger men[40]. It may have been a life-long problem with the man presenting for consultation when he finds himself in a new sexual relationship. Alternatively, and more commonly premature ejaculation occurs for the first time as a reflection of the man's feeling of erectile insecurity – he ejaculates quickly before he loses his erection. Treatment should then focus on improving erectile function. Rarely, the onset of premature ejaculation may result from neurological or prostatic disease, and clinical examination is therefore necessary.

In the absence of controlled research data, clinical experience suggests that cognitive behavioural approaches to premature ejaculation such as the stop–start and squeeze techniques[41] are usually ineffective in older men. Treatment with serotonergic antidepressants are highly effective[42], but side effects can be troublesome. Currently these drugs are not licensed to treat premature ejaculation.

More frequent than premature ejaculation is delayed or failed ejaculation, which troubles many older men. This may be a reflection of ageing but can also result from inadequate stimulation. Reduced force of ejaculation, a decrease in the volume of ejaculate and decreased ejaculatory sensation are common age-related effects. Regular pelvic floor exercises may improve ejaculatory sensation.

SEXUAL DISORDER IN OLDER WOMEN

Hypoactive Sexual Desire

Desire problems are the most common sexual problem of older women. A recent nationally representative probability sample of community-dwelling persons 57–85 years of age from households across the United States yielded a prevalence rate of 43%, closely followed by 39% of the sample complaining of arousal difficulties[3]. The majority of studies investigating sexual desire in this population report similar findings[43] – a reduction in sexual thoughts or fantasy as well as a reduction in sexual intercourse. As in men, the age-related decrease in sexual desire is caused by a variety of factors including the age, health, sexual desire and sexual problems of both the woman and her partner, relationship satisfaction, the woman's past level of sexual satisfaction, sexual comfort and sexual interest, medication affecting sexual response that either she or her partner is taking, and finally, the effects of the hormonal changes following the menopause. Although a reduction or lack of desire is common in older women, it does not signal the end of sexual pleasure.

Sexual Arousal Disorder

As with reduced (hypoactive) sexual desire, changes in sexual arousal are also caused by many factors in addition to the postmenopausal hormonal changes. More than a decade ago Goldstein *et al*.[44] showed that arousal difficulties in older women may be exacerbated or caused by atherosclerotic vascular disease, which results in delayed vaginal engorgement, diminished vaginal lubrication, pain or discomfort with intercourse, and decreased vaginal and clitoral sensations and orgasm. Since then the use of vasoactive drugs has been evaluated by many pharmaceutical companies as a means of enhancing sexual arousal in women, but to date no treatment has been approved.

Dyspareunia

Dyspareunia is described as recurrent or persistent pain associated with sexual intercourse. It is probably one of the most common sexual

complaints of older women seeking gynaecological consultation[45]. Pain that occurs in the absence of any infection or inflammation may indicate insufficient vaginal lubrication or incomplete arousal, so that the inner part of the vagina does not expand to make space for penetration. Lubricants and topical low-dose oestrogen treatment are available, if indicated. Alternatively, vulvodynia, which causes exquisite pain to the touch could be present, and this would require gynaecological assessment and possibly medication.

Orgasmic Difficulties

Some women experience changes in their orgasm with ageing, notably changes in the duration of orgasm, the ease and reliability of orgasm, and the number of uterine and vaginal contractions which accompany orgasm. Women who have lost their uterus and/or ovaries may have greater difficulty becoming sexually aroused and orgasmic because the uterus may contribute to arousal and orgasmic contractions. On the other hand the clitoris can be quite effective in providing erotic sensations and the ability to remain multi-orgasmic continues[21].

COMMON SEXUAL PROBLEMS IN COUPLES

A number of common sexual difficulties may come up during consultation which can be helped by relatively simple advice and education. They include (i) when to restart sexual intercourse after a myocardial infarction or cerebrovascular accident; (ii) identifying different positions and different timing for analgesic medication for intercourse when arthritis or pain is a problem; and (iii) how long to wait before resuming sexual activity and how much activity to attempt after surgery. It should be pointed out that weakness may hinder usual sexual activity and 'going slow' may be the optimum approach. Concrete examples, such as 'if you can walk a flight of stairs without shortness of breath, you can resume intercourse' may be helpful.

With patients or partners who have undergone mutilative surgery, mastectomy or ostomies, it is important to address fears of causing pain and the need to respond to fears of rejection because of drastic changes in body image. The healthy partner may be reluctant to discuss feelings of revulsion or contagion[46].

If intercourse is no longer a possibility, masturbation should be discussed as another source of self-pleasuring and as an appropriate activity to enhance individual or couple-pleasuring activities. Depending upon the individual's religious and cultural background, masturbation may not be perceived as an appropriate or comfortable option. If this is not the case, discussing the subject, and giving implicit permission, may be all that is needed to enable the couple to begin engaging in sexual exchange again.

CONCLUSION

What are the implications for clinical practice of this chapter? Physicians and other health care staff are generally known to feel embarrassed and to lack confidence in their ability to take an appropriate sexual history. This is particularly so when the patients' personal characteristics (such as their gender, age and sexual orientation) differ from their own[47]. This may especially disadvantage older people who are already assumed to be invisible and post sexual by society. Such people may be even less likely than most to approach health care staff with sexual problems and concerns, although research shows that most people hope that their physician will approach them[48].

Given that sex plays and increasingly important role in the lives of older women and men clinicians should ask – and be trained to ask – every patient, regardless of age, 'Are you experiencing any sexual problems or concerns?' The principles of taking a sexual history are not altered by the age of the patient[49]. Clinical competency in discussing sexual issues in an open and non-judgemental manner, and the level of training received in dealing with sexuality, is a major factor in determining how sexual problems present or whether they are presented at all.

One can only speculate on the number of patients who set out to seek advice for their sexual difficulty, but fail because of the discouraging response from the clinician involved. Although clinicians may feel awkward and unskilled, the very willingness to discuss sexual problems offers the patient an opportunity that society rarely provides. Physicians in particular are not only well placed to normalize and affirm the value of fulfilling sexual relations for the well-being of the older patient, but also have a responsibility to ensure that their sexual concerns and problems are appropriately and adequately addressed and managed.

Cultural Differences, Service Provision and Training in Old Age Psychiatry

Assessing Mental Health in Different Cultures

Rob Butler[1], Sati Sembhi[1] and Melanie Abas[2]

[2]*Institute of Psychiatry, Kings College London, London, UK*

INTRODUCTION

Assessing older people from different cultures requires a broad set of skills. Older people have acquired a wealth of life experience and knowledge. Clinicians need to understand how this and culture shapes their presentation and symptoms of mental disorders. Clinicians also need to be aware of their own cultural identity and to have some knowledge about customs and religions in different countries. Assessing older people includes asking about life history, social and family circumstances, and preferences for service delivery. This chapter offers an overview of how cultural competence can help with the clinical assessment. It includes some specific pointers for assessing depression, psychosis and dementia. It is worth noting that, due to a range of barriers, many older people from different cultures have poor access to psychiatric care and face a 'triple jeopardy' of disadvantage in terms of age, ethnicity and socioeconomic deprivation[1–3].

