Major advances have been made in our understanding of the cross-cultural validity of measurement and diagnosis of late-life depression and dementia. The prevalence of late-life depression meeting clinical diagnostic criteria has been found to be higher than the norm for developed Western countries in some but not all LMIC studies. Depression is consistently associated with high levels of disability and is considerably undertreated. Early indications are that patterns of risk association also seem to be somewhat different. With a large recent growth in the evidence base, the prevalence of dementia among older people living in LMIC, originally reported to be much lower than that in HIC, now seems to be quite similar worldwide. The possible exception is Sub-Saharan Africa, but the low prevalence of dementia seen in the one good quality study yet to have been conducted in that region[54] needs to be confirmed by more research. Possible similarities or differences in the risk factor profile for dementia across cultures, and between HIC and LMIC have attracted much attention[105], but very little is known due to the lack of informative incidence studies in LMIC. The incidence phase of the 10/66 Dementia Research group's population-based studies in Latin America and China, due to be completed in 2010, will go some of the way to redressing this imbalance[74]. Aside from prevention of disease and promotion of healthy functioning, there is an urgent need to strengthen the ability of community health services to deliver evidence-based mental health care for older people. This should be done in an integrated way, within an overarching chronic disease management framework. More research is needed, into the epidemiology of late-life mental disorder (particularly their aetiology), into the effectiveness of high-risk prevention strategies for late-life depression and interventions for depression and dementia[153].

Mental Illness in the Elderly in South Asia

Vikram Patel[1] and K. S. Shaji[2]

[2]*Government Medical College, Thrissur, Kerala, India*

South Asia will house over 100 million older people by 2020[1]. This chapter describes mental health problems that affect elders, focusing on the two commonest conditions: dementia and depression. The chapter will first review the epidemiology of these disorders and then consider the implications for care and policies in the region. While the scope of our chapter is intended to address the entire South Asian region, we note that as most of the research on mental illness in the elderly has been carried out in India, much of our discussion will pertain specifically to India.

DEMENTIA

Prevalence studies from the region have indicated a lower prevalence of dementia when compared to developed countries. However, there are wide variations in reported rates, ranging from 1.4% to 4.4%[2–7]. One study reported an incidence of Alzheimer's disease (AD) of 3.24 per 1000 person-years for those aged 65 years[8]. Dementia incidence is predicted to increase in the developing world in tandem with the ageing population and the increasing burden of vascular risk factors[9]. It is estimated that there are already about 1.5 million people with dementia in India and this number is likely to increase dramatically in the next four decades[1]. The major causes of dementia in the region are AD and vascular dementia. One study from Kerala reported that vascular dementia was more common than AD in a rural community sample[6]. A cross-national study compared *APOE*4* –AD epidemiological associations in India and the United States. Frequency of *APOE*4* was significantly lower ($p < 0.001$) in India. Correspondingly, the frequency of probable or possible AD was also lower in the Indian samples[10]. However, although there was a very low prevalence of AD in the Indian sample, the association of *APOE*4* with AD was of similar strength in Indian and US samples.

A challenge for the diagnosis of dementia, which relies heavily on interview-based examination, is the cultural and educational factors such as illiteracy. Several efforts have been made to improve the detection and diagnosis of dementia in this context. Screening questionnaires such as the Mini-Mental State Examination have been translated and validated for use in a North Indian population[11]. A scale for activities of daily living has also been developed by the same investigators[12]. In an epidemiological survey with a largely illiterate sample of 5126 individuals aged 55 and older in the rural community of Ballabgarh in northern India, the Hindi version of the MMSE, a neuropsychological battery, and the Everyday Abilities Scale for India (EASI) had sensitivities of 81.3%, 81.3% and 62.5%, respectively, with specificities of 60.2%, 74.5% and 89.7%, respectively. The combination of all three was 93.8% sensitive and 41.8% specific[13]. An advantage of the EASI was that it could also be administered to informants of subjects who were cognitively not testable. In this largely illiterate community, with a low prevalence of dementia, the combination of cognitive tests and a functional ability questionnaire had substantial value for population screening.

The 10/66 Dementia Research Group interviewed 2885 persons aged 60 and over in 25 centres, including several in India, China and South East Asia. The sample included 729 people with dementia, and three groups free of dementia; 702 with depression, 694 normals with high education and 760 normals with low education. Experienced local clinicians diagnosed dementia and depression. The Geriatric Mental State, the Community Screening Instrument for Dementia and the modified CERAD 10 word list-learning task were then administered by an interviewer, masked to case status. Each measure independently predicted dementia diagnosis. An algorithm derived from all three performed better than any individually and identified 94% of dementia cases with false positive rates of 15%, 3% and 6% in the depression, high education and low education groups. The algorithm developed and tested in this study provides a sound basis for culture and education-fair dementia diagnosis in clinical and population-based research in India[14].

Dementia remains a largely hidden problem in India. People do not differentiate between normal ageing and phenomena that are secondary to conditions like dementia[15]. Even when it is identified, it does not lead to caregivers receiving practical advice or longer-term support[16]. Given the low awareness about mental disorders in elders, there is a need to develop culturally sensitive methods for identification of probable cases. Shaji *et al*. have described a simple, cost-effective method of training community health workers to identify dementia in Kerala[17]. After two and a half hours of formal training, local community health workers in rural Kerala were asked to identify possible cases of dementia from the community they served. Diagnoses were then verified by a senior local psychiatrist with clinical and research interests in old age psychiatry. This method was found to have a positive predictive value of 64.7%. Later in this chapter, we will review the evidence on the burden of dementia, services for people with dementia, and innovative new strategies for addressing the needs of families affected by dementia.

DEPRESSION

There are a growing number of epidemiological studies of depression or common mental disorders (a broad diagnostic term which encompasses mood and anxiety disorders) in elders in the region, which have sampled general populations and clinical populations. Prevalence rates vary even more widely than those for dementia: rates in a community sample of elders vary from 6% in South India[18] to over 50% in rural West Bengal[19]. Median prevalence rates tend to be higher in clinical populations[20–23]. One of the largest recent population-based studies was carried out with 1000 participants aged over 65 years from Kaniyambadi block, Vellore, India[24]. The prevalence of depression (ICD-10) within the previous one month was 12.7% (95% CI 10.64–14.76%).

The common presenting complaints are tiredness, sleep complaints, aches, tingling numbness in the hands, and palpitations[25]. The hallmark cognitive feature is anhedonia or loss of interest. Suicidal feelings and agitation are also common[18]. The suicide rate is nearly twice as high in the 50+ age group (12/100 000) as compared to the national average (7/100 000). Co-morbidity with physical ill health is common; by some estimates, more than 90% of elders with a psychiatric disorder also have some physical disorder[18]. Risk factors for depression include female gender, low education, poverty, social isolation, chronic diseases such as diabetes, and family discord[20,21,23–26]. Nuclear family structures, in particular, appear to be associated with a higher risk[20]. The latter is on the rise as a result of the breakdown of traditional community structures as a result of the massive migration of younger productive members of families to urban areas and reduced economic activity in rural areas[15]. Older women face a triple jeopardy: that of being old, of being women, and of being poor. Elders living in rural areas may represent another risk group because rural areas lack resources, and with agriculture being the main occupation, there is neither income security nor any systematic provision for old age[27]. One outcome study was carried out with a sample of patients attending psychiatry services of a tertiary care hospital in India. After 12 months, only 28% of patients had recovered. Factors predicting good outcomes were shorter duration of episode and living in a joint family system[28].

Help-seeking is not uncommon for somatic complaints associated with depression. However, the commonest treatments in primary care are symptomatic. Thus, benzodiazepines for insomnia and vitamins and 'tonics' for tiredness are among the commonest prescriptions for common mental disorders in general health care, while antidepressants or psychotherapy are rarely offered[29]. Detection rates are very low, but there is good evidence that short screening questionnaires can considerably improve detection rates in primary care[30]. One study evaluated the sensitivity and specificity of a two-question screen to identify depression and common mental disorders in the elderly, against the gold standard criterion of a structured diagnostic interview. The two-question screen has a sensitivity of 93.8% and specificity of 48.2%[31]. There are no specific treatment studies for older people with depression in the region, but it would be reasonable to expect that the considerable treatment evidence on the care of depression in general in developing countries would also apply to older people[32].

CARE ARRANGEMENTS FOR THE ELDERLY WITH MENTAL DISORDERS

Ancient Indian scriptures advocate the preparation for old age by adopting the disengagement theory. Respect towards elders and the concept of obligation towards parents forms part of the cultural value system[33]. In contemporary Indian society, however, the position and status of the elderly and the care and protection they traditionally enjoyed have been undermined by several factors. Urbanization, migration, the break-up of the joint family system, growing individualism, the change in the role of women from being full-time carers, and increased dependency status of the elderly are some of the prominent factors. There have been changes in terms of education, aspirations and values, and the allocation of resources to different members of the family. Often the family has been unable to meet the financial, social, psychological, medical, recreational and welfare needs of the elderly[27]. Care has often been conditional upon the child's expectation of inheriting the parent's property[15]. Care for those with dependency needs was almost entirely family based, with little or no formal services. Not surprisingly, fear for the future, and in particular 'dependency anxiety' was commonplace among older persons[15].

Formal care arrangements for elders, for example in the public health sector, are scarce. Indeed, geriatric medicine as a special area of health care is not available in most medical colleges or hospitals in the region. The number of residential places for elders with severe mental disorders such as dementia is very low and inequitably distributed. There are no accurate estimates for the treatment gap for dementia in India in general, but a rough estimate is that this gap exceeds 90% in most parts of the country, with the exception of urban areas and the two southern states of Kerala and Tamil Nadu[34]. Studies by the 10/66 Dementia Research Network in Goa and Chennai examined the impact of care giving for elders[35]. Carers of people with dementia spent a significantly longer time providing care than did carers and co-residents of depressed persons and controls. The highest proportion of time was spent in communicating, supervising, and helping with eating and toileting. Levels of carer strain were notably higher among carers of people with dementia. They were 16-times more likely to have a common mental disorder than carers or co-residents of controls, and twice as likely as carers or co-residents of people with depression. Economic strain was indicated by the high proportion of caregivers of people with dementia who had given up work to provide care, coupled with the increased likelihood that the family had to meet relatively high health care costs. This was explained by the increased propensity for people with dementia to use expensive private medical care services rather than free or low cost government services.

There are several major barriers to closing this treatment gap, including the low levels of awareness about dementia and depression as medical disorders; however, the most significant barrier is the very low human resource capacity for the care of people with mental disorders. This scarcity of resources is true for all mental disorders across the continuum of life and has been systematically documented in the recent *Lancet* series on Global Mental Health[36]. South Asia lacks the economic and human capital to achieve widespread coverage of specialist services; furthermore, specialist services tend to focus almost entirely on medical interventions, which have only a limited role in the long-term care of people with mental disorders, especially dementia. In view of the above, those responsible for service development for families of older people with mental disorders should keep in mind that the service should be home based, address the diverse medical and psychosocial health needs of the affected persons and their caregivers and be provided at a cost that the family can afford (and therefore use public and low-cost service providers).

Thus, the challenge for South Asia is to develop culturally appropriate interventions that can be delivered within existing resources, such as supporting families in their role as caregivers.

A randomized controlled trial has recently been completed in two *talukas* of Goa, evaluating the benefits of a low-cost, home-based intervention aimed at supporting families affected by dementia[37]. The intervention was delivered by a community team and each team comprised two full-time Home Care Advisors (HCAs), a part-time local psychiatrist from the public health services and a part-time lay counsellor. The minimum requirements for being a HCA were knowledge of the local language, being literate, preferably having passed higher secondary school, and being motivated to be involved in the community care of older people. The specific components of the intervention carried out by the HCA were: basic education about dementia; education about common behaviour problems and how they can be managed; support to the caregiver, for example for an elderly caregiver living alone with the patient, in activities of daily living; referral to psychiatrists or the family doctor when behaviour problems are severe and warrant medication intervention; networking of families to enable the formation of support groups; and advice regarding existing government schemes for elders. The HCA applied a flexible home-care programme tailored to the needs of the individual and the family. The HCA were supported, and supervised, by the two part-time specialists. The intervention demonstrated a significant impact in reducing the caregiver burden, mental stress and distress due to the behavioural and psychological symptoms of dementia.

It is important to note that mental illness is seldom an isolated event among elderly people; thus, co-morbidity with other mental illnesses and physical health problems is typically the rule[19,27]. The most common problems include deficits of vision and hearing, hypertension, diabetes mellitus, cardiovascular disorders and osteoarthritis. Thus, an ideal model of care for mental disorders in older people must fully address their physical health needs as well. There is a need to raise awareness about mental disorders in late life in the community and among health professionals, and to improve access to appropriate health care for the elderly with mental illness. Health education should aim to educate health workers and the community to recognize the common symptoms of mental disorders and, in particular, to stress that depression and dementia are real disorders and not just the natural consequences of ageing. Caregiver strain has not been acknowledged; instead, a near mythical strength is attributed to the abilities of families to cope. This distracts from the need for a rational debate regarding the future balance between informal family support and formal care services, and hinders evidence-based policymaking. We suggest prioritizing home-based support for elderly persons with dementia and their carers. Collaboration is required with non-governmental organizations (such as the Alzheimer's and Related Disorders Society of India) that are pioneering programmes to empower the elderly and support families with a mentally ill elder and provide health care sensitive to their needs. Working with the existing manpower and health and social service infrastructure is likely to be more successful in meeting the mental health needs of elders in South Asia than developing specialized psychogeriatric services throughout the country.

Dementia and Depression in Africa

Olusegun Baiyewu

Department of Psychiatry, College of Medicine, University of Ibadan, Ibadan, Nigeria

INTRODUCTION

In 2001 it was projected that about 7% of Africans would be aged 60 years and over in the year 2002[1]. Although the emphasis of health care in Africa is on preventable and communicable diseases in children and nursing mothers, as over 50% of the population is under 18 years of age, it has been estimated that the number of people aged 60 years and older in Africa will increase over the next few years. It thus becomes increasingly important that chronic illnesses associated with old age are considered. In this category are dementia and depression. In the last decade, a few studies have been carried out in Africa on dementia and depression; although the quantity of research on older person is small, significant advancements have been made.

Depression

One of the earliest community surveys on depression in the elderly in Africa was the study by Ben-Arie *et al*.[2], but since the 1990s there have been a number of research reports on old age depression in Africa[3–6]. These studies were done in various locations, rural, urban and a combination of both and the prevalence rates varied depending on the methodology. For example, studies in which screening questionnaires alone are used tend to have higher rates, in the range of 20%, while those that have second-stage clinical diagnosis have rates ranging from 5 to 8%. A theme that emerges in all studies is that populations with high levels of depression correlate with low levels of education and low income.

Some hospital-based studies have looked at depression and other psychiatric disorders in clinic attendees[7], and in patients admitted to non-psychiatric facilities[8,9]. In these groups, high level of medical co-morbidity is a regular finding, though relationship between medical co-morbidity and depression is not often established. Another issue is that depression is often not recognized and neither is it treated[5]. Interaction between depression and chronic medical illnesses, such as heart failure, stroke and cancer, need further research. Intervention and outcome studies are also lacking.

Dementia

The flagship of dementia research in Africa is the Indianapolis–Ibadan Dementia Research Project, which has been ongoing since 1992. This group has reported prevalence and incidence rates for dementia and Alzheimer's disease in Ibadan and Indianapolis and found that rates for both conditions were lower in Ibadan elders than in African Americans in Indianapolis[10,11]. One important issue in assessment of cognitive functioning is that many questionnaires used in Western countries need modification when used in developing countries as the elders often have low education levels and have been involved in low occupational pursuits all their life. For example the Mini Mental State Examination (MMSE)[12] has both a ceiling and a floor effect due to education. In contrast, a screening questionnaire like the Community Screening Interview for Dementia (CSI-'D')[13] has little education or culture effect and has been used in disparate populations. Another questionnaire developed by the group is Stick Design[14], which resolves the graphomotor function difficulties experienced by people with little education when asked to carry out a constructional praxis test.

In this group of studies risk factors for poor cognitive functioning identified include age and female gender, but the most important risk factor for Alzheimer's disease, apolipoprotein E_4, is not related to either dementia or Alzheimer's disease in Nigerians[15,16]. A similar report from East Africa also found that ApoE4 is not related to Alzheimer's disease[17].

A study from Egypt, however, reported a prevalence of 4.5% based on DSM-IV diagnosis[18]. This is close to the 5% often reported in Euro-American studies.

A study of mortality in the Indianapolis–Ibadan group showed increased mortality in Ibadan generally and a higher though non-significant rate in demented subjects when the two sites were compared[19]. While this might be a reflection of poor health delivery service to the residents of Ibadan, it is important to note that mortality associated with dementia is not significantly different. Studies on behavioural and psychological symptoms in dementia (BPSD) have shown that the pattern of presentation is probably not different from that observed in other regions of the world. BPSD is related to cognitive and functional impairment and in Western societies, BPSD is one of the most important reasons for nursing home placement. Even though nursing homes are unpopular in Africa, there is evidence that caregivers of demented subjects who have BPSD experience considerable distress[20]. A small study of nursing home residents indicated that about 48% of the residents had dementia and 17% depression[21], rates that are not too different from those reported in Western societies. Nursing homes, however, need further study.

There is some controversy about why prevalence of dementia reported in Africa and some developing countries is so low. One argument is that the elders in these countries are shielded from

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

activities of daily life in the multi-generational living arrangements they tend to have; it is possible that mild dementia may be missed[22]. While that is so, it is possible that prevalence of dementia may be truly different. Differential mortality rates may affect the prevalence of dementia. Elders in developing countries are generally likely to have shorter life spans because of the poor health care available; but factors such as the lower level of cholesterol and other cardiovascular risk factors may also affect the prevalence of dementia. In a community survey of elderly residents, cholesterol and triglycerides were higher in Indianapolis residents compared with those from Ibadan[23].

COGNITIVE IMPAIRMENT

The border area between normality and dementia is often referred to as mild cognitive impairment (MCI)[24] or cognitive impairment no dementia (CIND)[25]. People with MCI or CIND have a higher rate of conversion to dementia compared with normal individuals. Although they have problems associated with memory which is about 1.5 standard deviation below the norm, they have little or no functional impairment.

Little or no information is available on MCI or CIND in Africans. Baiyewu *et al*.[26] reported a lower rate of conversion to dementia in Nigerians and it has been noted that conversion to dementia or Alzheimer's disease is not related to the presence of ApoE4, as is observed in many studies in Western society.

TREATMENT

Health care delivery in Africa is generally poor, this is more so for the elderly. There are very few specialized care facilities for the elderly. Elderly persons find it difficult to use general adult clinics in hospitals unless they have knowledgeable relatives or caregivers ready to take care of their needs. The situation is worse for mental health. Gureje *et al*.[5] observed that many of the depressed elderly persons they studied in the community had never received treatment. Anti-dementia drugs are not available in many African countries. To the best of the knowledge of the present author there has been only one study in which patients from South Africa were included as part of a multicentre drug trial study on dementia covering five countries[27]. Despite this, Ferri *et al*.[28] have estimated a 82% increase in the number of people with dementia in Africa between the years 2001 and 2020.

It could be argued that there are also non-pharmacological treatment options for dementia, but even these are not available in many African countries. The goal for the future is to raise awareness of these problems among policy makers so that they can be addressed.