CULTURAL COMPETENCE

Culture is a network of knowledge, meanings, ideas and social rules shared by a group, often referred to as an ethnic group, who may also share geographical origins, religion and language. Culture will affect how illness is understood, the presentation of symptoms, and expectations regarding treatment and treatment choice[4]. The culture of the clinician will often differ to some extent from that of the patient[5]. The clinical setting in which treatment occurs has its own culture, which in turn influences the clinical relationship. Cultural competence means having an awareness of all three dimensions – that is, the culture of the older person, the culture of the clinician and the cultural setting – even when these are not obvious[4]. A culturally competent clinician can recognize the diversity of viewpoints, is willing to seek background cultural information from other members of the ethnic group or experts, and is flexible in approaching the doctor–patient relationship[4]. It should be appreciated that, in today's multicultural world, many people move between or within different cultures, and so it is important to avoid making assumptions about a patient's background which can lead to ethnic stereotyping[6]. Awareness of one's own culture and of potentially strong feelings about another's culture is important. Respectful enquiry and a desire to learn about other lifestyles is the only way to engage with a patient's lived experience of ethnicity and its role in determining what is important for them. One consequence of cultural differences is that occasionally a patient may interpret a well-intentioned enquiry as intrusive or stigmatizing[6]. The Explanatory Models Approach is a method of understanding symptoms without making cultural assumptions[6]. The following questions form the basis of a discussion which explores the patient's experience and perception of illness:

What do you call this problem?
What do you believe is the cause of this problem?
What course do you expect it to take? How serious is it?
What do you think this problem does inside your body?
How does it affect your body and your mind?
What do you fear most about this condition?
What do you fear most about the treatment?

ASSESSMENT

The patient should be asked early on about his or her background and, for migrants, his or her place of origin, experience of migration and existence in the new setting. The clinician will sometimes need to work hard to develop rapport and trust. Within reasonable professional boundaries, the clinician should be willing to respond to any questions about him or herself. For example, with older Jamaican migrants, making 'a connection' with the doctor has been found to facilitate the assessment and acceptance of care[7]. The power imbalance in the patient–doctor relationship may evoke feelings of mistrust, particularly when the patient has been subject to discrimination. The clinician should be willing to discuss issues such as racism and social needs. It is helpful to show sensitivity, but not to neglect important areas on 'cultural' grounds (e.g. alcohol consumption in the case of Muslims). Ideas that appear persecutory must be explored and may reflect an appropriate response to injustice. History-taking should include use of traditional medicines and complementary treatments. Enquiries about spirituality may reveal deeply held views which are important for the patient to follow as part of recovery. Attitudes to death, widowhood and care homes may vary considerably. Consultation may be needed with a wide circle of people from the relevant culture.

FAMILY AND CARERS

Assessment will naturally include family and carers' roles and needs. The levels of caregiver stress, burden and depression vary across cultures. The use of prayer, faith or religion may be used as a coping mechanism. There may be a difference between generations in adapting to a new culture, for example because of fewer opportunities for older people to learn a new language or make social contacts at work. This may exaggerate differences between generations. Many groups, including refugees, may not have family support in their adopted country.

COMMUNICATION

Requiring patients to speak in a non-native language can distort the clinical picture. Language barriers can be reduced by employing an ethnically close bilingual worker. Alternatively, you can use a competent interpreting and advocacy service, preferably with individuals with experience in the mental health field. Some local services and national bodies, such as the Royal College of Psychiatrists in the UK, keep lists of psychiatrists who can speak different languages.

Using interpreters is a skill, and training is available for the effective use of such services. Before they begin, the clinician and interpreter should discuss their expectations of each other and of how the interview should proceed. It should be confirmed whether the interpreter's role will be confined to translating or will extend to advising on non-verbal communication and cultural appropriateness. The clinician should be aware that even though an interpreter may be from the same country as the patient, differences in class, gender, religion, tribal group and so on may limit their ability to accurately interpret their culture. Idioms and jokes should be avoided. The patient should be addressed in the second person. Clear, concise language should be used and interpreters given manageable chunks to translate. Sometimes, word-for-word translation will be needed rather than the interpreter's summary. The interpreter should be able to give an indication of language use and structure to aid assessment of formal thought disorder. The assessment will be more time-consuming and tiring for the patient, possibly requiring more than one session. Misunderstandings and miscommunications may occur even with trained clinical interpreters, often because information is skewed to fit the interpreter's or clinician's viewpoint[8].

Aspects of non-verbal communication differ, such as avoidance of direct eye-to-eye contact in some Asian and Pacific cultures. Many cultures do not shake hands. There are differences in expression, gesticulation, speech patterns and communication styles. In some cultures, saying 'yes' may not indicate an affirmative response but be a mark of respect or deference to the doctor. There may be taboo subjects, such as the discussion of death in some Asian cultures.

CONFIDENTIALITY

In cultures with an individual focus, the expectation is that the patient is assessed alone and confidentiality between patient and clinician maintained. However, in cultures where the social group is more dominant, family members may expect to play a full role in the assessment, and have access to all information. Equally, the family might have strong views about topics they do not want disclosed to the older person. Taking the time to talk this through will usually help in finding a compromise. It is important to explain where the information you collect will be stored and who will have access to it. Third-party information should be identified in case the privacy of the informant is infringed.

ASSESSMENT TOOLS

Most screening instruments, assessment tools and diagnostic schedules have been developed within a certain cultural setting. This means that they may lack validity if applied without modification to people from different cultures. The clinician is likely to need more time and perhaps a wider set of informants to assess psychiatric history and symptoms, in order to ensure diagnostic accuracy. Some specific examples of instruments for depression, functional psychosis and dementia are given below. A research tool developed for use in one culture will likely need to be adapted and translated, and then undergo reassessment for reliability and validity, before being used in a different culture[9,10].

DIFFERENT PRESENTATIONS OF EMOTIONAL DISTRESS

People from all cultures experience both somatic and psychological symptoms when emotionally distressed. One reason for a more somatic presentation may be that this is considered a more appropriate focus for medical consultation by some cultures. Secondly, there may be a continuum of experience and interpretation, with the more 'somatizing' culture at one end and the more 'psychologizing' at the other[11]. Finally, a large number of 'somatic' complaints are actually metaphors for mental distress. Many of these relate to heart discomfort (e.g. a heart that is 'sinking' or 'uncomfortable') and to abdominal sensation[12]. Culture-bound syndromes often represent cultural explanations for recognizable mental disorders[13]. For example, dhat, a belief that semen is leaking from the body in urine, is a complaint in India. It may be a presenting feature, and is used as an explanation for weakness due to depression or organic disease.

DEPRESSION

There has been much debate about the existence of depression as a universal cross-cultural category[11]. However, it is reasonably well established that depressive disorders exist across cultures and are very strongly related to local constructs[12]. While there are similarities in the cross-cultural expression and experience of depression, there are also differences. For example, depressed older Jamaicans and African Americans may describe feeling 'low', 'bad' or 'fed-up'[7], or they may have multiple somatic symptoms, or they may present metaphors for psychological distress. Some cultures emphasize their explanation (e.g. social or spiritual) for their symptoms. Depression in old age may be more difficult to recognize because symptoms such as poor concentration or lack of interest can mimic dementia, and carers may perceive them as an inevitable part of ageing. The validity of screening scales may vary; for example, a lower cut-off point for the Geriatric Depression Scale has been recommended for older African Caribbeans[14]. The prevalence of depressive symptoms and probable depression in older people varies across Europe and appears not to simply reflect differences in age, gender, education or cognitive function[15]. Depression at community level also appears to be highly correlated with anxiety[16]. As a result, it is important to enquire about the *full* range of affective and other symptoms; and a wide definition of mood disorders is likely to be most useful in the clinical setting. Cultures vary in the acceptability of suicide,

ranging from a belief that it is an acceptable way to avoid dishonour to a belief that it is never acceptable and is always a sin. Islam forbids self-killing; the Muslim person who expresses the wish that God 'takes back' his life may be indicating he has suicidal thoughts which must be taken seriously.

PSYCHOSIS

Psychotic symptoms and signs are similar in form across a wide variety of settings[17]. However, the content of delusions and hallucinations will be influenced by culture. Also, the patient's and family's explanation for the illness will depend on their cultural framework[18]. For example, someone from Zambia who upholds traditional explanatory models may explain schizophrenia in the same way as they might explain a stroke, depression or a burglary – as being due to bewitchment or to having angered a spirit. An apparently unusual idea, such as believing oneself to be bewitched, is only a delusion if it is out of keeping with the beliefs of others in the same culture. This can be explored by asking someone with appropriate knowledge. If faced with the patient alone, the clinician should ask how he or she came to believe this, and if others close to him or her agree. If a traditional healer told him or her so, and his or her peers agree, then it is at least likely that this is a culturally sanctioned belief. Another error is to assume that a belief is culturally normal when it is actually abnormal.

DEMENTIA

The prevalence of dementia is increasing worldwide as populations grow and people live longer. New tools are being validated across countries[10,19]. However, dementia is frequently unrecognized or misunderstood, and some languages lack wording for such impairment. Diagnostic criteria for dementia require the demonstration of cognitive impairment of sufficient severity to interfere with activities of daily living. Cultures vary in the extent to which they expect older people to take responsibility for aspects of daily living, such as domestic activities. Also, physical impairment is more common in socially disadvantaged people and will be difficult to distinguish from that due to dementia, requiring greater emphasis on physical examination and tests. Many cognitive tests include items affected by education and may have little relevance in certain cultures (e.g. 'take 7 from 100'). Bilingual immigrants often lose their adopted language quicker than their native one, leading to a possible overestimation of impairment. When testing those unfamiliar with such approaches, the clinician should be courteous and encouraging without 'helping', and give explicit instructions and some dummy tasks to allay anxiety. Rather than doggedly adhering to the original version of instruments, it is appropriate either to make rational adaptations or to develop new instruments. Novel adaptations will, of course, require translation, back-translation and retesting[9]. The Community Screening Instrument for Dementia[9] combines culture-fair cognitive testing with a structured informant interview. Fully operationalized criteria appear to improve measurement of dementia in cross-cultural research[19].

CONCLUSION

Training in cultural psychiatry needs to form an integral part of mental health training for clinicians[20]. Rather than regarding the acquisition of cultural competence as useful only in rare and exotic situations, it should be seen as an extension of good clinical skills. In the UK, the Royal College of Psychiatrists has developed a Race Equality Action Plan that emphasizes the importance of cultural capability in core training and education[21]. Clinicians are keen to acquire skills in the assessment and delivery of care to people from different cultures, and they should receive regular training in cultural capability, awareness, appropriateness and sensitivity to improve their knowledge, skills and attitudes[22].

The Cross-Cultural Epidemiology of Mental Illness in Old Age

Martin Prince

Centre for Global Mental Health, Department of Health Service and Population Research, Institute of Psychiatry, King's College London, UK

BACKGROUND

Discussion of the mental health of 'older people' most often focuses on those aged 65 years and over – that is, above the most frequent, statutory retirement age in Western nations[1]. This is arbitrary and culture-specific, and for research in low- and middle-income countries (LMIC) the cut-point is often set at 60 years. According to the Global Burden of Disease report, neuropsychiatric disorders account for 13.5% of the global burden of disease, and 27.5% of that attributable to non-communicable diseases (NCD)[2], while for those aged 60 years the proportion is smaller – 7.4% of the global burden of disease and 8.3% of that arising from non communicable diseases. While the prevalence of dementia rises sharply in later life, doubling with every five-year increase of age, that of depression is, perhaps, a little lower than among younger adults. Many people with chronic severe psychosis do not survive into old age, and there is a small incidence of late-onset psychosis. However, mental ill health in later life poses particular challenges for public health. Health profiles among older people, particularly the oldest old, are somewhat distinct, with mental ill health often complicated by co-morbidity with chronic physical and cognitive disorders, a combination that is particularly strongly associated with disability and dependency. Beyond the challenges of living with chronic disease and disability, further obstacles to the maintenance of good mental health into late life include retirement (loss of occupational role, status and income) and a shrinking social network (loss of spouses, siblings and friends through bereavement)[1].

Older people, their health and social welfare, have for too long been under-prioritized in global public health policy. This is now changing with increasing recognition, over the past 20 years, of their growing importance in LMIC[3]. Demographic ageing is proceeding more rapidly than first anticipated in all world regions, particularly China, India and Latin America[4]. The proportion of older people increases as mortality falls and life expectancy increases. Population growth slows as fertility declines to replacement levels. In the 30 years up to 2020 the oldest sector of the population will have increased by 200% in LMIC as compared to 68% in the developed world[5]. By 2020, two-thirds of all those over 60 will be living in LMIC[6], where, in the accompanying health transition, non-communicable diseases assume a progressively greater significance. NCDs are already the leading cause of death in all world regions apart from sub-Saharan Africa. Of the 35 million deaths in 2005 from NCDs, 80% will have been in LMIC[7]. This is partly because most of the world's older people live in these regions. However, changing lifestyles and patterns of risk exposure also contribute. Among the NCDs, dementia and depression in older people have only fairly recently begun to be given the attention that they deserve in population-based research in LMIC. The purpose of this chapter is to describe the contribution of this research to our understanding of the epidemiology of these disorders, to contextualize these findings with what has been observed in high-income countries (HIC), and to describe some of the methodological challenges to be overcome in conducting this research in varied cultural settings.