Dementia and Depression in China

Helen Chiu and Cindy Tam

The Chinese University of Hong Kong, Shantin, Hong Kong

According to data from the World Health Organization, 11% of China's 1.3 billion people were above the age of 60 in 2006. Life expectancy in China was 72 years for males and 75 years for females in 2006. The percentage of citizens over the age of 65 is projected to triple by 2050, from 8% of the population in 2006 to 24% in 2050, for a total of 322 million. China has 32 provinces and 2 special administrative regions (Hong Kong and Macau) and 56 ethnic groups. It has diverse geographic characteristics and demographic features, including dialects, customs and diet, which vary widely across the country.

DEMENTIA IN CHINA

Prevalence of Dementia

The number of people suffering from dementia in China was estimated to be 5 million in 2001, and it has been projected that there will be a more than 300% increase in this number by 2040[1].

Since 1980, a number of epidemiological surveys of dementia using standardized instruments and diagnostic criteria have been carried out. However, only a few of these studies have been published in international journals. Dementia prevalence estimates vary widely within China. This variation may be related to differences in population structure, genetics and lifestyle in the country's various regions, but it may also be due to different mortality rates of dementia and to methodological differences between studies. Chiu and Zhang reviewed 16 studies carried out between 1980 and 1999 and found the prevalence rates of dementia to range from 0.46% to 7.0%[2]. Dong *et al*. performed a meta-analysis of 25 Chinese studies that were conducted between 1980 and 2004 and comprised a total population of more than 76 000. They estimated that the overall prevalence of dementia in China was 2.8% in people aged 60 or above[3]. Alzheimer's disease and vascular dementia were found to be the most common types of dementia, with the prevalence rate of the former reported to be 1.6% and that of the latter to be 0.8%. Both reviews[2,3] found the rates of dementia, particularly that of Alzheimer's disease, to be lower than those reported in Western developed countries. In addition, Dong *et al*.[3] found that the prevalence of Alzheimer's disease increased significantly from 1980 to 2004, and reported that the gap in the prevalence of dementia between China and Western countries has been decreasing.

Several epidemiological surveys that examined the prevalence of dementia in different regions of China using larger samples were published in international journals between 2004 and 2008[4–8]. The initial screening for these surveys was usually performed using the Chinese version of the Mini-Mental State Examination, with diagnoses confirmed through neuropsychological assessment and clinical interviews. The results of some of these studies are presented in Table 117.1. A recent large-scale survey reported that the prevalence rates of Alzheimer's disease and vascular dementia were 3.5% and 1.1%, respectively. Greater prevalence of dementia was apparent in the northern regions compared with the south, but no difference was found between urban and rural Chinese residents[4,9]. The burden of Alzheimer's disease and vascular dementia was not distributed equally among all regions and sociodemographic groups. Significant north–south variation was observed for both Alzheimer's disease and vascular dementia, but was more pronounced for the latter than the former. In both crude and age-adjusted associations, the prevalence odds of vascular dementia were approximately double in northern areas relative to southern areas. He *et al*. reported that the northern cities of China have a threefold higher incidence of stroke compared to southern cities, a fact that may be associated with different exposures to such risk factors as hypertension, a diet high in salt, and heavy alcohol and cigarette consumption[10]. In addition to this north–south variation, Zhang *et al*. also observed an east–west difference in the prevalence of dementia. Western China is less developed than the east, and life expectancy is also lower in the former. Thus, the lower prevalence rate of dementia in the western part of China may reflect a higher case fatality rate following Alzheimer's disease onset in the younger age groups or fewer persons at risk of Alzheimer's disease surviving until the period of onset[9].

Incidence of Dementia

Studies on the incidence of dementia in China are scarce. Li *et al*. examined 1 090 elderly aged 60 or above in Beijing using the DSM-III criteria in a study that lasted from 1986 to 1989[11]. The annual incidence rate of dementia was 0.6%. A similar cohort study was conducted in the same urban district of Beijing from 1997 to 1999[6]. In this study, 1 593 elderly aged 60 or above were examined using the DSM-IV criteria. The annual incidence rate was 0.9%, which was

Rodriguez *et al*.[7]	Xicheng, Beijing Daxing	Urban Rural	1 160 1 002	≥65	DSM-IV dementia: 3.1 (urban) 2.0 (rural) 10/66 dementia: 8.0 (urban) 4.8 (rural)
Lam *et al*.[8]	Hong Kong	Urban	6 100	≥70	8.99 (mild dementia)

AD, Alzheimer's disease; VaD, vascular dementia.

significantly higher than that reported 10 years earlier. Zhang *et al*. examined 1 970 elderly aged 65 or above in Shanghai in 1987 and followed them up for five years[12]. They reported an annual dementia incidence rate of 1.15%. Qu *et al*. surveyed 2 197 elderly in Xi'an in 1998 and 2001[13]. The annual incidence rate of dementia was found to be 0.89% among the elderly aged 65 or above. Of particular interest is the common finding that the incidence rate of dementia was higher in the illiterate groups in these studies.

Treatment

Guidelines for the treatment of dementia have been published recently. These guidelines cover the pharmacological and non-pharmacological treatment of cognitive and neuropsychiatric symptoms in dementia. In a section on potential drug treatments, acetylcholinesterase inhibitors (AChEIs) and memantine are listed along with other drugs, such as antioxidants and vasodilators. In clinical practice, huperzine A is used much more often in the treatment of dementia in China than other AchEIs, such as donepezil or rivastigmine, as it is covered by the National Drug Catalogue (China) and is inexpensive. It is an alkaloid isolated from the Chinese herb *Huperzia serrata*, and it is a reversible inhibitor of acetylcholinesterase. Randomized controlled trials in China have reported huperzine A to have some success in improving general cognitive functioning for patients with Alzheimer's disease[14]. The other cholinesterase inhibitors and memantine are not consistently covered by the National Drug Catalogue.

The drugs used in the treatment of neuropsychiatric symptoms include AChEIs, antipsychotics, antidepressants, anxiolytics and mood stabilizing agents. The US Food and Drug Administration (FDA) warning of increased adverse cardiovascular events with the use of atypical antipsychotics in dementia is mentioned in the Chinese guidelines. Such non-pharmacological treatments as reminiscence therapy, validation therapy, reality orientation and behavioural modification are also recommended. These guidelines emphasize the comprehensive assessment of the needs of both patients and their caregivers, as well as a multidisciplinary management approach.

Although not mentioned in the national treatment guidelines for dementia, numerous Chinese medicinal formulations have long been used for the treatment of insomnia and memory deficits. Some of the herbs used in these formulations, such as *Ginkgo biloba* and the root of *Salvia miltiorrhiza* have been reported to exhibit cholinergic activities relevant to the treatment of Alzheimer's disease. In addition to these herbal agents, acupuncture has also been used in the treatment of dementia in China.

Access to Treatment

Zhang *et al*. found that about half of patients with dementia are classified as normally ageing and that only one fifth have adequate access to diagnostic assessment[9]. A low degree of public awareness, underdiagnosis and under-treatment are common hurdles to dementia care in China, which is similar to the case in other developing countries.

In general, patients with dementia are managed by traditional Chinese practitioners or primary care doctors, but their training may be inadequate. Those in urban areas may be managed by neurologists or psychiatrists, but there is no well-established referral system to specialist care yet in place. In Hong Kong, in contrast, psychogeriatric and geriatric services are well established, and these services play the main role in the medical care of patients with dementia.

Care of Dementia in China

The family has traditionally played a central role in support for the elderly in China. 'Filial piety' is a strongly held cultural norm that assumes that the care of older people with dementia will be provided primarily by the family. In recent years, however, the breakdown of the extended family, urbanization and the movement of young people to other cities for work have led to the weakening of family support for dementia sufferers. At the same time, community support and residential care facilities remain very limited in China and are particularly scarce in rural areas. All of these factors influence the pattern of care for dementia sufferers and create challenges for dementia care. In Hong Kong, in contrast, non-governmental organizations play a substantial role in providing community facilities and residential care for the elderly with dementia.

An organization called Alzheimer's Disease China was established in 2001 and is a member of Alzheimer's Disease International. In Hong Kong, the Alzheimer's Disease Association was set up in 1995, and the Hong Kong Psychogeriatric Association was established in 1998. Among their objectives are the facilitation of training, public awareness and advocacy for dementia.

DEPRESSION IN CHINA

Prevalence of Depression

Depression is one of the most common psychiatric disorders in the elderly population. Very few studies on the prevalence of this mood disorder have been carried out among the elderly in China. In 1999, Chen *et al*. conducted a meta-analysis of 10 epidemiological studies of the prevalence of geriatric depression in 13 565 subjects in China[15]. The pooled prevalence of depression was 3.86%, whereas that of depressive mood was 14.81%. The results reported in published Chinese studies vary, which may be due to methodological issues, non-standardized assessments and/or different definitions of depression.

The prevalence rates of geriatric depression in five recent epidemiological studies of major depression published in international journals from 2000 to 2008 are presented in Table 117.2. These studies adopted standardized instruments, and generally found lower rates than those reported in Western countries. The results of the Chinese studies can be interpreted in a number of ways. They may indicate a genuine rarity of depression. Indeed, some factors may protect the Chinese from depression, including such coping mechanisms as quiescence and stoicism, family and cultural support systems, and a traditional cultural belief in fatalism[21]. The lower prevalence rates may also be due to a lower level of reportage of depressive symptoms or the existence of 'depressive-equivalent' conditions. For instance, neurasthenia is a more generic label applied to wide-ranging symptoms, including somatic symptoms (such as insomnia, fatigue and dizziness), cognitive symptoms (such as poor memory and unpleasant thoughts) and emotional symptoms (such as excitability and nervousness), in addition to any depressive symptoms. Chinese patients and psychiatrists seem to prefer such a label to the psychiatric label of 'depression'[22]. Even in the 1990s, neurasthenia remained a more common diagnosis in Chinese patients than in other populations.

The elderly in rural areas seem more likely to suffer from depression than city dwellers[15,20]. The relatively lower socioeconomic status of the rural elderly, as well as a poorer health care system and fewer social activities compared to their urban counterparts may increase the risk[20].

Treatment of Depression

Of the subjects with geriatric depression interviewed by Ma *et al*., 25.2% received some type of treatment, with only 4.7% seeking treatment from mental health professionals[20]. This low rate of help-seeking behaviour may be explained by the following: (i) many Chinese people do not believe that depression is a treatable psychiatric disorder; (ii) stigmatization and discrimination prevent psychiatric patients from using mental health services in China; and (iii) the country offers inadequate access to community-based psychiatric services.

Treatment guidelines for depression have recently been published. Various types of antidepressants, including tricyclic antidepressants (TCA), selective serotonin re-uptake inhibitors (SSRI) and serotonin norepinephrine re-uptake inhibitors (SNRI), are available. The guidelines recommend the use of the newer antidepressants for geriatric depression, SSRI in particular, because they have less pronounced side effects and are safer for people with cardiovascular diseases. Modified electroconvulsive therapy was introduced to China only in recent years, and it is now recommended for the treatment of severe or treatment-resistant depression. Psychotherapy is briefly mentioned in these guidelines, but is not widely practised for depression. It is noteworthy that cognitive behavioural therapy training has only begun in recent years. Although not mentioned in the guidelines, acupuncture and traditional Chinese medicine have long been used to treat insomnia associated with depression.

ELDERLY SUICIDE IN CHINA

The suicide rate among the elderly is higher than that among the general population in China, which is similar to the pattern in many countries. What is unique in China is the fivefold difference between the urban and rural rates for suicide among the elderly[23]. The rates of suicide among elderly rural residents of China, particularly for women, are among the highest reported in any country. Between 1995 and 1999, the suicide rates of elderly rural and urban residents aged 60–84 were 82.8 and 16.7 per 100 000, respectively[23]. Wei *et al*.[24] studied 304 elderly suicides using psychological autopsy and found that 64.8% suffered from mental illness and 40.5% from depression. The most common method of suicide for this population is pesticide ingestion, followed by hanging[24]. Insecticides are readily available in rural areas, and emergency medical care in these areas is relatively limited. Moreover, the elderly in rural areas have limited access to health care in general and are offered little social and financial assistance. These factors may contribute to the higher suicide rates of the rural elderly compared with their urban counterparts. However, it is interesting to note that the prevalence of depression in older Chinese

Study	*Location*	*Sample/age*	*Diagnosis/instrument*	*Prevalence (%)*
Chen *et al*.[16]	Hefei (urban)	1 736 age ≥65	GMS-AGECAT	2.2 (point prevalence)
Chen *et al*.[17]	Yingshang (rural)	1 600 age ≥60	GMS-AGECAT	6.0 (point prevalence)
Lee *et al*.[18]	Beijing and Shanghai (urban)	547 age ≥65	DSM-IV/CIDI	2.6 (lifetime prevalence of major depressive disorder)
Lu *et al*.[19]	Kunming (urban and rural)	(5 033 age ≥15 in the survey)	DSM-IV/CIDI	3.63 for those aged ≥65 (lifetime prevalence of major depressive disorder) 2.09 (12-month prevalence)
Ma *et al*. (2008)[20]	Beijing (urban and rural)	1 601 age ≥60	DSM-IV/CIDI	7.83 (lifetime prevalence of major depressive disorder) 4.33 (12-month prevalence) 8.42 (12-month prevalence in rural sample) 2.55 (12-month prevalence in urban sample)

residents of rural areas remains low, although the suicide rate is high. The exact reason for this discrepancy remains unclear.

In the special administrative region of Hong Kong, the suicide rate is also relatively high among the elderly, at 50 per 100 000/year for those aged 75 or above. Chiu *et al*. investigated suicide among elderly Chinese in Hong Kong using psychological autopsy[25]. They found that 86% of those who had committed suicide had a psychiatric problem prior to doing so and that 53% had suffered from major depression, which is consistent with findings reported in Western countries.

CONCLUSION

Both dementia and depression are important and prevalent disorders in the elderly population. Although the reported prevalence rates of both syndromes are lower than those in Western countries, an enormous number of people are affected, given the sheer size of the population. As China's population is ageing rapidly, the country will face exponentially increasing demand for care for those elderly who suffer from these disorders. Mental health services for the elderly in China remain in the early stage of development. More epidemiological studies and clinical research are needed to guide the future development of such services and care.

Spirituality and Mental Illness in Old Age

Susan Mary Benbow[1] and David Jolley[2]

[2]*Personal Social Services Research Unit, Manchester University, Manchester, UK*

CONTEXT: SPIRITUALITY, FAITH AND RELIGION

Spirituality is an important concept and often regarded as intrinsic to mental health: the Health Education Authority includes it within its definition of mental health: 'the emotional and spiritual resilience which enables us to enjoy life and to survive pain, disappointment and sadness. It is a positive sense of well-being and an underlying belief in our own, and others', dignity and worth'[1].

Nevertheless spirituality is difficult to pin down, and its differentiation from (and relation to) religious faith is a matter of debate. The Church of England Archbishops' Council with the National Institute for Mental Health in England (NIMHE)[2] has defined it as: 'A quality that goes beyond religious affiliation: that strives for inspiration, reverence, awe, meaning and purpose, even in those who do not believe in God'. Thus spirituality can be independent of religious faith, or, as Paul Wilson[3] writes, 'Spirituality is the searching for the meaning of life. Religion is one way of conducting the search'. Much of the literature relates health to religious belief and practice rather than spirituality as such and only now are we beginning to tease out how spirituality and faith interact.

As a concept, spirituality is sometimes criticized as free-floating and nebulous, although it has gained acceptability and respectability in Western societies, where adherence to faith or religion is sometimes regarded with suspicion, or as primitive, old-fashioned or outdated. On a global level there is massive commitment to religious faiths[4,5]. Numbers of adherents to Islam continue to grow, and though there has been a decline in active belief and church going within the nominally Christian countries of the West, the number of Christians worldwide is sustained or growing[6]. Population movements mean that most countries are now home to communities of many faiths. Thus an understanding of the research evidence concerning the relationships between spirituality, religion and health is essential for health care practitioners. In addition, it is important to be aware of the influence of spiritual and religious beliefs on the perception and interpretation of symptoms by patients and their families. Beliefs will also modify views on the acceptability or appropriateness of interventions intended to be therapeutic.

Health is often divided into six dimensions: physical, mental, emotional, social, environmental and spiritual[7]. The first five are accepted routinely as significant in the understanding, aetiology and management of health/illness. Spirituality is the dimension that has been neglected in Western professional health care theory, research and practice during the twentieth century, with health care staff taking little account of patients' perspectives regarding their experience of health/illness. Recent years have seen a return to interest in alternative views of life and a corresponding increase in study and research in this area. At a basic biological level, George *et al*.[8] demonstrated an association between spiritual beliefs and enhanced immunity, while, within the realms of clinical psychiatry and behaviour, Strawbridge *et al*.[9] found that strong spiritual beliefs were associated with a reduced risk of suicide. The Royal College of Psychiatrists has established a Special Interest Group on spirituality[10]. The evidence is such that the National Institute for Health and Clinical Excellence's (NICE) guidance on the supportive and palliative care of adults with cancer[11] recommends provision of spiritual support services, and the NIMHE *Guiding Statement on Recovery*[12] includes consideration of spirituality as intrinsic to holistic treatment.

Why should strong spiritual beliefs be associated with better health outcomes? Could it simply relate to the social support provided by membership of a faith community? Is it possible that interest in spirituality/membership of a faith community is independently linked with better health? Or are there specific aspects of a faith (such as prayer or worship) that carry additional advantages to health? Is it the case that, as Andrew Sims writes, 'one of the best kept secrets of modern epidemiological medicine is the effect that religious belief and practice have upon outcome from both physical and mental disorders'?[13]

Chronic illness (whether physical or mental) is likely to be an area where the relationship between spirituality and health assumes particular importance. How does spirituality impact on long-term illness and coping? What effect does long-term illness itself have on spirituality and faith? How does chronic illness affect membership of a faith community? What of the families and carers of those living with long-term physical and/or mental illness? As yet we cannot answer these questions, but there is evidence which hints at possible answers. The evidence divides into qualitative (often personal accounts of living with a chronic illness, e.g. Robert Davis's account of changes in his faith and understanding while living with Alzheimer's disease[14]) and quantitative. Researchers are exploring this area, measuring associations using instruments such as Hill and Hood's Measures of Religiosity[15], which records 126 different measures of religion, faith, belief and spirituality, and the Royal Free Interviews for Religious and Spiritual Beliefs[16,17].

DEMENTIA AND SPIRITUALITY

Katsuno[18] studied 23 people with mild dementia attending a day centre in the United States, using both qualitative and quantitative measures, and found a positive correlation between strength of spirituality and quality of life. Religion was reported to be important in the everyday lives of 19 of the group. One main theme, 'Faith in God', and six related categories were identified: beliefs, support from God, sense of meaning in life, private activities, public activities, and changes arising from dementia. Katsuno argues from her sample that it is an individual's intrinsic religiosity, rather than the social support they receive from a faith community, which influences their quality of life.

We used the Royal Free Interview for Religious and Spiritual Beliefs: self-report version[19] in a memory clinic population in the West Midlands[20] to start to explore the following issues:

- How are spirituality and faith affected by dementia?
- How are spirituality and faith affected by caring for someone with dementia?
- How do religious communities view dementia and respond to its presence within their membership?
- How is the experience of dementia modified for patient and carer by their spirituality and faith?
- Are there opportunities for strengthening spirituality and faith and/or improving life for patients and carers in this situation?

A group of people attending a memory clinic in the West Midlands and their carers completed the Royal Free questionnaire and in additional semi-structured interviews were carried out with patients, carers and local faith leaders. The patients were mainly women living with Alzheimer's disease and they described themselves predominantly as Christian. They scored a mean of 24 on the Mini-Mental State Examination[21]. Our main conclusions were as follows: patients with dementia are interested in, and able to talk about, issues of faith and spirituality; the spectrum of their beliefs is similar to that of their main carers; the strength of their beliefs is at least as strong as their carers; and satisfaction with life and carer stress (as measured by the General Health Questionnaire[22]) appear to be independent of strength of spiritual belief in this population. Both patients and carers ranked the personal components of spirituality most highly: for carers, coping came highest ('do you believe in a spiritual power which helps you cope with events which occur in your life?'), and for patients' strength of belief ('how strongly do you hold to your spiritual/religious view of life?'). Both patients and carers considered practices associated with their beliefs to be very important.

What of people with more advanced dementia? Some formulations argue that as dementia progresses and erodes the individual's abilities, memory traces and emotional repertoire, their spiritual identity is lost to a primitive chaotic biological base. Others say that if you know the person well, their spirit remains available for contact, and, indeed, that their spirituality becomes more evident and precious[23,24]. Meeting spiritual needs is certainly accepted as part of supportive and palliative care in dementia as in other terminal conditions[11] and is anticipated in residential care, which pre-dates death for many people[25,26]. Lawrence[27] argues that 'spiritual matters remain pervasively in the background' as dementia progresses and that staff need to employ non-verbal methods and devote time to connecting with the spiritual needs of people with dementia. Families and carers who have sustained intense involvement through this final stage will take time to adjust to the transition to life without their relative after the latter's death. Their experience of communication may continue and the mode, manner and completeness of resolution will be influenced by their established beliefs[28,29].

DEPRESSIVE DISORDERS, PSYCHOSIS AND SPIRITUALITY

It is widely accepted that spiritual beliefs and religious practices can have positive effects on health and well-being in general. Lawler-Row and Elliott[30] reported an investigation of the role of religious activity and spirituality in the health and well-being of older adults and found that people with higher levels of existential well-being had lower scores on depression. It is said that people with a spiritual or religious affiliation are up to 40% less likely to get depressed than people who do not have such affiliation; an increased commitment to religion has been linked with lower levels of depression in medically ill hospital patients; and religious/spiritual commitment is associated with lower levels of substance abuse[2]. Koenig[31] studied older medical inpatients with major and minor depression and found that they were less religiously involved then non-depressed patients and that greater severity of depression was associated with lower intrinsic religiosity, less involvement in reading scripture and prayer, and lower religious attendance.

Ceramidas[32] has described a qualitative study of depression and Christian faith in later life. Those participants who had what is described as a 'closer relationship with God' found comfort and strength in the practice of their faith but did not experience their churches as safe places to disclose their depression, fearing stigma and rejection.

Suicide has been regarded as a sin by most major religions, and attracted strong religious sanctions in the past, although views have moderated over recent years. Depression with suicidal ideation is therefore strongly influenced by spiritual/religious beliefs and different communities respond to it in different ways. This can be particularly challenging in large multi-ethnic multi-faith cities[33].

THE SPIRITUAL NEEDS OF SERVICE USERS

Kitwood and Bredin[34] introduced the term 'personhood' and defined it as 'a standing or status bestowed on one human being by others in the context of relationship and social being. It implies recognition, respect and trust.' They went on to describe the main psychological needs of a person with dementia as attachment, comfort, identity, occupation and inclusion. These ideas were developed in the context of Kitwood's work with people with dementia, particularly in institutional settings, but the concepts can be applied more widely. Kitwood came from a faith background, but later preferred a non-religious vision and interpretation of spiritual life which could be turned into operational therapeutic activities[35,36]. In this he was a leader from whom followers are gaining strength and guidance in sensitizing services to the deeper needs of patients and families. This has additional benefits for care professionals, but makes additional demands on them.

There are practical ways in which staff can support the spiritual needs of service users[37]. First, it is essential to take time to discover something about the personal beliefs and family culture that have informed the individual's life to this point. This may be achieved by a one-to-one interview, but may be more complete with the assistance of family and friends. Just to talk about things with a sympathetic, non-judgmental listener will be helpful. From this it may be possible to identify contacts, tracts, music or other resources that can be used

for spiritual nourishment within a care setting. Alternatively, outside settings may be identified whose ambience brings meaning and sustenance. Faith, hope and compassion are contributory components of clinical care[38] and inevitably impact on the two-way relationship between service user and care provider. This means that carers who are open to the dimension of spirituality and faith in their work with patients require some sophistication in understanding the origins and limits of their own spirituality and how this may be used to strengthen and support their work. It is important to be aware that their own beliefs may be threatened (or be threatening) when exposed to new and different views and value sets. Thus there is need for support and supervision with reflection and growth from experiences gained. 'Do-it-yourself' is not a safe option for carers or those they care for. Addressing this issue is a task for every organization offering care to dependent and vulnerable people, and a complex matter that is rarely approached comprehensively.

Wallace[39] has described the development of guidelines to support staff working with people with dementia, and recently Gilbert[40] has produced guidelines on spirituality for staff in acute mental health services.

Post and colleagues[41] have addressed ethical aspects of attending to spiritual and religious aspects of a patient's experience. They consider the relationship between physician and patient, and the professional boundary between physician and chaplain, and note that patients' spiritual needs should be respected by those who aim to maximize therapeutic efficacy.

There are important ways in which faith communities can support people who have mental health problems[2]. For individuals who have active membership of an organization, this will include maintaining the continuity of established social contacts and allowing them opportunities for shared prayer, worship and rituals as well as pastoral care. Others, who have known a faith but fallen out of regular contact, may find the experience of illness acts as a trigger to reconsider their thoughts and beliefs. Still others may have had little or no contact with a faith community, but begin to wonder from their disability or distress, whether there is more to be learned. These are situations when hospital or health care chaplains can be helpful, but the first approach may come via a friend or family member to a local church or other faith centre. It is possible that what begins as a challenge from the threats that illnesses carry can become a source of unplanned enlightenment and positive growth. Faith communities are known to provide support and comfort in times of illness, loss and bereavement – but there is the possibility of much more[42].

THE SPIRITUAL NEEDS OF MENTAL HEALTH SERVICE STAFF

An area of potential difficulty is the possible dissonance between the spirituality and religious beliefs of service users and the staff who are supporting and treating them. The first step in dealing with this is to acknowledge it and then to provide information, education and support in reflective supervision so that unspoken fears and conflicts can be uncovered and examined.

Differences may be based, in part, on the generation gap between staff and the older people they are caring for. In all societies, older people are more taken up with spiritual/faith matters than younger people[43]. Older people have a role in maintaining traditions that were operative in their earlier years and will carry the culture of those times into the present. In addition, maturation takes place with accumulating years and the eventual approach of the end of life, bringing increased interest in matters of the mind and spirit, and less preoccupation with the pleasures of flesh.

But there are other factors, for paid carers are quite often drawn from a race, religion, country of origin, social stratum and language that set them apart from those they are caring for[44]. Within a staff group, there may be wide variation of experience and belief. This may be spread unevenly between those providing hands-on care and those with management responsibilities, and there can be hazards associated with cliques and groupings.

Such differences are inescapable features of the fabric of care: awareness of their potential to impact adversely on the quality of care is essential and needs to be built into education, training and reflective practice. One useful tool in this work is Cecchin *et al*.'s concept of 'prejudice'[45]. Prejudice is conceived as meaning 'any pre-existing thought that contributes to one's view, perceptions of, and actions in a therapeutic encounter'. Encouragingly, they argue that, when identified and confronted, prejudices can be construed creatively and usefully: 'any meeting of prejudices can create change'.

This change requires that, rather than one party attempting to impose the 'correct' view on any other, there is openness and negotiation between professional carers and those they care for. However, this runs counter to the power paradigm deemed usual within the staff–patient relationship. Involvement with, and respect for, family, friends and faith leader of the older person in discussions and care planning adds to complexity but also to the potential richness of care and health outcomes.

PAST, PRESENT AND FUTURE

There is evidence that people living with a mental disorder, including dementia, have spiritual needs which must be addressed in order to promote well-being and quality of life, that religious practices provide coping resources for people, and that their personal spirituality offers a source of comfort and strength for individuals[46]. Newitt[47] argues that people without religious faith also benefit from approaches that address aspects of spirituality. This is a tricky area, for there is no easily accessible formula or accepted approach when seeking to engage spirituality outside the rites of a faith. The Royal Free studies have found that high spirituality outside a faith carries a poor prognosis for health outcomes (M. King, personal communication), which is an interesting insight, but considering how it might be dealt with in practice is challenging.

There is much to be learned, but we have made considerable progress in giving back respect to spiritual and faith dimensions of individuals, families and communities. Perhaps health and social care professionals will now recognize the need to join more closely with colleagues who have expertise in matters of the faith and spirituality of service users and their families in order to improve both health services and health for older people with mental health problems in the future.

Development of Health and Social Services in the UK from the Twentieth Century Onwards

John P. Wattis

Centre for Health and Social Care Research, University of Huddersfield, Huddersfield, UK

IMPERIAL BEGINNINGS: THE POOR LAW AND THE ASYLUM

In Britain, the twentieth century dawned in a blaze of imperial glory. By the beginning of the twenty-first century, the world, including health and social services, had changed beyond recognition. In the year 1900, UK public health measures were rudimentary and confined largely to the establishment (in 1848) of sanitary authorities with medical officers of health to oversee sewers and water supplies. The poor law was still in force and poor law institutions were made deliberately unpleasant. This followed the principle of 'lesser eligibility', set out in 1834, which stated that those receiving poor law assistance should not be as 'eligible' (well provided for) as an 'independent labourer of the lowest class'[1]. For the poor sick this had been ameliorated, to some extent, by the setting up of poor law infirmaries in 1868, but there was still a vast gulf between these institutions and the voluntary hospitals, which were supported by rich philanthropists. Retirement pensions, even retirement itself, were things of the future and there was an association between poverty, ill health and old age which was recognized by an 1895 Royal Commission on the aged poor. Despite over 50 years of the National Health Service (NHS), the association between poverty, ill health and old age is maintained to this day.

Until the middle of the twentieth century, mentally ill people were still incarcerated in large county asylums. In 1808, partly as a response to the appalling conditions in some private 'madhouses', local magistrates had been given the power to set up asylums, and in 1845 this provision had been made mandatory. In recent years we have seen a return to the private sector for some aspects of health and social care provision for people with mental health problems.

From 1900 onwards, developments have been influenced by major world events, political philosophy, public opinion and the power of pressure groups. The Boer War, starting in 1899, revealed the poor physical fitness and ill health of many young men. Improvements in midwifery and child care were soon legislated for, with school meals starting in 1906 and the notification of live births, health visiting and the school medical service soon following. In 1908 the first national scheme for old age pensions was set up to try to alleviate poverty among old people. It was non-contributory and means tested. Initially, recipients also had to be 'of good character'!

The Royal Commission on the Poor Laws and the Relief of Distress in 1909 considered most of the issues of domiciliary and hospital medical care. A minority report condemned the poor law institutions as a public scandal, with the infirmaries understaffed and lacking skilled medical input[2]. Out of hospital, the poor law doctors had no contact with local authority public health services, the voluntary dispensaries were overcrowded and ineffective and the medical clubs, financed by workers' subscriptions, underpaid their doctors and did not cater for the chronic sick or dependants. The writers of this report dismissed the idea of a medical insurance system.

Yet, in 1911, the establishment of such a system marked an important development in the evolution of general practice in the UK. The medical profession fought for, and won, independence and capitation fees rather than a salaried service, and administration by insurance-based panels rather than local authorities[3]. Higher income groups, families and hospital care were excluded but the scheme was nevertheless a qualified success.

THE MINISTRY OF HEALTH: BETWEEN THE WARS

In 1918 the Ministry of Health for England and Wales was formed and the minister quickly appointed a consultative council, which in 1920 produced a report described by Pater[2] as 'nothing less than the outline of a national health service' (p. 7). Their scheme might well have avoided some of the split between general practitioners and hospital doctors that has been one of the problems of the NHS as it was eventually implemented.

Control of the workhouses passed to local authorities in 1930, the beginning of the end for the poor law. After a post-war cash crisis, the voluntary hospitals continued, becoming more specialized in acute care and leaving the chronic sick and infectious diseases to the local authorities. A number of reports pressed for a more coordinated hospital system and for universal health insurance. Knowledge was advancing. In 1935, Warren[4,5] began her work in developing geriatric medicine and, a few years later, pioneers began to write of the issues concerning old people with mental illness[6–8].

Before the Second World War, the Emergency Medical Service (EMS) was set up to cope with expected severe civilian casualties from the bombing of cities. On the declaration of war, 140 000

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

people, many of them elderly, were discharged from hospital over two days[9]. The EMS also coordinated the work of the voluntary and local authority hospitals, providing the framework for the future NHS Regional Hospital Boards. Physicians and surgeons from the elitist voluntary hospitals came face to face with the conditions of the former poor law institutions.

THE POST-WAR NATIONAL HEALTH SERVICE

The last of the series of British Medical Association (BMA) reports pressing for reform in 1942 coincided with the Beveridge report and was followed in 1944 by the NHS White Paper, enacted in 1946 and effective in 1948.

The National Health Service, as then set up, was tripartite. Primary care services – general practitioners, opticians, dentists and pharmacists – were answerable to local executive committees; maternity, child welfare, health visiting, health education, immunization and ambulances remained the responsibility of the local authority; and hospitals were administered by Regional Hospital Boards with teaching hospitals retaining boards of governors directly answerable to the Ministry of Health. One of the assumptions when the NHS was set up was that increasing health in the population would cause health expenditure to level off. It never did, and in 1956 the Guillebaud Committee, appointed to find ways of avoiding a rising charge upon the exchequer, concluded that there was no evidence of inefficiency or extravagance in the NHS. In fact, the committee was concerned about a lack of capital expenditure (a concern again of relevance more recently). In 1962, this problem was addressed in the Hospital Plan.

Meanwhile, in the mental health field, the idea of community care was gaining ground. Tinker[10] attributed this to five factors. First, there was a general dissatisfaction with institutional care and a search for alternatives. Some of the experiments in the 'therapeutic community' work of the Second World War[11] had challenged the accepted authoritarian culture of the mental hospital. In addition, the advent of electroconvulsive therapy (ECT), antipsychotics and effective antidepressants facilitated the move away from custodial care to medical treatment at home or in ordinary hospitals. Next, there were beginning to be practical problems in running residential establishments, including staff recruitment. Then there was concern about the cost of institutional care and, finally, a recognition that mentally ill people were entitled to live in as normal a way as permitted by modern treatments. The 1959 Mental Health Act liberalized the treatment of mentally ill people and opened the way for a move away from the old psychiatric hospitals to the new concept of psychiatric units attached to the district general hospitals of the 1962 Hospital Plan.

The large institutions were, in any case, rocked by a series of scandals about the mistreatment of patients. This resulted in the establishment of the Hospital Advisory Service (later the Health Advisory Service), effectively an inspectorate to monitor standards and spread good practice.

In general practice, a financial allowance for practices in deprived areas combined with other factors to promote the rapid development of local health centres and group practices from the mid 1960s. Local authorities produced their own health and welfare plans but there was poor coordination with the hospital authorities and the general practitioners' executive committees. Within the local authorities, the Seebohm report (1968) was followed by the Social Services Act, which required the setting up of social services departments. The Department of Health and Social Security was created in 1968 by the amalgamation of the Ministries of Health and Social Security, a merger that lasted for some 20 years.

REFORMS

In 1974, for the first time since its inception, the NHS itself was reorganized. The chief elements of this reorganization were the separation out of health and social services functions (now in the process of being reversed in children's services at least!), the integration of all health functions under one management and the establishment of area health authorities, generally coterminous with local authorities, to facilitate joint planning. Community Health Councils were also created to represent the views of consumers. Unfortunately, the reformed service did not work well. There were too many layers of responsibility, and taking decisions seemed to be delayed while information and responsibility were passed up and down the tree. There was an increase in clerical and administrative staff without a corresponding increase in managerial efficiency. During this period, important government reports were produced, including *Better Services for the Mentally Ill*[12] and *A Happier Old Age*[13].

In 1982 the Area Health Authorities were abolished and new district health authorities combined the functions of the old areas and districts. In some areas, coterminosity with local government was lost. A new government was determined to cut public expenditure, and the rate of growth of the NHS slowed. Following the Griffiths report[14], a general management structure was established within the NHS, and Family Practitioner Committees became independent. Government payment for continuing care was channelled to the private sector, and social services and hospital provision for this group of patients/residents was either reduced or failed to keep pace with demographic changes[15].

Psychiatric services were coping with the implementation of the 1983 Mental Health Act (MHA), which set up time-consuming quasi-judicial procedures for reviewing patients who were detained in hospital under compulsory orders. The new Act also set up a Mental Health Act Commission to review treatment of detained patients and to advise on certain types of treatment. This Act was revised in 2007 to incorporate a number of changes, including broadening the categories of those who could apply for admission under the MHA and of those who could be responsible for their care under the Act. Generally, in combination with the Mental Capacity Act, the new legislation has improved patients' rights under law, but at the expense of increasing bureaucracy.

MARKET FORCES AND COMPETITION: A RADICAL DEPARTURE?

Then came the most radical reform of the NHS attempted to that date, a reform not just of the service but of the basic philosophy of 'service' underlying it. Some suspected that it was the beginning of the end for the National Health Service. The political theory was that nationalized industries were subject to 'producer capture' and that the workers tended to run the service in their own interest rather than that of the 'customers'. Competition and 'market forces' were seen as the remedy. The 1990 National Health Service and Community Care Act introduced the concept of an 'Internal Market'. The new health authorities became planners and purchasers of health care at 'arm's length' from the providers, which were initially directly managed units (DMUs), and became semi-independent Trusts. The health authorities were provided with a budget for the local population and

placed contracts for care with Trusts or the private and voluntary sector in order to obtain the best 'value for money'. Quality was, at least in theory, specified in the contract, and monitored.

Competition and other features of business life were 'introduced' into the NHS, not least by setting up groups of 'fundholding' general practitioners, who were enabled to make their own contracts for secondary care. In fact, doctors, health care workers, general practices and hospitals have always competed on reputation, but money was the new incentive. Some of the changes were potentially positive, such as the setting up of Trust Boards to manage local services and an emphasis on sound financial regulation through corporate governance. Unfortunately, the bottom line was very clearly financial and in many cases clinical services were sacrificed to balance the books.

These proposals were pushed through in the teeth of strong opposition from staff and groups representing the consumer. Honigsbaum[16] analysed the situation in 1990 and concluded that if patient care suffered, then 'the nation may decide that the restraints imposed are not worth the savings they produce. Today, as in 1911 and 1948, it is the public interest that will predominate'. The medical profession were largely excluded from the plans for this reorganization. Klein concluded that, if a new political settlement were not reached between the government and the profession, it seemed unlikely that the NHS would survive long into the twenty-first century[17].

A NEW NHS?