DEPRESSION IN LATE-LIFE

'Depression', as a diagnosis applied in clinical settings, generally requires persistent and pervasive low mood and/or loss of pleasure, accompanied by other characteristic symptoms (including guilt, sleep and appetite disturbance), sufficient to cause significant distress and disability[8]. However, mood states do not fall naturally into discrete categories, but instead represent a spectrum from normality through increasing degrees of morbidity. As with any 'cut-off' applied to an underlying continuum (e.g. hypertension), the prevalence of the disorder depends substantially on the threshold that is selected. Severe depressive disorders have a high individual impact on those affected, but are rare. Milder syndromes have a lower individual impact but, given their higher prevalence, may have a substantially greater public health impact.

The Cross-Cultural Validity of the Assessment and Diagnosis of Late-Life Depression

There is reasonably strong evidence to support the cross-cultural validity of measurement of depression among older people. This has been most extensively studied with respect to the 12-item EURO-D depression symptom scale, which has been shown to have a similar factor structure in 14 European sites[9], as well as in India, China and Latin America[10]. Measurement invariance was later formally

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

established for the EURO-D across 10 European countries in the SHARE study, using confirmatory factor analysis to confirm a common factor structure and Mokken analysis to confirm a common hierarchical relationship between items[11]. The subsequent demonstration of higher levels of EURO-D depression symptoms among older people in three countries sharing a 'Latin' ethno-lingual heritage; France, Spain and Italy; after standardizing for age, sex, education and cognitive function suggested a possible role of culture in determining risk[12]. In terms of clinical diagnostic assessments of depression, the strongest evidence for cross-cultural validity exists for the Geriatric Mental State and its AGECAT algorithm, probably the most widely used such assessment internationally[13]. The instrument has been validated against most major diagnostic systems, but primarily only in HIC settings[13]. As part of the 10/66 Dementia Research Group's pilot studies in 26 centres in Latin America, India, China, Nigeria and Russia, its Stage 1 AGECAT depression algorithm was found to have sensitivity varying between 89% and 100% by region against a criterion of MADRS score of 18[10]. Specificity was difficult to establish, since depression was not formally excluded from the control groups, whose main purpose was to validate the dementia component of the algorithm. Nevertheless, the prevalence of AGECAT depression was negligible in these groups other than in Latin American sites[10]. The AGECAT depression algorithm was subsequently validated in Hefei City, China, where there was a diagnostic agreement of 83.6% and a Kappa of 0.67 against Chinese psychiatrists' independent gold standard diagnostic evaluation[14].

In the absence of qualitative research demonstrating the ecological validity of late-life depression as a pathological construct, the evidence for the cross-cultural validity of the commonly used ICD-10 and DSM-IV clinical diagnostic criteria among older people in LMIC is limited mainly to concurrent validation, that is from observations of cross-sectional associations with disability and impaired quality of life. In Nigeria[15] and Brazil[16], depression diagnosed was associated with high levels of social disability and impaired quality of life. In Mexico, Peru and Venezuela, high levels of disability were also identified in those with sub-syndromal depression identified with the EURO-D scale, suggesting a considerable prevalence (an additional 23–24%) of clinically significant disorder beyond the established diagnostic boundaries[17]. More research is needed to determine if these findings are typical of less developed regions in general.

The Prevalence of Late-Life Depression

The prevalence of late-life depression has been extensively studied in developed countries in the European, North America and Asia Pacific regions[18,19]. The main influence on prevalence is the criterion used to make the diagnosis[20]. According to rigorous research diagnostic criteria such as the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)* major depression and the *International Classification of Diseases, Tenth Edition (ICD-10)* depressive episode late-life depression is uncommon with a weighted mean prevalence of only 1.8%; when all those with clinically relevant symptoms are included, the weighted mean prevalence rises to 13.3%[18]. The relative lack of epidemiological data from LMIC is particularly striking – in the two systematic reviews, all of the 34 publications covering the period 1989–96[18] and the 122 papers covering the period 1993–2004[19] described research carried out in high-income countries. Recently published prevalence studies from Nigeria, Brazil, Latin America and China have helped to redress this imbalance. Two publications report an exceptionally high prevalence of DSM-IV major depression in Nigeria (7.1%)[15] and of ICD-10 depressive episode in Brazil (19.2%)[16]. The 10/66 Dementia Research Group has also recently reported on the prevalence of ICD-10 and DSM-IV depression in three Latin American countries, Mexico, Peru and Venezuela, which in these settings was closer to that reported in HIC, the prevalence of DSM-IV depression varying between 1.3 and 2.8% and that of ICD-10 depression between 4.5 and 5.1%[17]. Conversely, the prevalence of GMS/AGECAT depression in Hefei City, China, was only 2.2%, roughly five times lower than in European studies using the same assessment and case definition[14]. The prevalence in a rural village in Anhui province was slightly higher, at 6.0%[21].

In the few studies in LMIC to have examined this issue, treatment of clinically significant depression seems to be severely suboptimal – in the 10/66 Latin American studies only 24.1% of those in urban Peru with a current ICD-10 depressive episode, 18.8% in rural Peru, 11.8% in urban Mexico, 4.4% in rural Mexico and 19.6% in Venezuela reported ever having received in-patient or out-patient treatment for depression[17]: In Nigeria, only 37% of lifetime cases had received any treatment[15].

Sociodemographic Correlates of Late-Life Depression

The few studies to have assessed prevalence of depressive disorders across the adult age range suggest an increase from young to mid-adult age groups, followed by a fall in prevalence for older people within a decade of the retirement age[22,23]. A striking trend in the opposite direction has been observed in Nigeria, the authors speculating that lack of social protection for older people may have contributed to their much higher prevalence of DSM-IV major depressive disorder.[15] Studies from HIC that have focused upon depressive symptoms and broader depressive syndromes also indicate either an increase in their frequency[24] or stability with increasing age[25]. The exclusion, in some diagnostic criteria, of symptoms thought to be attributable to bereavement and physical illness may account in part for the apparent lower prevalence of depressive disorders in older people. In European studies, the prevalence of late-life depression is consistently higher in women compared to men[12,24], but the gender difference tends to be smaller than that found in mid-life. In European studies, the effect of gender is consistently modified by marital status, with marriage being protective for men but associated with higher risk among women[24]. A higher prevalence of late-life depressive disorder among women is also a consistent finding in studies in LMIC, replicated in Brazil[16], Nigeria[15] and the 10/66 Dementia Research Group Latin American studies[17]. However, in the 10/66 studies the association with female gender was entirely confounded by socioeconomic status and physical impairment, both of which were more common in women – a similar finding was reported in the SABE studies in six Latin American cities, although depression in that study was defined by a cutpoint on the Geriatric Depression Scale rather than a clinical diagnosis[26].