In fact, perhaps partly because of public dissatisfaction with what was happening to the NHS, the government was not re-elected, and a radical reforming Labour government came to power. From here, developments in the constituent parts of the UK became more dissociated. This account mainly follows what happened in England, since to follow all the differences following devolution would require more space than is available. The engines of privatization and the internal market were (temporarily) reversed and new reforms introduced. In December 1997 a White Paper, *The New NHS: Modern, Dependable*[18] outlined a comprehensive new vision for the NHS. Two of the main planks of the new policy were the setting up of primary care groups (PCGs) to replace the fundholding/non-fundholding split, and the introduction of comprehensive quality controls to ensure high standards and equity in access across the country. PCGs were local groupings of general practices, involved in the commissioning of local community and secondary services. In a further reform, they became Primary Care Trusts (PCTs), providing community services and commissioning secondary services. More recently still, the concept was developed of 'Care Trusts' which could provide primary care and some secondary services, such as mental health services. The 'Quality Framework' involved a three-layer approach[19]. *Clear standards of service*, set by National Service Frameworks (NSFs), and a National Institute for Clinical Excellence (now National Institute for *Health* and Clinical Excellence, but still known by the acronym NICE), which evaluated new treatments in terms of cost–benefit as well as the safety and efficacy demanded for licensing. The NSF for Older People was published in 2001[20]. The first of eight standards was 'rooting out age discrimination'. The seventh concerned mental health and included NICE guidelines for antidementia drugs (since revised to restrict use to those with moderate Alzheimer's disease). The new NSF made it clear that standards in the Mental Health NSF already published applied to older people. Local delivery of services was to be made dependable by a combination of lifelong learning[21] linked to professional self-regulation and clinical governance. *Clinical governance*[22] placed obligations on chief executives of NHS Trusts to make arrangements to monitor and continuously improve the quality of health care their organizations provided. This was underpinned by the *national monitoring* of standards involving a National Performance Framework, an inspectorate (the Commission for Health Improvement, renamed the Healthcare Commission and renamed and reorganized again in April 2009 as the Care Quality Commission) and a National Patient and User Survey. This ambitious vision set a massive agenda for change and demanded radical shifts in the management and clinical cultures of the NHS[23]. These well-intentioned reforms have been accompanied by a plethora of central guidance, much of it driven by a philosophy of competition and performance management that does not sit well with the complicated needs of patients and the real motivators of human behaviour. The emphasis on control and performance management clashes with the self-determination model that is rightly increasingly popular when it comes to service users and medical education[24].

PCGs initially resulted in a much greater influence for general practitioners and other primary care workers in the commissioning of secondary services. In the move to PCTs, PCGs were merged and grew, effectively to replace the former District Health Authorities (DHAs). They now have a board structure with executive and non-executive directors, analogous to the boards of existing secondary care Trusts. The strategic role of the former DHAs has been taken over by new Strategic Health Authorities (SHAs) covering areas even larger than the former Regional Health Authorities (RHAs). In England and Wales, 'standalone' Mental Health Trusts or Care Trusts have become the normal providers of mental health care. In smaller towns, a mixture of specialist Trusts covering wide geographical areas and of direct provision through PCTs remains. The provider Trusts have been encouraged to become 'Foundation' Trusts with yet another monitoring body (imaginatively called 'Monitor') overseeing the process. There was something of a scandal when a Trust preparing for Foundation status let its guard down on clinical quality and saw a significant increase in mortality rates. Shortly after Monitor cleared it to become a Foundation Trust, the Healthcare Commission was called in to investigate Mid Staffordshire NHS Foundation Trust and found serious failings. So far nobody at the Department of Health has publicly acknowledged that the pace of change and the New NHS structures might be causing damage.

The doctrine of 'commissioner–provider split', embodied in the new slogan 'World Class Commissioning', means that the mental health services as part of PCTs in England are unlikely to persist. For old age psychiatry, most current arrangements mean that the managerial separation between old age psychiatry and geriatric medicine continues. Unless imaginative and pragmatic solutions are found, this could result in many demarcation problems. However, a new culture of collaboration rather than competition could make all the difference (if not strangled at birth by political doctrine).

The *funding* of the NHS is probably even more important than its organization in determining the future of health care in the UK. It was the squeeze on NHS development in the 1980s that provoked the medical profession to campaign for more development money. In the light of international comparisons, both of spending on health care and the age structure of the population, this campaign seemed fully justified. Earlier reorganizations increased management costs and reduced the morale of many in the NHS. In the last 10 years there has been a marked increase in investment in the NHS. The controversial

Private Finance Initiative (PFI – rebadged as Public–Private Partnership, PPP) has continued to be a main strand of funding because it limits the Public Sector Borrowing Requirement. There is concern that PFI/PPP will result in a reduction in bed numbers and diversion of money away from services to support repayments to private providers in respect of capital developments; this is especially a risk if investment in the NHS slows down.

The government has recognized the need to train more doctors, nurses and other health care workers but, despite considerable investment, workforce planning is still problematic as demonstrated by the debacle in 2007/8 over the failed introduction of 'run through' training for doctors.

The direct reforms of the NHS were accompanied by a Royal Commission to review long-term care. The report of this Commission[25] controversially suggested that the personal care and residential elements of continuing care should be separately funded. It recommended that personal care should be paid for from general taxation, while living and housing expenses should continue to be means tested and subject to co-payment. The government did not make a positive response to this.

WHAT NEXT?

The 'Next Stage Review' of the NHS was commissioned in 2007 and published in 2008[26]. There are many recommendations and supporting documents available on the Department of Health website (www.dh.gov.uk). The review incorporates visions from each of the new Strategic Health Authorities and combines an emphasis on preventative medicine ('helping people lead healthy lives') and quality with a vision of partnership and local clinical leadership. Already there are signs that some of the good ideas are being slowly strangled by bureaucracy. If there is anything to learn from the last 10 years it is that too much ill-considered change produces a churning of management staff that reduces efficiency, and that too many central targets distort provision towards that which is politically fashionable or easy to measure (e.g. surgical waiting lists). At the same time, the pace of change and emphasis on 'top-down' performance management reduces the responsible autonomy we need to encourage for staff and service users alike. As this chapter goes to press a new UK government has just been elected which professes support for the NHS and a strong distaste for excessive bureaucracy and central control. We can expect more change.

The Pattern of Psychogeriatric Services

John P. Wattis

Centre for Health and Social Care Research, University of Huddersfield, Huddersfield, UK

HISTORICAL BACKGROUND

The roots of the National Health Service (NHS) and the development of psychogeriatric services in the UK are discussed in Chapter 119. The evolution of psychogeriatric services has been guided by professional knowledge and opinion, by the politics of the health and social services, by financial constraints and, occasionally, by public opinion. From the inception of the NHS, which effectively antedated the beginning of provision of specialist psychogeriatric services, until the 1990s there was a consensus about how developments in services should occur in response to changing demography and epidemiology as well as advances in medical knowledge. This consensus was shattered in the UK by the imposition of the ideology of 'market forces'. Much long-stay hospital accommodation was effectively 'privatized' by decisions to support patients in private nursing and residential homes from state funds and to close down as many long-stay NHS beds as possible. The ideology of market forces was also applied to local authority provision of community care. Since April 1991, psychiatric patients with social needs have been subject to a 'care-planning procedure' in which all parties, including social services, have to agree. In April 1993 the full implementation of the Community Care Act made local social services departments responsible for purchasing continuing nursing and residential home care, largely from the private sector and with a limited budget.

In the late 1990s, a government came to power that did not appear to share the vision of market forces as the best way to regulate the NHS. However, the internal market has crept back in England under the guise of 'world class commissioning' and 'contestability', and the NHS remains a 'political football'. Political devolution of health care arrangements has also resulted in different patterns of service development in England, Wales, Scotland and Northern Ireland. One can no longer write about 'UK' psychiatric services as a whole and this text mostly follows the situation in England. The professional consensus about how services should develop has been replaced by a centralized pattern of decision making and the important decisions, made at the inception of the specialty of old age psychiatry in the UK, about providing a comprehensive service for all severe mental illness in old age, whether organic or functional, have been disregarded in some areas.

THEORETICAL BASIS FOR PSYCHOGERIATRIC SERVICES

The pioneers of specialist psychiatric services for old people were motivated by the increasing need for psychiatric services for the age group, consequent upon increased life expectancy, the growing knowledge base about psychiatric disorders among old people, and the success of geriatric medicine. The special needs of older people were not always recognized by the generic services. Diagnostic problems included the differential diagnosis of dementia, the association of apparent cognitive impairment with some cases of depressive illness, and the non-specific presentation of disease in old people. The multiple pathology suffered by old people led to a need for new patterns of multidisciplinary working and for close liaison with physicians in geriatric medicine and social services[1–3]. As in the early days of geriatric medicine, assessment and treatment in the community were emphasized not only because of 'blocked beds' but also because a more realistic picture of the patient's health problems usually emerged. More recently, advances in psychosocial care[4], interest in the spiritual needs of old people[5] and the advent of new classes of antidepressant, antipsychotic and antidementia drugs (discussed elsewhere in this volume) have all had their impact on the organization and delivery of psychiatric services.

CARE OR TREATMENT: PRIMARY OR SECONDARY?

One of the key theoretical issues for the future development of community services is likely to be the distinction between care and treatment. 'Care' is a word with many connotations. Some are positive but, in the medical world at least, some are negative. For example, 'care' is seen as what is provided when there is no possibility of effective treatment, as in the 'prescription' of 'tender loving care' for the terminally ill person. 'Care' tends to be relegated to untrained (although not necessarily unskilled) workers employed by social care agencies and commissioned by social services departments, whereas 'treatment' is the province of highly trained personnel employed by the Health Service. The move to 'Care in the Community' has served to reclassify older mentally ill people, especially those with dementia, as not needing medical treatment. Thus long-term care of people

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

with severe dementia, once shared by psychogeriatric and geriatric services within the NHS, is now provided in private institutions and is 'means tested', reducing the burden on the state but increasing the burden on afflicted families.

This situation is further complicated by the tendency of some health planners to equate primary care with *low cost and community care*, and secondary care with *high cost and hospital care*. Old age psychiatry services straddle the hospital–community divide and provide essentially secondary services, largely in a community setting. The new term, 'intermediate care', describes well some of these community services, but some who use the term believe that community psychiatric nursing services should be part of 'primary care', when in old age they work most effectively as part of secondary community care. Certainly, with the increasing prevalence of dementia, it is essential that primary care services and general hospital services become more proficient in recognizing and managing these conditions appropriately.

KEY COMPONENTS OF PSYCHOGERIATRIC SERVICES

Catchment Area and Comprehensiveness

Until recently, virtually all psychogeriatric services in the UK worked to a defined geographical catchment area, and the vast majority aimed to provide a comprehensive psychiatric service to all people over the age of 65 years[6,7]. Many services are now also trying to provide for people with early-onset dementia, although often without any dedicated resources[7]. In some areas, managers are seeking to save money by closing specialist wards for old people with functional mental illness and diverting those who need inpatient care onto wards designed for working age adults. Some old age psychiatrists feel they are being pushed towards developing 'dementia only' services.

The Multidisciplinary Team

For some this is an outmoded concept, for others an ideal that cannot be obtained, but for many psychogeriatricians it is an essential context for all their endeavours. Most multidisciplinary teams for the elderly incorporate *community nurses*, a *social worker*, one or more *occupational therapists*, a *physiotherapist* and often a *psychologist*. Various patterns of working have evolved and been described but they have in common an attempt to involve all disciplines in formulating treatment plans for the patient. In parts of England, there continue to be problems in fully integrating social workers and psychologists into such teams.

Home Assessment

This lies at the heart of most psychogeriatric services. Until the last few years, around two-thirds of referrals were seen at home by a doctor, one-fifth by other members of the team and one-tenth in outpatient clinics[6,7]. Just over 1 in 10 were seen as liaison referrals, although in some services this rose to a quarter or even one-third, perhaps partly depending on the admission policies of local geriatric services. Less than 1 in 20 were admitted direct without prior assessment. Patterns described as 'New Ways of Working' have now spread from working age adult psychiatry to old age. Generally this involves new referrals being assessed at home by various members of the team, and the senior medical staff tend to see people in the outpatient department after a preliminary assessment by another member of the team (often a community psychiatric nurse). This has reduced the burden of new assessments falling on psychiatrists, and the impact on the quality of initial assessments has yet to be evaluated.

Community Treatment

Historically, the rate of acute admissions was only one-third of the rate of referrals, reflecting the fact that most home assessments do not result in admission but in treatment in the community. Home visits by community nurses are probably the commonest form of treatment in the community, although home visits by doctors and other members of the multidisciplinary team also play an important part. The rate of acute admission is probably reducing further as acute inpatient beds are closed.

Day Hospitals

In 1985, there were about 1.2 day hospital places per 1000 elderly people, and this had not changed significantly by the mid 1990s. Some services and Health Regions had relatively more and others less. The use of day hospitals varied from area to area, depending on the resource availability locally. The old government guidelines overestimated the need for dementia places. In many but not all cases of dementia, the need is for *care* rather than *treatment* and so a proportion of this day provision can be provided by social services or voluntary agencies. Here, however, issues will have to be addressed as to what kind of care is of most benefit to older people with dementia and their relatives, neighbours and friends. Elderly people with functional illness often have problems with psychiatric or psychological management that demand the *treatment* resources of a true day hospital or the more recently developed home treatment services. In the last five years there has been strong central pressure to close day treatment facilities, in some cases replacing them with home treatment teams.

Acute Inpatient Beds

The national rate of provision in 1985 was around 1 per 1000 elderly served, and again did not vary much over the next 10 years. In recent years there appears to have been a further reduction in acute beds. The reducing numbers may be insufficient to cope with the increasing demands caused by demographic changes and the loss of long-stay beds. Ultimately this depends on the community services available, since there is potential for considerable 'marginal shift' between community and inpatient resources. One study showed that around a quarter of acute psychiatric beds for all age groups were occupied by elderly people with depressive illness, and in many areas anecdotal evidence suggests that a greater proportion of acute psychiatric beds is being used for functional illness, principally depression. As with day hospital places, it appears that the old guidelines may have overestimated the needs for dementia assessment beds and underestimated the needs for patients with depressive illness and other functional illnesses. Because of the high prevalence of physical illnesses in mentally ill old people, it is recommended that acute beds should be on or adjacent to a general hospital site. Some services are now beginning to differentiate the assessment and management of behavioural problems in demented people, which can be carried out in the community or in community-based units, from the management of patients with depression, who often have major associated

physical illness or disability (and may need ECT) and are therefore better managed on an acute hospital site. The same may apply to atypical dementia patients requiring high levels of investigation or to patients with dementia and delirium. This last group may be best helped on geriatric medical wards.

Long-Stay Beds

The provision in 1985 was around 3.4 beds per 1000 elderly. Since then a large number of beds have been closed, with patients discharged to the private sector, where developments have been funded through the social security budget and means-tested contributions from patients and their families. In 1996 the number had reduced to around 1.1 beds per 1000 elderly. Since provision was largely (but not exclusively) for those with severe dementia, whose main need is for care rather than treatment, this development appears to demand a cautious welcome. Patients are generally being cared for in smaller units. However, there must be reservations. The smaller units are harder to inspect and they are not necessarily in the patients' communities of origin, since planning permission and housing costs enter into the commercial equation. They are subject to capricious changes in the market, including government refusal to pay the 'going rate'. They are not under specialist medical management and there is some evidence that this management may be one of the factors that reduces the rate of decline in demented elderly people (a factor which, if confirmed, might also have relevance in the day care setting). The switch to private care has been engineered for political reasons and its impact is yet to be fully assessed. Some psychogeriatric services have retained a proportion of their long-stay beds for rehabilitation and respite care. A survey of old age psychiatrists[8] showed the majority in favour of around 1.5 long-stay (including respite) beds per 1000 elderly in community NHS units, with national rather than local eligibility criteria. The use of such beds for respite care to support carers in the community is now well established, and there is a potential for developing community units as centres of excellence for dementia care and education, as well as bases for multidisciplinary community teams.

GUIDELINES

The first guidelines for provision of psychiatric services for old people came in a Department of Health circular in 1972[9]. The government White Paper, *Better Services for the Mentally Ill*[10], in 1975, suggested that services for old people should often be provided by a psychiatrist with 'a special interest', and incorporated guidelines for bed and day hospital provision for the 'elderly severely mentally infirm'. Subsequently, the Royal College of Psychiatrists produced guidelines intended to help College representatives reviewing job descriptions for new or replacement consultants. These were endorsed by the Health Advisory Service in its report, *The Rising Tide*[11], and by the joint Royal College of Physicians and Psychiatrists report, *Care of Elderly People with Mental Illness*[12]. The second joint report[13] adopted a more multidisciplinary approach and described the different types of mental illness in old age as well as appealing for equity and 'national reference frameworks', which corresponded closely to the concept of 'National Service Frameworks' introduced by the new government[14]. Since the turn of the century there has been a plethora of government guidance, especially on dementia, culminating in the National Dementia Strategy[15]. Unfortunately, despite their excellence in many respects, none come near to specifying resources to be deployed even in the surrogate way of the old 'bed norms'. Further, many old age psychiatrists fear that the needs of older people with functional mental illness, especially depression, are being sidelined.

Reality and Guidelines

Although, in the UK, old age psychiatry has been recognized as a specialty by the Department of Health for many years, we are still awaiting the collection of routine statistics. Initial manpower statistics appeared to be grossly inaccurate. The most comprehensive data available are from the 1985 survey, updated by the 1996 survey, which unfortunately did not achieve such wide coverage. There are also now agreed international standards for old age psychiatry services[16], and an international survey has established that basic levels of service exist in 12 countries worldwide[17].

SPECIALIST SERVICES OR NOT?

In view of the documented rapid expansion of services over the years, this question may seem superfluous. However, it was possible, as a result of the 1985 survey, to compare services where psychogeriatricians worked half-time or more in the specialty, with those where the consultant commitment to the elderly was less than half-time[18]. Specialist services had generally higher staffing ratios (with the exception of non-consultant medical staff), a higher proportion of acute beds on general hospital sites and a greater proportion of long-stay beds within the area served. These last two could be regarded as surrogate indicators of quality of care. In addition, the specialist psychiatrists were more likely to look after all mental illness in old age (the pattern of service recommended by the Royal College Faculty for the Psychiatry of Old Age). They were also reported to be more likely to engage in teaching and to show an interest in research in the specialty.

CONCLUSION

Readers wishing to see a more comprehensive narrative of the early development of old age psychiatry in the UK are referred to a historical study hosted by the Glasgow University website: www.gla.ac.uk/media/media_107314_en.pdf. Psychogeriatrics has 'come of age' in the UK. Provision, although geographically patchy and relatively under-resourced, still provides one model for future developments. This model, fostered in the National Health Service with its principles of equality of access, payment from general taxation and central planning, survived the major changes of the 1990 'reforms'. However, centrally directed changes, under the regime of equity and quality proposed by the last UK government, appear to be sometimes having perverse effects and introducing greater (and perhaps inappropriate) variability. Old age psychiatrists need to show leadership in these times of rapid change, and governments need to furnish adequate resources and ensure national standards, both in terms of quality and quantity of provision.

The Multidisciplinary Team and Day Care Provision

Martin Orrell[1] and Kunle Ashaye[2]

[2]*Mental Health Unit, Lister Hospital, Stevenage, Hertfordshire, UK*

THE MULTIDISCIPLINARY TEAM

The multidisciplinary team assessments and treatment of older people with mental health problems enables a holistic approach to care for and meet the complex health and social needs this group of patients may present with. The concept of the multidisciplinary team has been described as a group of members of different professions whose working skills, when combined for the needs of the patient, aim to exceed in quality the simple summation of their individual abilities[1]. In describing features of a successful multidisciplinary team, Rosenvinge included communication within the team; high quality leadership; maintaining audit activities to help maintain and improve service delivery and management; and maintenance of morale of team members[1]. Multidisciplinary team members may include psychiatrists, mental health nurses, occupational therapists, social workers, clinical psychologists, physiotherapists, speech and language therapists, pharmacists and support workers. Improving multidisciplinary assessments to promote health and social care of community-dwelling frail older people has become an important issue for policy makers throughout the developed world[2]. In England, the introduction of the Single Assessment Process was to help multidisciplinary team members target the complex needs of older people, and may help identify appropriate team members or specialists to help meet those needs; however, in many areas it has not been effectively implemented[3]. It has, however, led to an increase in multidisciplinary assessments[2]. Multidisciplinary teams are found in various settings in mental health services for older people, such as community mental health teams, day hospitals and day centres, along with newer services like the Assertive Outreach Teams and Crisis Assessment and Treatment Teams.