There have been many reports from cross-sectional community surveys, from a variety of cultures, of associations between late-life depression and socioeconomic disadvantage, for example with respect to educational level, occupational social class and income[19]. These are highly correlated variables, and it is difficult to determine the effect of one independent of the others. Reverse causality is possible – those whose adult life has been scarred by depression may experience lifelong occupational and economic disadvantage. Findings from LMIC are currently inconsistent – suggestive trends in the

direction of an association between socioeconomic disadvantage and depression were observed, rather inconsistently, in the five sites in the three 10/66 Latin American countries[17]. Level of education seemed to be more relevant than income or wealth. Food insecurity was strongly associated with depression in Mexico, with non-significant trends in Peru and Venezuela. Depression in Hefei City, China was also positively associated with economic disadvantage[14]. Unusually, in Nigeria, an association was observed in the opposite direction, with the highest prevalence of depression among older people with the highest economic status[15].

The Aetiology of Late-Life Depression

To date there have been no prospective studies of potential aetiologic factors for late-life depression in LMIC. There have, however, been a large number of well-designed cohort studies carried out in Europe and North America, the findings from which have been subject to systematic review[19,27] and quantitative meta-analysis[27]. There is strong and fairly consistent evidence to support an increased risk for incident depression associated with female gender, disability, prior depression, bereavement and sleep disturbance. Disability is probably the most salient of these factors. Prospective studies in older adults have consistently indicated a very strong association between disability at baseline and the subsequent onset of depression[28–32]. In one of these studies[31] the population attributable fraction was as high as 0.69. In general, the level of disability associated with a health condition, rather than the nature of the pathology mediates the risk for depression[31,33,34]. Stroke may be an exception as some studies show persistence of associations with depression after adjustment for disability[35]. Three population-based studies have suggested an interaction between disability and social support, with the strongest effect of disability in those with the least social support[31,32,36]. However, there is also strong evidence for causal pathways leading from depression to the progression or emergence of disability[37,38]. Cross-sectional data from the 10/66 studies in Mexico, Peru and Venezuela also support a strong association between limiting physical impairments and depression, with a past history of depression being the other consistently observed association[17].

One of the more consistent findings from previous Western research is the apparent salience of contact with friends, in particular intimate, confiding relationships to mood and morale in older people. While older people typically receive instrumental support from spouses and relatives, they value friends for companionship and emotional support. In the longitudinal Gospel Oak study, no contact with friends was the only social support variable prospectively associated with the onset of depression[31]. The social environment for older people is affected by the ageing process. Social networks deteriorate with increasing age consequent upon bereavement. Social engagement, such as visiting friends, is impaired in those with disability. Women typically have more supportive and extensive networks of friends than men. Married older men cite their wife as their main confidant, whereas women more often cite a friend outside the home. There have been few such studies conducted in other cultural settings, but in a cross-sectional study in Cuba, social networks, mainly centred around children and extended families, were associated with fewer depressive symptoms in both older men and women[39].

DEMENTIA

Dementia is a syndrome due to disease of the brain, usually chronic and progressive, in which there is disturbance of multiple higher cortical functions, including memory, learning, orientation, language, comprehension and judgement. Diagnosis is on the basis of decline in cognitive function and independent living skills. There are many underlying causes. Alzheimer's disease, vascular dementia, dementia with Lewy bodies and frontotemporal dementia are the commonest. Mixed pathologies may be the norm. Studies in developed countries have consistently reported Alzheimer's disease (AD) to be more prevalent than vascular dementia (VaD)[40]. Early surveys from South-East and East Asian countries provided an exception with an equal distribution of AD and VaD[40]. More recent research suggests this situation has now reversed[41,42]. This may be due to increasing longevity and better physical health: AD, whose onset is in general later than VaD, increases as the number of very old people increases; while better physical health reduces the number of stroke sufferers and thus the number with VaD[41]. This change also affects the gender balance among dementia sufferers, increasing the number of females and reducing the number of males. Some rare causes of dementia (subdural haematoma, normal pressure hydrocephalus, hypercalcaemia and deficiencies of thyroid hormone, vitamin B12 and folic acid) may be treated effectively – these may, theoretically, be overrepresented in LMIC, but their contribution particularly in young onset cases has yet to be investigated.

The Validity of Dementia Diagnosis Across Cultures

The validity of the construct of dementia in less-developed settings is supported by three qualitative studies in India. The features of dementia were widely recognized, and named[43–45]. However, there was no awareness of dementia as an organic brain syndrome, or medical condition. Rather, it was perceived as a normal, anticipated part of ageing. The consequences are little help seeking from formal medical care services[44], no structured training on the recognition and management of dementia at any level of the health service, and no constituency to advocate for more responsive dementia care services[45]. Behavioural and psychological symptoms of dementia (BPSD) can lead to stigma and blame attaching to the carers as well as the person with dementia[46]. In India, likely causes were cited as 'neglect by family members, abuse, tension and lack of love'[44], and carers tended to misinterpret BPSD as deliberate misbehaviour[45].

The validity of methods used in cross-cultural research is fundamental to the success of the enterprise. Without this, informative cross-cultural comparisons are impossible. Many potential obstacles needed to be overcome[47]. Those with little or no education may appear to 'fail' on cognitive screening tests even in the absence of cognitive impairment or decline. The task may be unfamiliar to them, or the information requested irrelevant. Tasks involving literacy, numeracy or drawing are particularly problematic, but in practice any cognitive item for which the probability of a correct response is strongly influenced by education will tend to be biased. Culture, including language, may also influence the salience and feasibility of cognitive items, and their relative difficulty. Cultural influences, as we shall see, may also impact on the assessment of social or occupational disability, since the normal roles of older people may vary considerably between cultures.