THE ROLE OF DAY HOSPITALS

Day services available to older people with mental health problems include day centres and day hospitals. Psychiatric day hospitals for older people tend to be managed and provided through health services and run by multidisciplinary teams consisting of the various mental health professionals. Day centres tend to be managed and funded through local authorities, social services or voluntary organizations with fewer or no health professionals. The first psychiatric day hospitals were opened in the Soviet Union in the 1930s, probably as a result of inpatient bed shortages, and by the early 1950s many had been opened worldwide in developed psychiatric services[4]. In the United Kingdom, the first psychiatric day hospital was the Marlborough Day Hospital in London, opened in 1946[5]. Other psychiatric day care services for older people followed, with dramatic increases in the 1960s and 1970s[6]. The main factor in the growth of day hospitals was attributed to the development of new psychiatric treatments such as neuroleptics. They enabled the mentally ill to be treated in day hospitals, providing a high level of care during the day, but returning to their homes each evening.

The development of effective community support systems is essential for the successful shift from inpatient to community care for mental health services. The identified needs of severely mental ill individuals in the community include medication monitoring and therapy; psychosocial treatment, day and vocational activities; supported and supervised residential services[7]. Day hospitals with their various functions are ideally placed to play a significant role in assessment and community care.

The psychiatric day hospital provides short- and medium-term care to the mentally ill, with the option of receiving at times intensive psychiatric care without hospitalization. In the 1970s, a fully integrated psychiatric service for older people was described by Donovan *et al*. (1971) to include a day hospital serving four functions[8]. These functions were:

1. The outpatient investigation and treatment of older patients with physical and psychiatric disorders.
2. The continued observation of patients discharged from hospital.
3. To prevent deterioration from self neglect, loneliness or apathy.
4. To offer respite to carers, hence delaying or preventing inpatient admission.

Holloway (1988) described four main functions of day hospitals for mentally ill persons[9]. They are similar to those above and include:

1. An alternative to admission for people who are acutely ill and cannot be maintained as outpatients.
2. A service for support and monitoring in the often difficult transition between a stay in an inpatient ward and life at home.
3. A source of long-term structure and support for those with chronic handicaps, preferably in a friendly, low pressure environment.
4. A site for relatively brief, intensive therapy for people with personality difficulties, severe neurotic illnesses or in need of short-term focused rehabilitation.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

In recognition of their important place in the care of older people, guidelines for current service provision for older people with mental health problems have included the provision of day hospital places[10,11].

For older people, Corcoran *et al*. (1994) described two objectives of the day hospitals established in Ireland as being[12]:

1. To provide acute psychiatric treatment, thereby functioning as an alternative to admission for patients of over 65 years with functional psychiatric illness.
2. To treat patients with behavioural disturbances associated with dementia.

These objectives are similar to those described above for generic psychiatric day hospitals, though the distribution of diagnoses is different[8,9]. This is especially so in the case of persons with dementia, who are more likely to be found in a day hospital for older people than in a generic psychiatric day hospital. With such varied clientele, outcome and needs in various day hospitals will depend to a large extent on the type of patients being served, and available resources. One benefit of the above-listed functions taking place in day hospitals is that attenders are not taken away from home into hospital, but return home each day. This ensures that routines which may be difficult to re-establish after a long stay in hospital are less disrupted, other than due to illness, and so probably reduces the risk of institutionalization. Furthermore, reports obtained from home, by relatives and carers, give day hospital staff an extra tool in monitoring progress of attenders. For patients with cognitive impairment, maintaining them at home while attending the day hospital is likely to reduce problems of disorientation, resulting from movement into new environments like inpatient wards, as day hospital patients return to the familiar surroundings of their homes each day.

Shah and Ames (1994) described potential functions of an old age psychiatry day hospital as including: assessment, treatment, rehabilitation, long-term support, development of social networks and support of carers[13]. According to Rosenvinge (1994), characteristics of older patients' needs most likely to be met in a psychiatric day hospital can be grouped into functional and organic illnesses[14]. They include:

1. Assessment and management of acute functional illness.
2. Maintenance treatment of high-risk or vulnerable patients.
3. Continuation of treatment of discharged inpatients.
4. Assessment and management of patients suffering from dementia.
5. Provision of long-term support for those with severe dementia.
6. Treatment possibilities in dementia, such as advances in drug treatments requiring close supervision.

These characteristic needs are likely to be found in a wide variety of patients who are likely to benefit from day hospital care.

EVALUATION OF DAY SERVICES

Woods and Phanjoo (1991), in a retrospective study of day hospital patients with dementia, observed the outcome of care after three years[15]. Circumstances of discharges were classified into planned and unplanned. Of the 145 discharges, 65 (45%) were unplanned, with reasons ranging from emergency admission in 14 (9%), to death or physical illness in 40 (28%) and refusal to attend in 11 (8%) patients. Of the planned discharges from the day hospital, only 11 (8%) were discharges to the community, with the remaining 69 (48%) transferred to long-term care in hospital or nursing\residential homes. Though not a randomized controlled study, the authors suggested that outside factors, such as the presence or absence of spouses or others who have taken on the role of carers affected outcome among day hospital attenders. Day hospital patients with spouses were observed to be less likely be admitted to residential or nursing homes than those without spouses. Reasons that they proposed to account for the differences were that the patients with dementia remained longer with their spouses, and that when care was required, the severity of problems presented with at the time would require long-term hospital care rather than placement in residential or nursing homes. The findings of their study would suggest that it is essential that day hospital studies take into consideration such external factors as living spouses, carers and social support networks of patients.

In a study reviewing the impact of closure of a geriatric day hospital, following closure due to staff industrial action, Bhattacharyya *et al*. (1980) found few ill effects on patients over a six week period[16]. Ratings of mobility, self care, continence, mental state and need for services such as general practitioner, 'meals on wheels', day care or home help revealed minimal differences before and during the day hospital closure. Of the 55 patients in the study, most had cerebrovascular disorders, arthropathy and/or cardiovascular disorders, and only 9 patients had problems with dementia or depression.

In a similar study in older patients with mental health problems, Rolleston and Ball (1994) observed the impact of a two week closure of a psychiatric day hospital[17]. Data on well-being of patients and their carers were collected over eight weeks, to include three weeks prior to closure, two weeks of day hospital closure and three weeks following re-opening of the day hospital. They used two brief questionnaires, designed for patients and their main caregivers respectively, asking whether they felt the same, better or worse than usual, during the preceding week. They found a trend towards decline in well-being during the day hospital closure, which returned to pre-closure levels for both carers and patients on re-opening the day hospital. These findings would suggest that the day hospital was of benefit to both carers and patients. However, this study suffers from the arguments against many day hospital studies, in that they are not randomized controlled studies, hence no consideration is taken for confounding variables, such as the festive season during which closure took place, compliance with medication and/or the social network available to replace the day hospital over the same period.

Corcoran *et al*. (1994) noted that day hospital treatment enabled the older people with functional illnesses to be treated in the community with low usage of beds, and provided short/medium-term care for patients with dementia who had little support from statutory services[12]. They reviewed all regular attenders of two day hospitals over a three-year period, in which 139 (59%) patients had an organic disorder, mainly dementia, and 98 (41%) patients had a functional disorder, with the most common diagnosis being depression. There was a low uptake of community services at the time of day hospital admission, despite the relatively high level of dependency, especially among patients with dementia. During the course of the study, the uptake in community services, such as meals on wheels, home help and day care, doubled. The average length of admission was five months for those with functional disorders and eight months for those with dementia. Of those patients with functional disorders, 71% were managed effectively through the day hospital and community psychiatric nursing visits, while 25% of them required inpatient care, of which two-thirds were for deterioration in physical health. In the

case of those patients with organic disorders, 88 (63%) entered into residential care, on average about eight months after initial referral to the day hospitals. In 20% of patients with dementia, the day hospitals served as a long-term supportive facility, with average attendance of 18 months among this group of patients with severe dementia. This study highlights the benefits of day hospital care in older persons with both functional and organic disorders, though it can be argued that the lack of a control group or comparison with any alternative form of care weakens its findings. The authors themselves acknowledge the importance of an increased range of support services in the community for day hospital attenders.

Johansson and Gustafson (1996) observed that the old age psychiatry day hospitals offered flexible and effective care, especially in supporting people with dementia at home[18]. The most frequent psychiatric symptoms that they observed among the day hospital attenders included delirium, anxiety, sleep disturbances and depressed mood.

Kitchen *et al*. (2002), in a study evaluating care provided through day hospitals, revealed insufficient clinical disciplines in terms of lack of psychiatrists, occupational therapists and psychologists in several day hospitals[19]. The physical environments were often unsuitable, highlighting the need for purpose-built or adapted day hospitals for older people.

COMPARING DAY HOSPITALS AND DAY CENTRES

Day hospitals, being a health resource, are often located on or close to hospital sites, whereas day centres run by local authorities are more community based, often closer to the clients they serve. Eagles and Warrington (2002) suggested that day centres could carry out similar roles to the day hospitals, as attendees had similar characteristics across both settings, such as severity of dementia, dependency and the range of behaviour problems[20]. They further argued that unless the benefits of mental health staff in day care were demonstrated, resources would be focused on using cheaper untrained staff in day hospitals.

Furness *et al*. (2000) compared the characteristics and unmet needs of 129 older people attending day hospitals and day centres[21]. The day centres had a higher proportion of people with cognitive impairment, while day hospital attendees had increased behavioural problems and psychotic symptoms. There were similar high levels of high satisfaction expressed by carers of both groups. Collier and Baldwin (1999) found that day hospital patients presented with more behaviour problems than those attending day centres[22]. Though considerable research has been carried out comparing day centres and day hospitals, it has been suggested that they form part of a continuum. Day hospitals, with the various health professionals, can offer the short-term care required for patients with acute and increasing mental and physical health problems who need ongoing multidisciplinary team assessments, review of medication and psychological treatments. Day centres with more untrained staff should have the long-term goals of ongoing social care support and daytime respite for carers for relatively stable patients with enduring mental health problems.

DAY HOSPITAL VERSUS COMMUNITY MENTAL HEALTH TEAMS: THE DEBATE

The lack of adequate scientific data concerning the effectiveness of day hospitals has led to both an enthusiasm for newer service models and, contrastingly, the more conservative approach of leaving the day hospitals as they are. According to Howard (1995), in favour of day hospitals for older people is the fact that carer support by day hospitals has been endorsed by the National Institute of Social Work[23]. Most psychiatrists with access to day hospitals find that they can be used to prevent inpatient admission and facilitate early discharge from wards. Howard mentions that day hospitals may increase carer strain, caused by preparing patients to attend day hospitals and disruption of normal routines. Other arguments include that there is no evidence that day hospital attendance delays or prevents admission of patients with dementia to acute or continuing care placements.

Ball (1993) reviewed the future of day care in old age psychiatry, in which day hospitals undertook a wide range of activities, ranging from acute management of functionally ill to long-term management of patients with dementia[24]. He noted that high levels of distress and depression were found among carers of patients with dementia and this could be relieved by attendance at a day hospital. Though claiming that models exist to examine the effectiveness and efficiency in day hospitals, he failed to give any examples, except to propose that their days may be limited with the coming of community teams working with small local units. To the present date, no randomized controlled trial of the two services in older people with mental health problems as been undertaken.

Day hospitals and day centres provide not only social contact for the elderly mentally ill, and support over crisis periods, but the former also provide treatment in the community. It is argued, however, that these are roles that community mental health teams could also be able to undertake. The community teams working with small local units would be able to target specialist care at groups of patients in need of support, and guidance to those carers providing for their ordinary needs[25].

The day hospital is no longer uniformly or unreservedly accepted as an essential service component in old age psychiatry[23]. Despite the wide use of day hospitals in old age psychiatry, debates still continue over the effectiveness of day hospital care, as it has not been well researched[6,26]. Fasey (1994), in arguing against day hospitals, highlighted the expenses, which included transport, capital investments and highly trained staff[6]. He questioned whether there could be a better and more cost-effective way of delivering the same service. An example he gave was the use of day centres with professional staff providing support and training to less skilled day centre staff. It was further noted that the stated aims of day care, such as delaying or preventing admission of persons with dementia and decreasing carer burden with daytime respite were not achieved[15,27,28]. However, 10 of the 155 day hospital patients with dementia followed up by Woods and Phanjoo (1991) were still attending after three years, indicating that day hospitals can serve long-term needs of patients and their carers[15]. Diesfeldt (1992) undertook a retrospective, longitudinal study of older people with dementia, involving a day care centre rather than a day hospital[27]. Over the five-year period of the study, 150 (67%) of the 224 patients admitted to day care died. At time of admission, 148 lived in the community, but by the fifth year, only 9 (4%) patients still lived in the community and 65 were in long-term care residential/nursing homes. This study highlighted the well-known fact that dementia is associated with increasing dependency and mortality. However, the outcome of day care is difficult to identify, in light of the fact that it was a retrospective, longitudinal, descriptive study rather than a randomized controlled one.

Hassall *et al*. (1972) and Arie (1978) have highlighted problems with day hospitals, including the fact that a high proportion of day hospital attenders had been inpatients[29,30]. This implies that the day

hospital failed to serve as an alternative to inpatient care, and is further supported by the findings of Greene and Timbury (1979) that significant numbers of day hospital attenders were admitted to long-stay care six months later[31]. In this latter study, most of these patients who went on to long-term care in a residential\nursing home or hospital had dementia and had been admitted because of their families' inability to cope, and their admission to day hospital was for, on average, six months.

Despite doubts about the usefulness of day hospitals, Corcoran *et al*. (1994) indicated that 71% of patients with functional disorders were managed effectively in the community with a combination of day hospital care and visits by nurses[12]. They also observed that day hospital attendance enabled thorough assessment and treatment, ensuring that only those with illnesses who could not manage in the community with maximum support were transferred into residential care.

The focus of shifting psychiatric care to the community, coupled with poor scientific evidence of day hospital care effectiveness, has resulted in support for community mental health teams in place of day hospitals[23]. In evaluating the multidisciplinary approach of community mental health teams to psychiatric diagnoses in the elderly, Collighan *et al*. (1993) noted a high degree of accuracy when compared to independent formal assessments and consensus diagnoses by research psychiatrists[32]. A total of 378 new referrals to a community mental health team for older people were assessed independently by the team and research psychiatrists. The research assessment consisted of a structured psychiatric interview, full medical and psychiatric history, physical examination and routine blood investigations. Level of agreement between team and research diagnoses was between 90% and 99%. This finding suggests that community multidisciplinary team assessments are at least no worse that those done by psychiatrists, and possibly more likely to flag up problems in non-clinical areas like housing and social support.

Community mental heath teams, like day hospitals, are staffed by nurses, occupational therapist, psychologists, psychiatrists and social workers[33]. The teams are said to provide care that is less focused on a hospital or institution setting[34]. However, it is uncertain whether they lead to benefit for seriously mentally ill people, their carers and society, with respect to how they function or behave[35]. Lives of carers, especially relatives of persons with severe mental health problems, may be disrupted by the high degree of dependency and uncertainty that care involves. The profile of mental health is frequently raised in the media when there is an untoward event involving persons with mental health problems heightening the negative attitude and fear of the public at large. Some of the problems of community mental health teams, and possibly day hospitals too, emanate from this, in that people frequently do not want mental health resources near their homes, or make relocation and employment of persons with mental health problems more difficult.

A review of the literature on the use of community mental health teams in the care of older people does not indicate a marked difference in outcome from day hospital care. In a follow-up study of older people with mental health problems, referred to four community mental health teams, Bedford *et al*. (1996) reviewed outcome after six months of referral to the teams[36]. They noted a poor outcome in patients with dementia, in that, over the six-month period, 22 of the 63 patients with dementia moved from living at home into institutional care settings and 11 (17%) had died. A recent systematic review of the literature by Hoe *et al*. (2005) found the evidence for the effectiveness of day hospital care for older people with mental health problems increasing[37]. It was observed that the day hospitals were effective in meeting the needs of patients.

THE FUTURE: INNOVATIVE DAY CARE AND DAY SERVICES

The National Service Framework for Older People is an essential component of the UK government's plan to develop health and social services[38,39]. Key components include care of people with dementia and depression; range of community- and hospital-based services that should be made available; emphasis on the need for integrated, joined-up care and highlighting of the need for specialist mental health services to provide outreach. These requirements are likely to lead to more integrated day services, involving health authority, local authority and voluntary agency jointly run day services, with outreach day care available in the community rather than residing on hospital sites. It has been observed that, despite the introduction of the National Service Framework for Older People, there are substantial variations in service provisions[40]. This may lead to the continued differences observed in day care provision as well.

Some recent innovative practices in day care have included the fast-track day hospitals providing rapid assessment and treatment of behavioural problems in dementia[41], and Alzheimer's cafés, run jointly between statutory and voluntary services providing support to carers of patients with dementia. Crisis Intervention teams, more commonly placed in Adult Psychiatry, are becoming more accessible to older patients, and dementia care multidisciplinary teams offering intensive dementia care at home are being established, preventing hospital admissions. These developments may lead to less reliance on day care.

The Meeting Centres Support Program (MCSP) integrates different types of support for persons with dementia and their carers. The programme focuses on persons with mild or moderate dementia living in the community, and their carers. It is offered by a small professional staff (2 or 3 professionals for 15 people with dementia and 15 carers) in social cultural community centres in the neighbourhood, which is why it is called the Meeting Centre Support Program. Studies comparing MCSP to routine day care have found the programme to be more effective in influencing the feeling of competence of carers, and appeared to delay nursing home placement, along with a positive effect on behaviour and depressed mood[42,43]. In a later study, aside from delay in institutionalization, MCSP proved more effective in decreasing psychological and psychosomatic symptoms in carers of people with dementia than routine day care[44].

In England, the drive towards creating more capable teams and new ways of working in multidisciplinary teams is leading to changing responsibilities and roles of various disciplines[45]. Other team members are expected to carry out psychiatric assessments, prescribe and be the responsible clinician, which were once considered the traditional roles of the psychiatrists. This may lead to a different picture of staff and skill mix in multidisciplinary teams in various settings such as in day care services and community mental health teams.

With the expected rise in elderly population, governments are going to look more closely at various innovative cost-efficient means of delivering health care. It is likely to lead to even more demands to assess the effectiveness of day care services and the need to make day care more efficient and accessible. A comprehensive and flexible mental health service is likely to best serve and meet the changing

needs of older people with mental health problems. The delivery of such care through multidisciplinary teams available in such settings as community mental health services, day hospitals and day centres will ensure the adaptability to meet varying needs of this group of patients.

BACKGROUND

All health and care systems have to address the difficult problem of providing appropriate treatment and care for people with severe dementia, who often have a complex combination of needs. This usually requires a variety of service provision options tailored to the needs of particular individuals and their families, which may include domiciliary support models, private care home and nursing home facilities and directly run National Health Service (NHS) nursing homes and NHS continuing care facilities. Within the UK system, services for people with dementia who have the highest level and greatest complexity of need are provided within the framework of 'NHS continuing care'. This has been technically defined as care for an individual whose treatment needs can only be met by NHS provision, usually meaning 24-hour specialist nurse input, with continuous overview supervision by an NHS specialist consultant. Depending on the needs of particular individuals and the service models in operation in different localities, this can be provided through intense NHS support for people in their own homes, through provision in private nursing homes with additional NHS support or through directly NHS-managed NHS continuing care units. Traditionally, these 'NHS units' were hospital wards, but the service provision has become more flexible, and the continuing care units are now more frequently stand-alone units, run by the NHS, but located in community settings.

This chapter is very much a personal view of the authors, highlighting the context of NHS continuing care and the key elements which the authors believe are essential to enable people to 'live well' with severe and complex dementia.

UK LEGAL STATUS OF NHS CONTINUING CARE

Various legal challenges have enabled refinement of the system and the models of care. Importantly, people who need NHS continuing care, whatever the setting in which that care is provided, receive the care free of charge. This is of course in complete contrast to care provision within the nursing homes, for which people contribute substantially to their financial cost using a means-tested formula[1]. It has, however, been clarified that NHS hospital trusts are obliged to provide adequate NHS continuing care provision in some form. This has led to several major changes in practice:

1. A widespread review of continuing care provision within individual organizations, and an increased flexibility of that provision, which by and large has been helpful and appears to have reduced the widespread dismantling of NHS continuing care provision that was previously occurring as part of achieving 'cost efficiencies'.
2. Setting up of review panels to consider all individuals referred for NHS continuing care to ensure that those individuals have sufficiently complex needs to require NHS continuing care rather than an alternative form of care such as that provided by private sector nursing homes.
3. Ongoing review of people receiving NHS continuing care to ensure that their level of need continues to meet the criteria for this type of care provision. This is a marked departure from the traditional philosophy, which was that NHS care provision was a 'home for life', and a change to a model where the expectation is that most individuals will achieve a reduction in the complexity of their needs as part of the treatment and care that they receive, enabling their needs to then be met within a private sector care facility.

The Alzheimer's Society presented a comprehensive review of the definitions, framework and criteria for costings in 2007, and updated in 2008 to include new legal precedence[1].

CONTINUING CARE NHS MODELS

Traditionally, NHS continuing care has been provided in dedicated inpatient ward environments. These wards still exist in some NHS settings but are poorly designed for the provision of care for people with severe dementia and often concurrent behavioural and psychological symptoms of dementia (BPSD). There are usually a limited number of private rooms, with dormitory facilities that make it difficult to respect privacy and dignity and to meet the needs of individual patients. In addition, the environments are not designed specifically for people with dementia, are often in a poor state of repair, are rarely 'homely' and infrequently have access to outside space. As a result, many NHS organizations have now either built or leased smaller, purpose-built units in a community setting, or set up contracts with private sector providers to offer NHS continuing care beds with an agreed level of NHS support. Although the provision of

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

better designed, more homely facilities is likely to be an advantage, there has been limited evaluation of either model.

WHICH PATIENTS ARE PLACED IN NHS CONTINUING CARE

The proportion of people residing in care facilities who have dementia has consistently increased over the last 20 years, with most reports over the last decade indicating that at least two-thirds of care home residents have dementia, even though only a quarter of care home beds are registered specifically for people with this level of need[2,3]. As a consequence, there has also been some blurring of boundaries between different types of care provision with respect to the needs of the individuals for whom they cater. For example, the proportion of people with dementia in nursing homes and specially register beds is not substantially different from that in 'ordinary care homes'[2–4]. There also appears to be a similar blurring of boundaries between the specialist nursing homes and NHS continuing care, with a similar proportion of people with a similar severity of dementia and comparable high levels of BPSD in both settings[4]. This possibly suggests that some people are being placed in private sector care homes when their level of need may require NHS continuing care, either within a dedicated unit or by providing much more substantial NHS support to enable the effective care of those individuals.

WHAT IS THE QUALITY OF CARE IN NHS CONTINUING CARE ENVIRONMENTS

There is an absence of published audit data or randomized controlled trials to provide a meaningful evaluation of usual NHS continuing care or novel models of care provision. An audit of 17 care facilities across the UK conducted in 2001 included 10 private sector residential or nursing homes and 7 NHS continuing care units[5]. Disappointingly, based upon daytime evaluation of well-being and activities, a similar pattern of impoverished daytime activities and poor overall well-being was evident in both care settings, and there was no evidence that NHS continuing care offered improved activities, well-being or quality of life for care recipients.

This does not reflect our anecdotal experience of clinical practice, and it will be increasingly important for more widespread evaluation of care using standardized approaches to measure overall quality of care provision, to enable benchmarking against the best care services and to enable continual improvement of professional practice and the quality of treatment and care provided.

Additional information is available from studies examining the transfer of people to different care environments when NHS continuing care facilities have closed. The primary outcome measure in these studies has tended to be mortality rates[6] rather than wider health outcomes, and the effects of relocation on older people with dementia are not straightforward, with conflicting findings reported in different studies. For example, some authors such as Robertson *et al*.[7] reported that disruption associated with the move was associated with higher mortality among residents after the move, while others found no increase in mortality or health problems[8]. However, two consistent findings did emerge from the literature relating to the relocation of older people with mental health needs. Firstly, that the moving of patients and staff together ('en bloc') minimizes disruption associated with the relocation. Secondly, that an individualized and comprehensive preparation programme is vital in maximizing the holistic outcome for the resident.

In a more recent report examining relocation of an NHS continuing care unit within the South London and Maudsley NHS trust, 23 residents from an NHS continuing care facility were relocated, 9 residents underwent individual transfers over a 12-month period and 14 were transferred 'en bloc' to a new unit[9]. The baseline assessments included an assessment of quality of life, which indicated 'adequate coping' and suggested considerably better quality of life than had previously been reported among people with complex mental health problems residing in long-term care[10].

Importantly, the group of residents who were moved individually to new accommodation showed a significant decline in behavioural disturbance (as measured by the Neuropsychiatric Inventory), while the group who moved together to the new unit showed no change. This unexpected finding may be explained by the fact that considerable effort was taken to re-accommodate residents to locations of their and their relatives' choice. Those residents who moved away to new units were often situated much closer to their relatives, which may have provided greater opportunities for social interaction. This in turn may have had a positive impact on residents' behaviours. This does indicate that successful transfer of individual patients from NHS continuing care to other care environments can be achieved with careful planning and assessment[9].

Several studies have evaluated more specific models of providing NHS continuing care, such as the *domus* model. 'Domus care' is provided in small units based in the community, operating with core 'person centred' principles and a 'rites-based philosophy' that the domus is the person's home. Evaluation of this model has demonstrated advantages over traditional NHS continuing care settings[11]. In particular, BPSD and communication skills improved significantly among residents, although providing this type of care was twice as expensive as traditional models. While it is encouraging that good quality care can result in improvements in well-being and communication, it is unclear whether this is a specific feature of the domus model, related to better staffing ratios or an example of what can be achieved by motivated staff in a well designed environment. As a proof of concept it is, however, extremely important, as it demonstrates that it is possible to provide high quality care that meets the needs of these individuals.

The recent change in NHS continuing care to focus on 'rehabilitation' to reduce the level of need and enable transfer to other settings such as private nursing home facilities is contrary to the 'domus philosophy', and is likely to result in significant changes in care practice and the style of treatment and care. Further evaluations will be needed to determine whether this has a positive or negative impact on people with dementia living in these environments.

WHAT IS NEEDED TO PROVIDE TOP QUALITY NHS CARE

Provision of high-quality NHS continuing care for people with dementia requires a highly skilled group of staff, a well-designed, purpose-built environment and excellent links with other medical, social care and palliative care teams to provide a physical and social environment that can meet a broad range of need. Key areas include basic activities of daily living (ADLs), social needs, BPSD, transfer, mobility and reduction of falls risk, management of pain and concurrent physical health needs, feeding, skin care, other needs related to end-of-life issues, working with families and understanding the legal framework within which this care must operate.

UNDERSTANDING OF RELEVANT LEGAL FRAMEWORKS

The majority if not all of the people in NHS continuing care settings will lack capacity to make decisions regarding their medical treatment or long-term care. Many such individuals can be looked after in these settings under the general provisions of the Mental Capacity Act 2005 in the best interest of these individuals so long as their care regime is not considered to deprive them of their liberties[12]. Those whose care regime is so restrictive as to amount to deprivation of liberty will come under the new Deprivation of Liberty safeguards which can authorise detention in the individual's best interests for up to 12 months after 6 assessments (the main issues are highlighted by Behan in a Department of Health Document, 2007)[12].

Some individuals may initially be admitted to an NHS continuing care unit under the auspices of the Mental Health Act (see[13] for more detailed guidance on the 2007 Act), or such an order may be applied at some point during an individual's care. These are mainly patients who object to being looked after in such settings.

Specific decisions regarding resuscitation and other end-of-life treatment issues are complex and fall under various legal frameworks. Staff working within this sector therefore would need to understand a complex network of legal frameworks, and how to work within these frameworks to achieve a level of treatment and care that meets the best interests of the individual patient. At an organizational level this requires excellent training and processes, and at a unit management level requires excellent operationalization of these processes so that they contribute to, rather than hinder, good quality treatment and care.

SUPPORTING BASIC ACTIVITIES OF DAILY LIVING

Most people with dementia of a severity sufficient to require residence in a care home or NHS continuing care setting will require at least some assistance with basic self care, usually requiring help, prompting or supervision for washing, dressing and going to the toilet. The opportunities and skills to engage in other more complex activities such as cooking, making tea and activities outside the care facility such as shopping are likely to be limited by safety concerns, the organization of the care setting and the skills of the individual. With well-thought-through care plans and an appropriate level of assistance and supervision it is, however, possible to enable many individuals to take part in a limited number of more 'general' activities as part of supporting social needs (see subsequent section). In NHS continuing care settings this will vary hugely between different individuals depending upon the balance of complex needs. Some patients will have very severe dementia, while others may have dementia of moderate severity with additional BPSD and/or physical health care needs. A full assessment of every individual is therefore essential, working to the principle of maximizing people's abilities and competencies. Assessment tools like the Pool Activity Level[14] and the person's life story work[15,16] will inform the care planning process. As part of this assessment, detailed personalized care plans should be developed, outlining skills which it is important to enable people to continue using, self care activities which can be partly completed by the individual with appropriate prompting and help, and self care activities which need to be undertaken for the individual. In the latter circumstance it is also important to plan the support with self care in such a way as to maximize the opportunities it creates for normal social interaction, to minimize anxiety and distress, to make the assistance less challenging for the individual and reduce the likelihood or impact of BPSD (see subsequent section). Supporting an individual's basic activities of daily living is vital and requires good care planning, but would not on it's own constitute a level of need requiring NHS continuous care. When ADL needs are linked closely to other needs such as BPSD, skin care and feeding, the complexity of the 'need', and the skills needed to meet the 'need' effectively increase substantially.

Case Example

Mr Bell, a 65-year-old gentleman, was fully dependent on staff for all his needs. He was also bed bound. Whenever staff attended to his personal care, they would come out of his room exhausted and complaining that he was resistive and aggressive and it was 'a fight' caring for his needs.

But when Mary (staff member) attended to his personal care, she did not have the same experience. She would call him by his preferred name David, and explain to him step by step what she was going to do for him. She would inform him that she was going to wash his face before applying the wet flannel. She would also ask if he could relax his arm while she tried to take off the sleeve of his shirt. After much explanation and time taken with David in carrying out his personal care, Mary and her colleague would feel happy that they managed David's personal care without much struggle. David too looked comfortable sitting up in bed.

MEETING SOCIAL NEEDS

As part of statutory and regulatory frameworks and in developing care standards, the social needs of residents in care homes and NHS continuing care environments have been rather neglected. This is a major oversight as it is fundamental to everyone's well-being, and something which needs to be a key part of the care planning for every individual. People all have a large social need, which is frequently unmet in care settings. At as gross level, this is well evidenced by the fact that, based upon large studies of Dementia Care Mapping[17], people spend less than 15% of their daytime period engaged in social interaction or any other positive or enjoyable activity[5].

Often, the knee-jerk reflex to addressing social needs is to organize 'activities', usually games (e.g. bingo, a quiz), dancing/singing/music or an opportunity for reminiscence. In itself, if well planned, this type of activity can be very positive for residents who enjoy these types of event, but thought does need to be given to individual choice and to the development of more personalized care plans for every individual. It is rarely possible for 'Care home wide' activities to be undertaken more than a few times a week, and therefore, although a positive contribution to social need, they are generally a small contribution.

Talking to an individual, their families and friends to build up a life book, which includes details of their hobbies, interests, usual household activities and occupation, is an excellent way of learning more about each individual, developing material for reminiscence and for identifying specific individualized activities which may be beneficial or enjoyable for a particular person. A care plan can then be developed to create opportunities for specific activities that can be safely undertaken with the right level of support. Several excellent

research studies have shown the value of enhancing individualized care planning and individualized activities to improve well-being and reduce agitation[18,19].

Case Example

Ethel, an 80-year-old lady, would shout and scream every afternoon. The staff would play the same music (1950s songs); two of the residents would sing the songs, but Ethel would continue to shout loudly. Janet (staff) approached Ethel and asked her what was troubling her; Ethel just replied 'I am bored'. Janet asked her what she would like to do; Ethel replied 'push me around'. Ethel was chair bound and when she was well, she enjoyed going out for walks. Janet pushed Ethel's chair around the unit, into the garden and around the corridors of the unit. While Ethel was going round the unit and into the garden, Janet talked to her about the plants, flowers and pictures on the wall. Ethel would respond with 'that is lovely' or 'push the chair faster'. All the time Ethel was travelling around the unit, she stopped shouting and spoke quietly to Janet.

In addition, it is important to think about the environment: organizing chairs in a way that facilitates conversation; availability of 'coffee rooms'; providing a choice of television and radio programmes which is not over-loud or intrusive to other residents; providing interesting reading materials and objects for people to enjoy and which can facilitate conversation and reminiscence; providing adequate and interesting indoor and outdoor space to enable people to walk about in a safe and enjoyable way.

In people with very severe dementia, it is possible but more difficult to meet social needs. Again it relies on an individualized assessment, but often people may be more responsive to one-to-one interaction. Sometimes conversation or music may be perceived positively, but for many individuals touch is the most beneficial interaction – holding an individuals hand or an aromatherapy massage may, for example, give the greatest benefit.

Staff need to be encouraged to take steps toward positive risk taking when caring for a person with dementia. This will allow more creative approaches to care for people with dementia if staff are supported by management. Care that is collaboratively planned and managed by a multidisciplinary team after discussions with the person with dementia and their family will ensure that care provided is person centred.

Case Example: Individual Care Plan

John, a 70-year-old gentleman, used to be a dancing instructor. He would often walk up and down the corridor with his head bowed low. Staff had to listen very carefully to what he was saying, at times it was clear but, most times, his speech was muddled. But when staff offered to dance with him down the corridor, he would hold his head up a little, held good eye contact with the staff and, with a smile on his face, danced down the corridor.

MANAGEMENT AND PREVENTION OF BEHAVIOURAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA (BPSD)

Approximately 80% of individuals in NHS continuing care experience BPSD at any one time[5], and probably all individuals experience at least one of these symptoms longitudinally[20]. BPSD are almost always present and severe at the point of admission to NHS continuing care, and are the usually part of the complex need for which NHS continuing care is considered necessary for a particular individual. Aggression and restlessness are the most frequent symptoms, occurring in 60% or more of residents[5], but delusions and shouting are also frequent and problematic, while other less frequently occurring problems, such as sexual disinhibition and concurrent bipolar disorder, can be extremely challenging.

One of the advantages of working in a continuing care setting is that it affords a 'protected environment' with a skilled multidisciplinary work force, which allows time to conduct a detailed assessment and plan interventions carefully. A broad multidisciplinary clinical assessment can therefore be undertaken to inform any changes in treatment. As in any setting, the assessment includes screening for physical health problems such as infection, pain or dehydration, which are common, and often precipitate BPSD. A comprehensive review of pharmacological treatments may identify therapies exacerbating depression, other BPSD or confusion[21]. Visual and auditory impairment can also precipitate BPSD[22], and should be treated when possible. These principles are outlined in more detail by Lyketsos and colleagues (2006)[23]. A careful psychiatric assessment is also important, as specific psychiatric symptoms such as florid delusions or depression may be underlying or contributing to the presentation of other behavioural symptoms such as aggression or agitation. In parallel, a detailed assessment can be undertaken of the frequency and severity of any presenting BPSD and any associated risks to the individual, to other residents or to staff. An approach such as an Antecedent Behaviour Consequence diary can be used to clarify the pattern of occurrence and to identify triggers and re-inforcers.

The strength of this approach is that it provides an overall assessment of the situation, and allows medical, psychiatric and environmental precipitants to be targeted through specific treatments or care plans. It also provides an assessment of risk, which enables the team to carefully balance the risks and benefits of different treatment approaches, including the information to make a carefully weighted decision regarding whether pharmacological treatment is necessary. The assessment also provides the opportunity to get to know the individual and build up a 'life story' and develop a better understanding of the person's preferences by talking to the individual, their family and friends. This enables their needs to be met more effectively, improves communication and interpersonal relationships between the person and the staff, engages the family and provides important information for the development of care plans and for specific non-pharmacological interventions for BPSD. Again, an advantage of a continuing care environment in this situation is that the multi-skilled staff group and NHS medical/psychiatric support means that a less invasive option can often be implemented as a first-line strategy, as detrimental outcomes can be rapidly contained and management plans can be revised quickly. In practice, the most frequent practical management problem is physical aggression occurring when an individual is being assisted with personal care. In our experience, with a careful ABC (antecedent behaviour consequence) assessment, good interpersonal skills and a well-thought-through care plan, it is usually but not always possible to successfully manage and improve

the symptoms and the 'personal care experience' for the person and the staff without recourse to pharmacological intervention. If pharmacological interventions are necessary, best practice guidelines appropriate for all individuals with dementia should be applied[24]. This is not discussed in detail here as the same principles apply to the management of dementia in general (for a review of evidence see[21]), but the principles should include limiting the use of atypical antipsychotics to short-term prescribing (up to 6–12 weeks) for serious management problems in most situations; the judicious use of other pharmacological interventions when appropriate, and the use of care and caution to limit multiple prescribing[21,24,25].

Case Example

Peter, a resident in a continuing care unit, was screaming whenever he was awake. The staff could see that he was distressed, but he was unable to communicate his reasons for his distress. The doctor prescribed antipsychotics to reduce his distress but the screaming continued. After much multidisciplinary discussion, it was decided to discontinue all medications except analgesia and to spend more individual time with Peter. The screaming stopped and Peter's distress was reduced to a minimum. To this day, we do not know whether the side effects of the medication were causing Peter's distress or the increased time spent with Peter alleviated his distress. The staff became more aware of the importance of observing for side effects of medication, especially for people who have difficulties in communicating verbally.

Paul, a resident in a continuing care unit, kept coming in to the staff office, especially at meeting times. This was disruptive to the staff as they had to stop their meeting to answer Paul's questions and requests for help. Reading through Paul's life story, the staff realized that he used to work as an administrator. The staff decided to make space for a table and chair in a corner of the dayroom. They left some paper and pens on the table. They informed Paul that the space was for him to do some work if he so wished to do. Paul sat at the table and wrote on the paper, occasionally he would go into the office but, most times, he would sit at his table writing or tidying up papers.

MAINTAINING MOBILITY AND MINIMIZING FALLS

Many individuals with moderately severe or severe dementia begin to lose independent mobility and even ability to mobilize with assistance. As mobility problems progress, even transferring from bed to a chair can be problematic. Mobility problems are likely to present even greater challenges in patients with motor disability related to vascular dementia and stroke or with other physical health problems impacting on the locomotor system, such as severe arthritis. Even in individuals who are able to mobilize, falls are a major clinical problem. Fifty percent of people with Alzheimer's disease fall over a three-year period, and fractures are extremely common[26,27].