The history of cross-cultural research in dementia is characterized by careful attention to the applicability and validity of the measures employed. In the 1990s, the National Institute of Aging funded US–Nigeria and US–India studies developed[48] or adapted[49,50] cognitive tests to render them suitable and normed for the cultural setting, and also developed culture-specific assessments of

functional impairment[51]. In the wake of these efforts, the 10/66 Dementia Research Group carried out pilot studies in 26 centres from 16 LAMIC in Latin America and the Caribbean, Africa, India, Russia, China and SE Asia, demonstrating the feasibility and validity of a one-phase culture and education-fair diagnostic protocol for population-based research[52]. The Geriatric Mental State (a structured clinical interview assessing dementia, depression and psychosis syndromes)[53], the Community Screening Instrument for Dementia (a cognitive test, and informant interview for evidence of intellectual and functional decline, used in the US–Nigeria study)[48] and the modified CERAD 10-word list-learning task (used in the US–India study) each independently predicted dementia diagnosis[49]. A probabilistic algorithm derived in one-half of the sample from all four of these elements performed better than any of them individually; applied to the other half of the sample it identified 94% of dementia cases with false positive rates of 15%, 3% and 6% in the depression, high education and low education groups[52]. This algorithm (the 10/66 Dementia Diagnosis) was 'education-fair' in that the false positive rate among those with low levels of education was low, and 'culture-fair' in that equivalent validity was established for a wide variety of countries, languages and cultures. It therefore provides a sound basis for dementia diagnosis in clinical and population-based research.

The prevalence of DSM-IV dementia was strikingly low in the US–Nigeria and US–India studies[54,55]. The validity of this criterion, developed in the USA, had not been established in LMIC settings. In the 10/66 Dementia Research Group studies, a computerized application of the DSM-IV criterion was devised and validated[56]. The relative concurrent and predictive validity of the two diagnostic approaches, 10/66 Dementia and DSM-IV dementia, could thus be compared. In the Cuban 10/66 population-based study, the 10/66 dementia diagnosis agreed better with Cuban clinician diagnoses than did the DSM-IV computerized algorithm, which missed many recent onset and mild cases[56]. An essential feature of the dementia syndrome is that it is a progressive neurodegenerative disorder; the principal rationale for an early diagnosis is that it alerts the person concerned and their family to the probability of future deterioration. The 10/66 Dementia Research Group confirmed the predictive validity of their diagnosis in the population-based study sample in Chennai, South India, identifying a high mortality rate, and greater cognitive and functional decline over three years among 10/66 dementia cases and those with cognitive impairment but no dementia[57]. There was also clear evidence of clinical progression and increasing needs for care among the large majority of 10/66 dementia cases. The strong predictive validity of the 10/66 dementia diagnosis was consistent with a lack of sensitivity of the DSM-IV criterion to mild to moderate cases, and, thus, with the notion that it may underestimate prevalence in less developed regions[57].

The Prevalence and Incidence of Dementia

Dementia is largely a disease of older persons; only 2% of cases are to be found in those aged under 65 years. After this the prevalence doubles with every five-year increment in age. The EURODEM meta-analysis of European population-based studies from the 1990s used data from 11 studies carried out in eight European countries[58]. Prevalence was consistent across sites; the pooled prevalence for males and females is shown in Table 114.1.

The annual incidence rates reported in the EURODEM meta-analysis[59] are roughly one-quarter of the point prevalence (Table 114.1), suggesting an average disease duration (from onset to death) of four years. Clinical studies have suggested a duration of five to seven years from diagnosis. A recent meta-analysis[60] of the age-specific incidence of all dementias was based on data from 23 published studies. The incidence of both dementia and AD rose exponentially up to 90 years, with no sign of levelling off. The incidence rates for VaD varied greatly from study to study, but the trend was also for an exponential rise with age. While there was no sex difference in dementia incidence, for the oldest old the incidence of AD was higher in women, and for the younger old the incidence of VaD was higher in men.

Table 114.1 EURODEM meta-analysis of European population-based studies: pooled prevalence for males and females

	Annual incidence per 100 (68)		*Prevalence (%) (67)*	
	Males	*Females*	*Males*	*Females*
Age groups				
60–64	0.2	0.2	0.4	0.4
65–69	0.2	0.3	1.6	1.0
70–74	0.6	0.5	2.9	3.1
75–79	1.4	1.8	5.6	6.0
80–84	2.8	3.4	11.0	12.6
85–89	3.9	5.4	12.8	20.2
90+	4.0	8.2	22.1	30.8

In LMIC there is more uncertainty as to the frequency of dementia, with few studies and widely varying estimates[47]. Early onset cases are again rare, although this may be changing in those world regions where HIV/AIDS is endemic. In 2004, Alzheimer's Disease International convened a panel of international experts to review the global evidence on the prevalence of dementia, and to estimate the prevalence of dementia in each world region, the current numbers of people affected, and the projected increases over time (Lancet/ADI estimates). A tendency previously noted for age-specific prevalence to be lower in LMIC than in the developed north[47,54,55] was supported by the consensus judgement of the expert panel[61]. Differences in survival could only be part of the explanation, as estimates of incidence in some studies[62,63] were also much lower than those reported in the West. Differences in levels of exposure to environmental risk factors may also have contributed, with low levels of cardiovascular risk[64] and hypolipidaemia[65,66] in some developing countries suggested as explanations. Other potential risk exposures will be more prevalent in LMIC, for example anaemia associated with AD in rural India[67]. High infant mortality may contribute to population differences in dementia frequency; constitutional and genetic factors that confer survival advantage in early years may protect against neurodegeneration or delay its clinical manifestations. It seems plausible that as patterns of morbidity and mortality converge with those of the developed West, then dementia prevalence in LMIC will do likewise[68]. While studies of secular trends in Sweden, 1947 to 1952[69] and in the US, 1975 to 1980[70], suggested no change in the prevalence of dementia over time, it is possible that age-specific prevalence of dementia in HIC might fall in the future because of reduced incidence linked to improvements in cardiovascular health or rise, due to reduction in mortality among those with dementia.

However, the Lancet/ADI estimates were described as 'provisional', given that prevalence data were lacking in many world regions, and patchy in others, with few studies and widely varying estimates[61]. Coverage was good in Europe, North America and

in developed Asia-Pacific countries: South Korea, Japan, Taiwan and Australia. Several studies have been published from India and China, but estimates were too few and/or too variable to provide a consistent overview for these huge countries. There was a particular dearth of published epidemiological studies in Latin America[71–73], Africa[54], Russia, the Middle East and Indonesia. Therefore, there was a strong reliance upon the consensus judgement of the international panel of experts for LMIC.