There are, hence, a number of important challenges to maximize mobility and minimize fall risk. The importance of a multidisciplinary team is immediately evident. Good access to physiotherapy, consultation/liaison from Geriatric Medicine, robust assessment procedures and good quality person-centred care planning, focusing specifically on mobility needs, are all essential components. The assessment and care planning procedures will need to determine the level of support needed to enable walking and transfer, such as appropriate walking aids, assistance from staff and a programme to maximize skills, for instance ensure adequate time spent walking to maintain strength, specific exercises to help maintain strength and balance. These types of programmes are clearly beneficial among older people without cognitive impairment[28], although the evidence is less clear in the context of dementia[29]. Nevertheless, this probably is good practice, and will have concurrent benefits such as maintaining muscle strength and improving mood.

A careful assessment of fall risk needs to be undertaken for all individuals. Where possible, person-centred exercise and mobility programmes can then be developed which maximize benefits but reduce risk, for instance supervision needed when walking in outside spaces, or vigilance to ensure assistance during all walking. The assessment may also highlight the need for a more specific physiotherapy evaluation or a medical assessment of specific risks, for example syncopy; or additional measures to reduce risk such as protective underwear, well-fitting footwear, good lighting, corrected vision with spectacles and clear pathways.

For individuals who are unable to mobilize, but can weight bear to transfer from bed to a chair, similar vigilance is required in completing an assessment, an evaluation of risk and a care plan to promote maintenance of skills using practice and exercises. Maintaining the ability to weight bear and avoiding the need for a hoist is a major factor in maintaining some independence and is therefore a very important clinical objective.

Given the severity and complexity of problems in these individuals, even with the best practice and care, disability is progressive and many individuals will eventually lose their ability to weight bear. Under such circumstances a hoist will be needed to transfer a person from a bed to a chair or from a wheelchair to a sitting chair, both important to enable social interaction and to protect skin. Being transferred using a hoist can, however, be a frightening experience. Safely operating different hoists appropriate to the needs of the individual requires practical skills, but excellent interpersonal verbal and non-verbal communications to prevent and reduce fear and anxiety are also critical.

ASSESSMENT AND TREATMENT OF PAIN

Pain can be very difficult to assess in people with severe dementia, but has a massive impact on the quality of life of an individual and contributes to the emergence of other problems such as BPSD. Jiska Cohen-Mansfield and colleagues[30] have recently reported a series of studies developing clinical instruments to assess pain, and demonstrating clear benefits in behaviour and mood with the implementation of appropriate analgesia based upon these assessments. In clinical practice these instruments are an excellent and practical tool. Assessing pain also relies on a detailed knowledge of the individual. As a rule of thumb, if there is a possible indication of pain, or a physical ailment which is likely to be causing pain, our usual practice is to err on the side of providing analgesia, but in the context of careful evaluation of benefits.

ADDRESSING PHYSICAL HEALTH NEEDS

Many individuals living in continuing care environments have vascular dementia, providing the additional challenges of managing disabilities and providing rehabilitation for stroke-related impairments,

and providing optimal medical management of related cardiovascular disease and vascular risk factors. For example, there is accumulating evidence that good control of blood pressure, lipids/cholesterol and diabetes significantly reduces the progression of disability and cognitive impairment (e.g. PROGRESS 2001[31]). This again emphasises the need for multidisciplinary working and the importance of open access to geriatric medicine expertise and specialist clinics as appropriate for specific individuals.

More generally, many individuals with dementia in NHS continuing care have concurrent physical illnesses as part of the complexity leading to their placement in this type of facility. High quality treatment and management of these conditions may be important in stabilizing cognitive decline, but is definitely critical in reducing additional disability, minimizing associated pain and discomfort and maximizing quality of life.

Many individuals are on multiple pharmacological treatments, many of which are not well tolerated in people with dementia or which may impact upon cognitive function. Ongoing review of medication is therefore also a key part of good management. The National Service Framework recommends three-monthly medication reviews[32]. For people in NHS continuing care settings, informal medication review should probably happen more frequently, but a more formal three-monthly review is also good practice.

NUTRITION AND FEEDING

Maintaining good nutrition is an important part of maintaining health and well-being. In particular, minimizing weight loss is a key objective, and good nutrition will help to prevent skin breakdown and the development of ulcers. In addition, food is a major source of pleasure to most people and it is a potential opportunity to provide people with some pleasure and enjoyment. Food tastes often change with advancing dementia, and a preference for sweet food types is common. Many people also, however, continue to appreciate food consistent with their own culture, and occasional 'themed' meals may give an opportunity for group participation and other related activities.

Poor appetite or reduced food intake are common problems which need careful assessment and specific personalized care plans. Reduced appetite may be related to depression, physical illness or altered food preferences, all of which can be addressed if identified. Some patients may develop marked restlessness, sometimes of a severity which makes it difficult to encourage people to sit and eat meals or to drink adequately. Again this needs careful assessment to exclude bipolar illness or other specific causes, and may require specific pharmacological or non-pharmacological interventions.

As dementia progresses, a substantial proportion of individuals lose the ability to feed themselves. With a good care plan that assesses level of ability, people can be enabled to continue feeding. For example, providing just one implement of cutlery if coordination of more than one item is challenging, or the provision of finger foods. If diet is changed in this way, it is important to still think about the nutritional value and taste of the food. The Alzheimer's Society has provided a series of booklets which addresses these issues comprehensively[2,3].

Either because of very severe dementia or as a result of concurrent cerebrovascular disease, some individuals will lose or partially lose their swallowing reflex or their ability to coordinate swallowing. Under these circumstances, aspiration of food is a major health risk. In individuals where there is any level of concern, it is important that a careful assessment of swallowing is carried out. Often a specific care plan, such as having meals in a fully upright position, having a 'soft diet' and thickening drinks, will be sufficient to enable meals to be taken safely. In some circumstances, where even these measures are not sufficient to enable food to be taken orally, difficult decisions need to be made in conjunction with family members regarding alternative feeding methods and/or end-of-life care.

OPTIMAL SKIN CARE

Vulnerability of skin to 'break down', and the prevention and treatment of ulcers in pressure areas represent an enormous clinical challenge in the clinical care of people with severe dementia in continuing care settings, particularly in people with limited or no independent mobility, spending a substantial proportion of the day sitting or lying down. Nursing staff require expertise in prophylactic skin care, and access to specialist nurses when ulcers develop and need to be treated. Specialist beds and mattresses are needed for some individuals, together with a breadth of clinical expertise encompassing use of mattresses, management protocols and care plans and the use of appropriate dressings. In addition, the management of related pain/discomfort and infection is important.

END-OF-LIFE ISSUES

Although this may change to some extent as NHS continuing care evolves, and is no longer 'a home for life' for all residents, currently the majority of individuals receiving treatment and care in these settings will die within NHS continuing care facilities. There are many advantages to this, in particular that the staff know the individual and their family well, and understand the needs of the individual and the family members, and the person is cared for in a familiar and comfortable environment. End-of-life issues therefore need to be tackled proactively, so that the wishes of the individual and of the family can be met as far as possible with respect to resuscitation, other medical treatment issues and key care decisions. In addition, the staff group needs to be familiar with and have access to expert advice regarding best practice management protocols to manage pain, distress, discomfort and dehydration in terminal care situations, and to provide support as appropriate to family members.

Working with families: family members continue to be a vital part of people's lives even when they have severe dementia and are residing in NHS continuing care environments. As part of the initial assessment when people are first placed in NHS continuing care, the family can provide key information to confirm the past medical and past psychiatric history, and even more importantly are able to convey an understanding of an individuals personality, background, likes and dislikes, hobbies, occupation and other important considerations such as religious and cultural issues and how important they are as part of someone's life. This enables a 'life book' to be developed and enriches the opportunities to develop better, more personalized care plans that are better suited to meet people's social, cultural and spiritual needs.

Many family members feel disengaged when an individual moves into continuing care or a nursing home. It is important to break down those barriers and to enable people to play an ongoing and active part in the care and support of the individual with dementia, and to help the family, where appropriate, contribute to the implementation of care plans to meet social needs. It is also important to help the person with dementia to continue to feel that they are an important and contributing member of the family, for which links to all generations of the family can be very helpful.

Particularly when advanced directives are not in place, families also play a vital role in the best practice meetings to make key medical and care decisions.

CONCLUSIONS

Providing good quality care to people with complex needs and severe dementia is difficult and requires a multidisciplinary, multi-skilled team with excellent access to appropriate specialist services. Often NHS continuing care has been seen as a low priority, and investment in team development and skills has not always been at the forefront of service planning. As illustrated by specialist models and pockets of excellence, it is possible to meet the needs and enable a good quality of life for even the individuals with the most severe dementia and complex concurrent problems.

Applying the principles of the ten essential shared capabilities for the mental health work force in dementia care will promote care that is truly person centred[33].

Overview of Law, Ethics and Mental Health in Old Age

Julian C. Hughes

Northumbria Healthcare NHS Foundation Trust and Institute for Ageing and Health, Newcastle University, UK

INTRODUCTION

An overview should clarify how things fit together. Where there is a high degree of complexity, however, this might not be possible; or, at least, it might require some digging to unearth the connections. I am going to suggest that what we have to look for in law and ethics is coherence in terms of our patterns of practice. In addition, I wish to point to the notion of the person as being in some sense fundamental.

MORALS AND PRACTICE

Consequentialism and Deontology

Consequentialism suggests that whether an action is good or right depends on its consequences. The best-known consequentialist theory is utilitarianism, which states that actions are right insofar as they maximize happiness or pleasure and minimize the opposite[1]. If, for instance, it seems likely that Mrs Jones will kill herself because of her depression and we have good grounds to believe that she will enjoy her life again if she were to receive appropriate treatment, then treating her would seem to be the ethically right thing to do, even against her wishes. But this depends upon a careful assessment, because although compulsory treatment would seem to maximize happiness, such treatment must not be so unpleasant or upsetting as to cause her permanent discontent.

We can see immediately, therefore, how complicated things might become in pushing forward this argument. What if, for instance, it could be known for certain that Mrs Jones would never be happy again? Should she then be left untreated or at least not treated against her will? A legal issue, about her ability to make decisions for herself, arises and reflects the Law's emphasis on the rights of competent persons to control what happens to their bodies under normal circumstances. Generally speaking, it is only when a person is not 'of sound mind' that others are allowed and required to make decisions on the person's behalf.

To return to the case of Mrs Jones, just as utilitarians might argue that it is best to have a rule that people like Mrs Jones should be treated because this is more likely to maximize happiness (i.e. rule utilitarianism, as opposed to a focus on particular and individual acts, which is called act utilitarianism) so too we could more simply argue that we have a duty (*deon*) to treat Mrs Jones. We quite often speak of a duty of care, for instance, which carries with it the idea that this is something we must do – and the difference between this and utilitarianism is shown by the fact that we add 'whatever the outcome'. In deontology the consequences are not the main issue. What is at stake is how people should behave as rational agents in the world. Given some of our typical concerns as human beings – that we should have a basic level of certain sorts of good (warmth, clothing, food) – it can be argued in deontological mode that there is a duty, for those who are able, to provide these goods to people who lack them. Duties are sometimes thought of as being corollaries of rights. Hence, if a person has a right to be told the truth about his condition, we have a duty to be honest with him. A right to basic standards of care carries with it a duty to provide such care. A right to privacy entails a duty not to invade the person's privacy, to confidentiality a duty to maintain confidences.

Four Principles

In clinical ethics it has become commonplace, partly in order to avoid the complexity of the arguments that emerge in discussions of consequentialism and deontology, to use the four principles of medical ethics[2]. These provide an easy way to access the relevant arguments in connection with health care decisions. Autonomy, often regarded as the main principle, stresses self-rule: the person with dementia should still be able to make decisions for him- or herself. But the second and third principles, beneficence and non-maleficence, stress the need for carers to seek to do good for those they care for and to avoid them coming to harm. So, at some point, doing good for the person with dementia may involve taking over certain decisions in order to avoid harm. Perhaps, because of cognitive impairment, the person's money now needs to be controlled by someone else to avoid financial abuse. Finally, the principle of justice stresses the need to treat people fairly. So resources to help people with dementia should be distributed evenly, or at least in a fair manner (albeit what is considered fair in one political system may not be considered fair elsewhere).

The principles of medical ethics give us a framework within which to discuss moral dilemmas. One of the complaints about these

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

principles, however, is that they do not give us a way to decide between them. Perhaps someone thinks Mrs Jones should be left to make her own decisions about whether or not she commits suicide (i.e. her autonomy should be respected), while someone else feels that compulsory treatment would do her good (i.e. beneficence) and avoid her coming to unnecessary harm (i.e. non-maleficence). The difficulty of deciding between principles seems intractable.

Ethics of Care

In response to the messiness of moral decision-making in the real world, a new approach to ethics has emerged from practice[3]. Whereas the more traditional theories stress calculations of pleasure, rules and principles (they also seem to hold out the possibility of *definitive* answers), the newer approach stresses context and the nature of our relationships within contexts of care. The move from rules to relationships has been regarded as a key feature of feminist ethics. But there have been several such approaches – communicative ethics, narrative ethics, hermeneutic ethics, situation ethics – all of which stress the importance of person-to-person interactions and the nature of our interdependency[1,3]. For any given situation the key elements in deciding the right thing to do will be the nature of the communication, the way in which the stories of those concerned (the actors) interact, the meaning of the events viewed from different perspectives with different interpretations, and so forth. This can lead to the conclusion that there are no definite answers in ethics, because (for any given case) we shall always be told that it depends on the details of the context and the perspective. But, to my mind, this is too relativist, as if anything goes and nothing can be called right or wrong. Rather than say that no 'definite' answers can be given, I should rather say that the answers are not 'definitive' in the sense that they are not final and unconditional. They are revisable and open to new interpretation.

Casuistry

Being open to appeal in the light of new evidence is the approach of casuistry, which considers matters case by case, where the factual details of the case must be understood and those making decisions must immerse themselves in them, but where cases are then compared to sentinel or paradigm cases, where decisions have already been made[4]. Appeal is then made to appropriate moral principles to explain the important moral distinctions between cases, but it is always left open that decisions might be revised in the light of alternative information. Thus, the casuistic process underpins law, allowing a development of legal thought in response to new cases, but with reference to established principles. The same holds for clinical decisions, which tend to be (at one and the same time) both practical and ethical. As with other types of care ethics, casuistry pays attention to the fine-grained details of individual circumstances, which will have a determining effect on our judgements about what might seem either right or wrong in a given case.

Virtue Theory

Virtue ethics draws on a long tradition going back to Aristotle and is based on the idea that the right or good thing is that which the virtuous person would do[5]. Hence, in the case of Mrs Jones, it would be appropriate to look towards those we consider to be good (in the sense of virtuous) in order to decide matters. Although virtue ethics is a well-established ethical theory, it has much in common with the ideas that come from the ethics of care. This is partly because the very notion of 'care' reflects important virtues – compassion or charity – that lie at the heart of clinical practice. In addition, it would not be a virtuous thing to make an ethical decision in a particular instance without being aware of the details of the case.

Some people complain that making a decision about who is virtuous is just too subjective: we might differ in our opinions. This is true, but the fundamental claim of virtue theory is that there are features of the world on which we can agree, even if there is potential disagreement about how these considerations apply in particular cases. Thus, we can agree that we do well as human beings, we 'flourish', if we are brave, compassionate, honest, trustworthy, just and so on. We would not, after all, usually seek advice from someone whom we regarded as cowardly, malicious, dishonest or untrustworthy. In particular, we would want them to be prudent or to show practical wisdom, one of the other virtues highlighted by Aristotle, so that they had a good grasp of the ends at which we should be aiming in our clinical decisions and of how to achieve those ends. We might want to argue about whether a particular decision is just and compassionate, and we need practical wisdom to decide when, for example, to be brave; but in all such cases we are then arguing about the virtues and about what it might be to flourish as a human being. In a sense, then, virtue ethics stresses neither consequences, nor rules or duties, but what we *become* by what we do.

We shall do the right thing for Mrs Jones if we approach her with compassion, with empathic understanding; but we may be required to show steadfastness, to insist she is treated against her wishes on the grounds of our experience (or practical knowledge), which suggests that people with even severe depressions can be helped and that it is certainly worth trying to do so. Similarly, the person with dementia may require a good deal of honesty and integrity to be shown towards him in order that he might comply with decisions being made about his care. It may be that the manner of our dealings with those we care for is crucial and this also falls under the description of the virtues: we can do things in a way that shows basic human charity, or we can behave crassly.

Patterns of Practice

How does all of this come together in terms of our day-to-day actions and decisions? We do not, after all, routinely consider ourselves to be making ethical decisions. The emphasis on care and virtue ethics, however, helps to underscore the important point that clinical decisions are by their nature ethical: we cannot escape the reach of values in what we do, even in the case of making a diagnosis. An especially good example of this is making a diagnosis of mild cognitive impairment (MCI), which might seem like a benign activity, but is underpinned by a raft of value judgements and ethical concerns[6]. Hence, we should look at our normal patterns of practice since these provide evidence of our values and presumptions[3,7].

Does this mean, however, that just any old patterns of practice will do? On my view the clear imperative is that our patterns of practice should show both internal and external coherence[7]. Internal coherence relies on casuistry: does this decision in these particular circumstances cohere with similar decisions I have made in the past and, if not, what are the morally different aspects of the case that allow me to make the different decision? External coherence is based on acknowledgement of the virtues: does this decision square with the virtues? In other words, can I demonstrate that this is the sort

of decision someone would have to make in order to flourish or do well as a human being? In the next section, we shall gesture at how this might work in particular cases.

ETHICS AND THE PERSON

There is, however, one final plank to put into place, which concerns our notion of personhood.

Person-Centred Ethics

Since the seminal work of Tom Kitwood[8], the notion of person-centredness has become ubiquitous in dementia care. This is a broad notion that is, in fact, co-terminous with a number of other types of care: patient-, family-, relationship- and client-centred care all share a number of characterizing themes. They all emphasize: respect for individuality and values, attention to meaning, social context and relationships, an inclusive model of health and well-being, the importance of lay knowledge, the idea of shared responsibility, communication, respect for autonomy and the notion of the professional as a person[9]. Person-centred care, therefore, suggests a broad conception of the person, one that allows and encourages a holistic view, that sees the person as situated in a variety of fields (biological, psychological, social, spiritual, legal, cultural, historical and so forth) and also as an embodied agent: neither simply a disembodied spirit, nor just physical matter[10]. This is the broad view of the person that should underpin our thoughts about our patterns of practice. In occupying this place, it underpins the notion of person-centred ethics too; that is, an approach to ethics that places decisions and actions in the context of the person, where this context is drawn broadly. Some examples should help to make this plain.

Case Study 1

Mr Phipps lives alone and develops the delusion that he is being watched because a neighbour thinks he is a paedophile. He believes there is a conspiracy to kill him by poisoning his food. So he'll only eat food if he can be absolutely sure of its source. He becomes socially withdrawn and gradually loses weight. A decision will have to be made about when to intervene because he will not comply with medication or outside help, although he does not object to seeing health professionals.

The broad notion of person-centred ethics supports the view that Mr Phipps should be taken seriously. He needs to feel he has the support of those who want to help him. They must try to understand how he acquired his odd beliefs. It might be there is a way to pacify his concerns, partly by understanding his social and cultural background. But carers must take seriously his physical and mental health needs too. They will have to be aware that at some stage his physical health will be compromised by his behaviour and so compulsory treatment may become an option. In judging their practices with respect to Mr Phipps, health care workers should be considering the need to approach him with compassion, honesty and integrity. Without these virtues, their practice will not demonstrate external coherence. They might consider, too, how their management of Mr Phipps coheres with their management of similar cases. Why have they not yet used compulsory powers to enforce treatment as they have done before? Well, perhaps it is because Mr Phipps continues to eat so that his physical condition is not yet as precarious. Or perhaps they feel that they are slowly but surely establishing rapport–not achieved in former cases–which might negate the need for compulsory treatment. Thus, person-centredness and an approach that considers practice in terms of internal and external coherence provides room for a thorough account of the ethical justification for the actions taken, but always against the background possibility that things might need to be re-evaluated, either because of a change in Mr Phipps's state, or because of an alteration in the context that surrounds him.