The 10/66 Dementia Research Group prevalence studies

The 10/66 Dementia Research Group subsequently completed its population-based surveys (2003–7) of dementia prevalence and impact in 12 sites in eight LMIC (India, China, Cuba, Dominican Republic, Brazil, Venezuela, Mexico and Peru)[74–79], with a second wave of surveys underway in Puerto Rico, Sri Lanka and South Africa. Cross-sectional comprehensive one-phase surveys were conducted of all residents aged 65 and over of geographically defined catchment areas in each site with a sample size of 2000–3000 in each country. The net result is a unique resource of directly comparable data on over 20 000 older adults from three continents. All studies used the same cross-culturally validated assessments (dementia diagnosis and subtypes, other mental and physical health, anthropometry, demographics, extensive non-communicable disease risk factor questionnaires, disability, health service utilization, care arrangements and caregiver strain). The prevalence of DSM-IV dementia varied widely, from less than 1% in the least developed sites (India and rural Peru) to 6.4% in Cuba[75]. 10/66 dementia prevalence was higher than that of DSM-IV dementia, and more consistent across sites, varying between 5.6% and 11.7%[75]. The discrepancy was explained by the observation that informants in the least developed sites, particularly India, were less likely to report cognitive decline and social impairment (an essential criterion for DSM-IV dementia diagnosis) even in the presence of objective memory impairment[75]. Levels of disability were similar for 10/66 dementia cases regardless of whether or not they were confirmed by the DSM-IV dementia algorithm[75]. After standardizing for age and sex, DSM-IV prevalence was similar in the urban Latin American sites to that in Europe, but in China the prevalence was only one-half, and in India and rural Latin America one-quarter or less of the European prevalence. The group concluded that the DSM-IV dementia criterion is likely to have underestimated dementia prevalence, particularly in regions with low awareness of this emerging public health problem. There are several possible explanations for the discrepancy between objective cognitive impairment and informant reports[75].

1. The high levels of instrumental support routinely provided to all older people may mean that objective cognitive impairment may be less likely to lead to noticeable impairment in the performance of normal social roles, particularly in the early stages of dementia. More attention may need to be given to developing culturally relevant assessments to detect the consequences of early intellectual decline.
2. A culture of respect to elders making it difficult for informants to disclose report decline (supported by the finding of lower informant report scores for heads of household and male participants[75]).
3. Low awareness of dementia may mean that decline is attributed to 'normal ageing'[44,45] and hence not worthy of mention given the implicit focus of the assessments upon abnormality.

The World Alzheimer Report – new estimates of global prevalence of dementia

Since the Lancet/ADI estimates were published, the global evidence base has expanded considerably. There have been new studies from Spain[80,81], Italy[82] and the USA[83]. The exciting development, however, has been an explosion of studies from LMIC, and other regions and groups previously underrepresented in the literature. These included 10/66 Dementia Research Group studies in Brazil, Cuba, Dominican Republic, Peru, Mexico, Venezuela, India and China[75,76], and further new prevalence studies from, Brazil[84], Peru[85], Cuba[86], Venezuela[87], China[88], Korea[89], India[90], Thailand[91], Australia (indigenous people[92]), Guam[93], Poland[94] and Turkey[95]. The leaders of the Lancet/ADI review were commissioned in 2008 to assist the World Health Organization in updating the Global Burden of Disease (GBD) estimates, by conducting fully systematic reviews of the prevalence and incidence of dementia, and associated mortality, in 21 GBD world regions. This provided an ideal opportunity to revisit the literature, and to assess the extent to which it was possible, in some or all regions, to summarize the evidence on the prevalence of dementia by quantitative meta-analysis of the available data, rather than relying on expert consensus. Findings from this exercise were published in Alzheimer's Disease International's World Alzheimer Report[96].

The systematic review identified 147 prevalence studies worldwide since 1980. A recent marked increase in the number of studies from LMIC was accompanied by a sharp decline in research in high income countries. In many of these countries, the evidence base is fast becoming out of date. When compared with the earlier Lancet/ADI consensus, after age standardization to the Western European population structure, the new estimates of dementia prevalence for all those aged 60 years and over were higher for three regions – Western Europe (7.29% vs. 5.92%), South Asia (5.65% vs. 3.40%) and Latin America (8.50% vs. 7.25%). Those for East Asia were lower (4.98% vs. 6.46%). However, in comparison with the much greater heterogeneity seen in the Lancet/ADI estimates, regional estimates had generally converged (Figure 114.1). While there was a four-fold variation in prevalence overall, from 2.07% (sub-Saharan Africa, West) to 8.50% (Latin America), most of the standardized prevalences lay in a band between 5% and 7%. The major source of variation was clearly the very low estimated prevalence for the four sub-Saharan African regions.

When regional prevalence estimates were applied to population estimates, it was calculated that there were 35.6 million people with dementia worldwide in 2010, the numbers nearly doubling every 20 years, to 65.7 million in 2030 and 115.4 million in 2050. These figures for global prevalence were approximately 10% higher than the earlier Lancet/ADI estimates. In 2010, 58% of all people with dementia worldwide lived in LMIC, rising to 71% by 2050. Proportionate increases over the next 20 years in the number of people with dementia will be much steeper in low- and middle- compared with high-income countries (see Figure 114.2). The World Alzheimer Report forecast a 40% increase in numbers in Europe, 63% in North America, 77% in the southern Latin American cone and 89% in the developed Asia-Pacific countries. These figures are to be compared with 117% growth in East Asia, 107% in South Asia, 134–146% in the rest of Latin America, and 125% in North Africa and the Middle East.

The Impact of Dementia

Worldwide, surprisingly few epidemiological studies of dementia have gone beyond reporting on prevalence, incidence and aetiology of dementia. The impact of dementia upon the individual, the family and society has been little studied. In the Global Burden of Disease report, dementia was accorded a higher disability weight than almost any other condition and contributed 11.2% of all years lived with disability among people aged 60 and over; more than stroke (9.5%), musculoskeletal disorders (8.9%), cardiovascular disease (5.0%) and all forms of cancer (2.4%). The global economic cost of dementia was recently estimated at US$317 billion, 77% attributable to HIC where costly long-term care services are widely available[97]. In HIC, as the disease progresses, formal sector care costs increase and institutionalization is the main cost driver. Informal (family) care is more important in resource poor countries, accounting for 56% of costs in LIC and 42% in MIC, compared with just 31% in HIC[97]. According to the 10/66 Dementia Research Group pilot study in 26 LMIC centres, levels of carer strain were as high as those typically seen in European studies. In addition, care giving in LMIC often leads to substantial economic disadvantage[98]. A high proportion of carers had to cut back on their paid work, and paid carers were also common[98]. Compensatory benefits for carers and disability pensions for people with dementia were practically non-existent[98,99].

The 10/66 Dementia Research studied the relative contribution of chronic physical, mental and cognitive disorders (common physical impairments, depression, dementia, hypertension, diabetes, heart disease, stroke, chronic obstructive pulmonary disease and arthritis) to disability, in the baseline phase of its population-based studies in Latin America, China and India[99]. Contrary to the Global Burden of Disease report, which cites blindness and deafness as the two leading contributors to years lived with disability among older people in LMIC, dementia made much the largest contribution to disability, with a median population attributable fraction of 25.5% (range across sites 19.3–43.5%). Other substantial contributors were limb impairment (11.7%, 5.6–34.0%), stroke (11.5%, 2–21.2%), arthritis (9.9%, 2.8–35.0%), depression (8.3%, 0.5–22.9%), eyesight (5.7%, 0–17.6%) and gastrointestinal impairments (5.1%, 0–23.2%). These findings suggest that chronic diseases of the brain and mind deserve greater prioritization. Aside from disability, they lead to dependency

and present stressful, complex long-term challenges to carers. Societal costs are enormous[97]. Evidence from population-based research on ageing and dementia from LMIC should help to stimulate a wider debate about older people's health and social care needs, and how they should be met[100].

The Aetiology of Dementia

Currently most of the evidence from population-based studies on the aetiology of dementia comes from HIC, since the few incidence studies conducted in LMIC gathered data on a very limited range of potential risk exposures at baseline[63,101].

Genetic and environmental factors

The rare early-onset form of AD is highly heritable, and single-gene mutations at one of three loci (beta amyloid precursor protein, presenilin1 and presenilin2) account for the majority of cases. Late-onset AD is a multi-factorial disorder. The apolipoprotein E (*apoE*) gene polymorphisms account for up to 50% of the population attributable fraction, the e4 allele being enriched among AD cases[102,103]. The association between APOE e4 and dementia has been observed in population-based[102,103] studies in India, China and Latin America. However, the association seems to be attenuated among those with African ancestry[104,105] and no association was observed among older Nigerians[106]. Modest concordance rates among monozygotic twins for dementia diagnosis suggest a substantial environmental influence[107]. Evidence from cross-sectional and case-control studies suggest associations between AD and limited education[108], and head injury[109,120], which, however, are only partly supported by prospective studies[111]. Depression is a risk factor in short-term prospective studies, but this may be because depression is an early presenting symptom, rather than depression being a cause of dementia[112].

Dementia, cardiovascular risk factors and cardiovascular disease

The health transition currently underway in many LMIC will see an epidemic of cardiovascular disease (CVD). Latin America exemplifies the third stage of health transition. As life expectancy improves, and high fat diets, cigarette smoking and sedentary lifestyles become more common, so CVDs have maximum public health salience – more so than in stage 2 regions (China and India) where risk exposure is not yet so elevated, and than in stage 4 regions (Europe) where public health measures have led to reduced exposure to cardiovascular risk factors (CVRF)[113]. This is a matter of concern with respect to dementia in LMIC, given that recent research from developed countries suggests that vascular disease predisposes to AD as well as to vascular dementia[114]. While there has been no research to date on associations with dementia in LMIC, the INTERHEART cross-national case-control study suggests that risk factors for coronary heart disease operate equivalently in all world regions, including Latin America and China[115]. Despite occasional negative findings from large prospective studies[116,117], the accumulated evidence from HIC for a causal role for CVRF and CVD in the aetiology of dementia and AD is very strong. In short[118–120] and longer latency[121,122] incidence studies, smoking increases the risk for Alzheimer's disease. Diabetes is also a risk factor[123], and in longer term cohort studies, midlife hypertension[124,125] and hypercholesterolemia[125] are associated with AD onset in later life. Aggregated cardiovascular risk indices incorporating hypertension, diabetes, hypercholesterolaemia and smoking incrementally increase risk for dementia incidence whether exposure is measured in midlife[121] or a few years before dementia onset[120]. Recent studies report associations between metabolic syndrome and incident cognitive decline[126], and insulin resistance and impaired executive function[127]. This has led to the hypothesis that atherosclerosis and AD are convergent disease processes[128], with some common pathophysiological and aetiological factors (APOE e4 polymorphism, hypercholesterolaemia, hypertension, hyperhomocysteinaemia, diabetes, metabolic syndrome, smoking, systemic inflammation, increased fat intake and obesity).

Nutritional factors

In LMIC, dietary deficiencies, particularly of micronutrients, are widespread and strongly linked to poverty. Deficiencies of folate and vitamin B_{12} are of particular interest given their consequences; anaemia, neuropathy, hyperhomocysteinaemia[129], increased risk of stroke and IHD[130]. Vitamin B_{12} deficiency is strikingly prevalent (>40%) across Latin America[131–133], linked to gastrointestinal infections and diets deficient in meat and dairy produce[131]. Folate deficiency is endemic in those living in poverty[132], and after economic crisis[133]. Diets deficient in legumes may have contributed. Micronutrient deficiency is probably more prevalent in the elderly but there are few data on this age group[131]. Research on micronutrients and dementia in developed countries has focused upon antioxidants[134] with less attention towards deficiencies in vitamin B_{12} and folate, which result in hyperhomocysteinaemia; only four small incidence studies[135–138], all underpowered and with inconsistent findings. Two out of three studies testing for an effect of folate were positive[135,136], in one case independent of homocysteine[135]. B_{12} was associated in only one out of four studies[136].

Iodine deficiency has also been a major public health problem in most Latin American countries[139]. Iodized salt is now generally available but iodine content is poorly regulated[139]. The prevalence of sub-clinical hypothyroidism was as high as 16.1% in post-menopausal Brazilian women[140]. Overt hypothyroidism is a potentially reversible cause of dementia. Sub-clinical hypothyroidism (raised TSH levels with normal T4) is more prevalent, affecting up to 20% of older people in developed countries. It is associated with elevated total cholesterol and progression to overt hypothyroid disease, possibly also CVD[141]. It was strongly associated with risk for dementia in one cross-sectional study[142]. Conversely, a small incidence study reported a strong association with sub-clinical hyperthyroidism (low TSH)[143].

Opportunities for prevention

Currently, efforts to prevent and control the coming epidemic of cardiovascular and other chronic non-communicable diseases in LMIC are in their infancy[144]. Advocated measures include the implementation of tobacco-free policies, taxation of tobacco products, comprehensive bans on advertising of tobacco products, salt reduction through voluntary agreements with the food industry, and combination drug therapy for individuals at high risk of CVD[144]. The detection and control of hypertension, hyperlipidaemia, diabetes and metabolic syndrome is poorly implemented by overstretched primary

care services that struggle to cope with the double burden of historic priorities (maternal, child and communicable diseases) and the rising tide of chronic disease in adults. Health systems are not trained, equipped or structured to deal with the latter. Given the strong evidence for CVD and CVRF as risk factors for dementia, the success or otherwise of these initiatives should in principle have an important effect on the future prevalence and incidence of dementia in LMIC[61]. Against this, is the disappointing evidence from prevention trials. One trial of antihypertensive agents has reported a protective effect on dementia[145], but four others did not find effects on cognitive function in primary analyses[146–149]. Three large trials of cholesterol lowering agents have also failed to find effects on cognitive function[150,151]. A randomized controlled trial of HRT in post-menopausal women indicated, against expectation, that women randomized to HRT had nearly double the risk of going on to develop dementia in the short follow-up period[152].

CONCLUSION