In many places risk assessment has become the preoccupation of health care managers to the detriment of overall clinical care.

Case Study 2

Mrs Hayward has a moderate to severe Alzheimer's dementia and her family has taken the unhappy decision that she needs to be looked after in a private nursing home. She settles into the home quite quickly and soon becomes very friendly with a man, who also has dementia, whom she refers to as her husband (who had died six years previously). She frequently directs him into her bedroom and one day the staff find him there in a state of undress. A risk assessment concludes that she is at risk of being sexually assaulted by the man, so – since he does not have family whereas Mrs Hayward's have complained – he is moved to a different wing of the home.

This might seem like a perfectly reasonable solution to a potentially difficult situation and one that many health care professionals might endorse. However, it is important that we know the details of the case before we can make this judgement. From the mere outline of the story we do not yet know the thoughts of the main actors in this narrative. Even in the moderate to severe stages we know that people with dementia are able to convey meaning and present them-*selves* precisely as persons[11]. We need to take this person-centred view. On the same ground, we need to consider the value of the relationship for both Mrs Hayward and her friend. Even when people with dementia cannot make choices based on full recollection of their past values or wishes, they can still be valuers[12]. But this potentially sexual relationship is not the only relationship in which Mrs Hayward is situated, for the feelings of her family are not completely irrelevant to our estimation of what is right and wrong. They know more of her history, of her previous beliefs and wishes, all of which must be relevant. It is noteworthy that all of this takes us a long way from mere 'risk assessment', which should now be seen in the context of a fuller approach to the person as a whole.

Having taken a broad and detailed view of Mrs Hayward's standing as a person in this particular context, we can then attempt to judge the decision to move her friend against both

similar decisions we might have made in the past and against the broader canvas of the virtues. We need, at least (even if the answer will be negative), to ask whether there might have been a more compassionate or prudent way to deal with the problem. The legal framework for such a decision would be to assess the capacity or competence of those involved to make this particular decision and, if it is deemed they lack capacity, a decision should be made in the person's best interests. But the point has to be made repeatedly that this does not mean assessing her best *medical* interests, it means taking a broad view, which reflects the broad nature of our standing as persons in worldly contexts.

ETHICS AND RESEARCH

Making decisions for others and doing what is best for them are issues that come to the fore in connection with research. Many people lack capacity to consent to participate in research and research is often unlikely to benefit the person individually. This has led, therefore, to a good deal of consideration of the use of surrogates to make decisions for people who are incompetent. Some have also argued that advance directives might be useful as a way to record a person's competent wishes. A surrogate is usually approached to find out what the person is likely to have thought about entering research. And it is usually regarded as good practice to try to seek the person's assent even if they cannot give full consent[13].

For people who lack capacity to consent, research should only be on the condition that affects them. This reflects the principle derived from the philosopher Kant, that people should always be treated as 'ends in themselves' and never as mere means. If the person cannot consent, there should either be some likelihood of benefit, or any harm should be (according to the Mental Capacity Act that covers these matters in England and Wales) 'negligible'. Once again, however, judgements will need to be made about what is appropriate and in keeping with standard and acceptable patterns of practice. The requirement that ethical approval should be sought from an established research ethics committee is one way in which patterns of good practice can be assured.

CONCLUSION

This brief overview has attempted to show the connections that hold together ethics and law in connection with mental health care for older people. What we see are patterns of practice that derive their strength from their coherence. In one direction this points towards the internal coherence of our decisions and actions one with another, where differences need to be justified in terms of established moral precepts. In the other direction we are impelled towards the virtues, where our actions must cohere with those inner dispositions (the virtues) that help to define what would constitute a flourishing human life. Underpinning our understanding of our practices, however, is a broad and complex notion of personhood, which provides the context in which we make decisions.

This framework, it can be argued, forms the basis of a moral and legal approach to health care. It is especially pertinent to the health care of older people, where mental ill health increases the person's vulnerability.

This is most distinctly seen, perhaps, as the person approaches death. When palliative care becomes appropriate, our patterns of practice must tend towards an acceptance of the concrete realities of the situation and life should not be prolonged; but neither should it be shortened. For this would rock the basis of our established social and legal practices, predicated on respect for the dignity of the human person broadly conceived, which prohibit the taking of innocent human lives.

The US System of Geriatric Mental Health Care: Financing and Future Challenges

Stephen J. Bartels

Dartmouth Centers for Health and Aging, Dartmouth Medical School, Lebanon, NH, USA

INTRODUCTION

The ageing of the 'baby boomer' generation will result in nearly 15 million older adults with mental illness by 2030, dramatically challenging the nation's capacity to adequately serve this population[1]. Further compounding this challenge is a fragmented mental health service delivery system for older adults, a paucity of providers trained in geriatrics and insufficient financing of mental health services under Medicare and Medicaid[2,3]. Major financing and regulatory policy reforms are necessary to provide older adults with the array of services they need.

This overview of the US mental health services delivery system for older adults reflects the assumption that 'form follows finance'. In this chapter, we provide an analysis of the major issues pertaining to mental health policy and ageing, with a focus on: (a) financing geriatric mental health services and (b) future policy directions and challenges.

FINANCING GERIATRIC MENTAL HEALTH SERVICES

Medicare and Medicaid are the primary financiers of the US system of geriatric mental health services. Structured into the delivery of Medicare and Medicaid services are several key components including: (a) Medicare beneficiaries and expenditures; (b) Medicare's benefit design including fee-for-service and managed care arrangements; (c) the emergence of managed Medicare, the Balanced Budget Act of 1997 and Medicare Part C; (d) Medicare Part D prescription drug coverage; (e) dually eligible Medicaid and Medicare beneficiaries; and (f) Medicaid beneficiaries and expenditures. The following sections provide an overview of each area including historical context and current issues.

Medicare Beneficiaries and Expenditures

Medicare is a federally funded health insurance programme. It was enacted in 1965 under President Johnson to cover health care for the elderly. Medicare benefits expanded in 1972 to include coverage of the disabled and individuals with chronic renal failure. Approximately 95% of older Americans receive Medicare health insurance[4]. Medicare comprises the second largest social insurance programme in the United States after social security[5]. In 2008 Medicare expenditures amounted to $468 billion and covered 45.2 million Americans, including 37.8 million individuals aged 65 years and older[6].

Medicare's Benefit Design for Mental Health Services: Fee-for-Service and Managed Care Arrangements

Medicare consists of four components (Parts A, B, C and D). This section reviews the four components of Medicare along with legislation enacted to restore parity in the administration of Medicare mental health benefits.

The fee-for-service (FFS) Medicare insurance programme covering health services is composed of two components (Part A and B). Part A, typically referred to as Hospital Insurance, covers inpatient psychiatric hospital care (up to 190 days lifetime maximum) and partial hospitalization[7]. Part A also covers hospice and home health-care services. Part B, or Medical Insurance, covers medically necessary physician and related ancillary services.

Medicare reimbursement policies have historically posed challenges for older adults and disabled persons seeking outpatient mental health services. Prior to the mid-1980s, Medicare payment policies supported reimbursement for acute inpatient care while restricting payments for outpatient services[8]. Restrictions on outpatient services included a $500 annual cap for outpatient psychotherapy, in conjunction with requiring a 50% co-payment. The Omnibus Budget Reconciliation Act of 1987 (OBRA-87) increased the $500 cap for psychotherapy reimbursement to $2200, yet retained the 50% co-payment. OBRA-87 also exempted medical evaluation and management of psychotropic medications from an annual cap. Subsequently, the Omnibus Budget Reconciliation Act of 1989 (OBRA-89) eliminated the annual cap on psychotherapy, yet retained the 50% co-payment[9]. Sustaining the discriminatory policy of a 50% co-payment for psychotherapy services set the stage for the Stark–Wellstone Medicare Mental Health Modernization Act of 2001 aimed at achieving mental health parity. This act was essential to the future development and enactment of legislation that restored parity in the delivery of mental health services.

In honor of the late Senator Paul Wellstone, the Wellstone–Domenici Mental Health Parity and Addiction Act (MHPAEA) was enacted in October 2008. MHPAEA required equal coverage for

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

mental health and physical health care in group health plans by 2010. According to MHPAEA, equal coverage includes annual and lifetime limits, deductibles, co-payments, number of visits and other similar coverage requirements[10]. Although MHPAEA does not apply to Medicare beneficiaries, it does apply to Medicaid managed care health plans. Medicaid beneficiaries have access to mental health and substance abuse services at parity with other medical benefits[11].

Enactment of the Medicare Improvements for Patients and Providers Act (MIPPA) of 2008 restored parity in the delivery of mental health services to Medicare beneficiaries. Prior to MIPPA, Medicare beneficiaries were subject to a 50% co-payment for outpatient mental health services (but only 20% for medical services). Following enactment of MIPPA, co-payments for mental health services will be reduced to 45% in 2010, 40% in 2012, 35% in 2013, finally reaching parity with medical co-payments of 20% in 2014[11]. This legislation represents a major step towards eliminating the barriers that older adults face in accessing mental health services.

The Emergence of Managed Medicare, The Balanced Budget Act of 1997 and Medicare Part C

Managed care programmes were developed to control the escalating costs of delivering quality care to Medicare beneficiaries. This section provides an overview of managed care and legislation aimed at controlling Medicare expenditures. This section also includes a review of Medicare Part C.

The Balanced Budget Act (BBA-97) of 1997 made significant changes in the payment methodology to Medicare Risk Contracting (MRC) plans. Medicare Part C also introduced managed care alternatives to fee-for-service Medicare. In addition, Medicare Part C, or 'Medicare + Choice', expanded Medicare to health maintenance organizations, preferred provider organizations, provider sponsored organizations, religious fraternal benefit plans, private fee-for-service plans, point-of-service plans, PACE (Programs of All-Inclusive Care for the Elderly) and medical savings plans[12]. However, due to the Plans' inability to manage payments to providers, in addition to modest increases in Medicare plan payments, many providers left the programme. The result spurred an increase in premiums with a reduction in benefits[13]. New legislation became necessary to restore Medicare Part C and patient choice.

In 2003, President Bush signed into law the Medicare Prescription Drug, Improvement and Modernization Act (MMA) (Pub. L. 108-173). MMA expanded the role of private health plans through prescription drug plans and renamed Medicare + Choice to 'Medicare Advantage'[13]. The enactment of MMA enabled Medicare beneficiaries to choose from a variety of health plan options, including regional preferred provider organizations (PPO), health maintenance organizations (HMO), Medicare Special Needs Plans, Medical Savings Accounts (MSAs) and traditional fee-for-service (FFS) Medicare. The legislation also included a prescription drug benefit that allowed beneficiaries to choose among competing prescription drug plans. Although many Medicare Advantage plans offer mental health coverage to beneficiaries (coverage typically consists of a maximum of 20 outpatient visits and 30 hospital days per calendar year), most plans do not cover chronic mental illness in their standard benefit package. Despite the original intent of containing costs through competition by private insurance plans, Medicare Advantage has been characterized as government subsidization of health insurance companies at higher than average costs. In 2009, Medicare Advantage Plans have come under scrutiny by the Obama Administration as a potential source of savings[14].

Medicare Part D Prescription Drug Coverage

The major impact of MMA was the introduction of Medicare Part D and the provision of a prescription drug benefit under fee-for-service Medicare. The implementation of Medicare Part D was meant to protect beneficiaries from the increasing cost of drug expenditures and to reduce costs associated with the underuse of medications[15]. In this section the implementation of Medicare Part D is reviewed along with suggested strategies to improve the delivery of prescription coverage to beneficiaries.

The introduction of Medicare Part D was largely welcomed as a means to address a longstanding lack of coverage for prescribed medications, yet presented specific challenges in covering psychiatric medications. Approximately 25% of Medicare beneficiaries are treated with psychiatric medications[16] that are prescribed on a long-term basis. Some insurers, in an attempt to manage costs, initially provided Part D formularies with restrictions to discourage individuals with psychiatric disorders from enrolling in plans. Despite Part D guidelines intended to ensure patient access to prescribed medications, administrative tactics prohibited some beneficiaries from obtaining medication. Tactics included limited formularies, extensive use of prior authorization and step therapy requirements. Part D plans also included the preferred use of less costly medications, although many were inappropriate for older adults according to Beer's criteria[17].

Despite the welcome coverage of medication prescriptions, clinical providers experienced significant administrative burden with the implementation of Medicare Part D. For example, with some plans, every hour of direct patient care resulted in approximately an hour of administrative time[18]. Additionally, some psychiatrists reported making medication decisions based on whether exceptions or appeals would need to be pursued. Some also avoided patients whose care would entail higher administrative costs. These unintended consequences associated with the administrative burden of Medicare Part D have been cited as potential sources of compromised quality of care for some patients with psychiatric illness, an already vulnerable group[18].

Recent changes have been implemented to improve the administration of Part D. According to a 2009 Medpac-funded report the minimum cost for specialty tiered drugs was raised to $600 a month. Since long-term users of specialty tiered drugs reach the maximum relatively quickly, they also qualify for catastrophic coverage. Federal reinsurance limits the beneficiary's expense by paying 80% of costs once they qualify for catastrophic coverage[19]. Finally, the recently passed health-care reform legislation will result in removing the "donut hole" gap for covering costs of medications in excess of $ 2,830 and up to $ 4,550 by the year 2020.

Dually Eligible Medicaid and Medicare Beneficiaries

Some older adults are eligible for both Medicare and Medicaid benefits. This population of individuals is referred to as 'dually eligible'. This section provides an overview of the dually eligible population including estimates of expenditures for individuals with serious mental illness (SMI) (including schizophrenia, bipolar disorder and treatment refractory depression).

Many dually eligible beneficiaries are over the age of 65, have significant disabilities and often have fewer financial resources than the average Medicare beneficiary. According to a 2008 report by MedPac, dually eligible beneficiaries account for a disproportionate amount of Medicare spending. Dually eligible beneficiaries account

for 16% of Medicare beneficiaries and 25% of Medicare spending. Medicare spends 1.8 times more on dually eligible beneficiaries as compared to non-dually eligible beneficiaries. According to MedPac, $6212 is spent per non-dually eligible beneficiary while $10 994 is spent per dually eligible beneficiary. An assessment of total spending (including Medicare, Medicaid, supplemental insurance, and out of pocket spending) on dually eligible beneficiaries averaged about $23 554 per person in 2005. This amount is more than twice the amount of other Medicare beneficiaries[20]. Similarly, the dually eligible beneficiaries comprise a major portion (42%) of Medicaid spending[21].

A 2003 study of Medicaid and Medicare dually eligible expenditures indicated that the highest per capita spending was on older beneficiaries with schizophrenia. According to this report, dually eligible beneficiaries age 65 and older with depression cost roughly $27 850, while beneficiaries with dementia and schizophrenia cost $39 154. Conversely, beneficiaries in this age cohort without mental illness generated a per capita cost of $10 898. Per capita spending by diagnosis increases with age. This study indicates a greater service need and cost for dually eligible older adults (age 65 and older) with mental illness[22].

Medicaid Beneficiaries and Expenditures

While Medicare covers a portion of health-care expenditures for the elderly, the Medicaid programme also provides additional benefits and services to some older adults. This section provides an overview of this joint federal–state Medicaid programme which represents one of the largest public health-care insurers in the United States. Medicaid delivers health-care services to poor, blind or disabled individuals, including individuals with serious mental illness. People with SMI may also be covered by Medicaid. Total Medicaid expenditures in 2007 were $333.2 billion. In 2007 57% of Medicaid expenditures were federally financed (190.6 billion), while 43% (142.6 billion) were financed by state funding[23]. By mid-2007, 61.9 million people (one in every five people in the US) were enrolled in Medicaid. Spending on individual beneficiaries averaged an estimated $6120 in 2007. Although older adults and disabled people represent less than a third of Medicaid enrollees, almost three-quarters of the Medicaid budget is expended on this population of beneficiaries[21]. Adults 65 and older covered by Medicaid averaged $14 058 per beneficiary, while disabled persons averaged $14 858 per beneficiary[23].

A considerable amount of Medicaid spending is dedicated to long-term care services in a variety of settings. In 2006, approximately one-third of Medicaid expenditures were for long-term care, including care in nursing homes, as well as home and community-based services (HCBS)[24]. Although nursing home care for adults is an area that Medicaid is required to cover, states may choose whether or not to cover alternative models of community-based long-term care services such as PACE or services for older adults in mental institutions[21]. Medicaid is also accountable for a significant share of the cost of mental health services. In 2001 Medicaid payments comprised more than one-quarter of all mental health expenditures, including both private and public payers. No other payer, including Medicare, spent more on mental health services[25].

Variability in the structure and design of the Medicaid programme limits generalizations that apply to the entire system of care. Many states differ with respect to eligibility criteria (particularly with the dually eligible Medicare–Medicaid population), breadth of coverage for inpatient and outpatient mental health services, prescription coverage, arrangement of co-payments, pre-authorization guidelines for inpatient and outpatient services, and managed care options. A common attribute of most Medicaid programmes, however, is a 20–30% reduction in reimbursement rates for procedures and services relative to the standard fee-for-service charges[26].

Each state is provided the opportunity to administer Medicaid benefits in novel ways through the implementation of 1115(a) waivers or demonstration projects. The Secretary of Health and Human Services, via Section 1115(a), may approve demonstration projects that are time limited to test and evaluate entrepreneurial approaches to delivering and financing health care. According to the Centers for Medicaid and Medicare Services (CMS), many states use Section 1115(a) waivers to implement Medicaid. Various project areas include designing state-based models for eligibility determination, administration, delivery systems, coverage and benefits, quality assurance, access, systems support, financing issues, implementation time frames and evaluation. Demonstration projects typically last for five years and may be renewed for an additional period of time. Also, demonstration projects must remain 'budget neutral', meaning projects cannot cost the federal government more to implement the project than it would cost without the waiver[27].

FUTURE CHALLENGES IN MENTAL HEALTH POLICY AND AGEING

Over the past three decades policy and legislative endeavours have shaped the current financing and delivery system for older adults with mental illness. There are numerous future challenges in mental health policy that will require targeted efforts to meet the needs of an ageing America. Among the most pressing include: (a) Medicare's impending insolvency and health-care reform; (b) implementing integrated mental and physical health care and a true 'medical home'; (c) the changing landscape of long-term care on the increasing need for home and community-based options; (d) the ageing of the population with serious mental illness (SMI); (e) addressing the workforce gap in geriatric providers; and (f) bridging the gap between research, practice and policy.

Medicare's Impending Insolvency and Health Care Reform

According to a 2009 federal report, Medicare will be insolvent by 2017[6]. At the current growth in expenditures, Medicare and Medicaid are predicted to consume 15% of the gross domestic product (GDP) by 2040[28]. Part of the challenge of financing Medicare is directly associated with the demographic realities of an ageing US population.

Older age is associated with increasing episodes of acute medical care (including hospitalizations, surgical procedures and home health care). Older adults constitute a group that have a high risk for needing intensive and expensive services, resulting in 'adverse selection' for individuals with high insurance premium costs. For example, insurance plans (such as Medicare) that primarily target older adults are much more likely to selectively attract patients who present a higher financial risk, and less likely to have the capacity to spread the risk over healthier beneficiaries who are less costly. In addition, older adults disproportionately represent beneficiaries with low incomes. Approximately one-quarter of older adults are at or near the poverty level, including 16% living in poverty and an additional 9% living between poverty and 125% of the poverty level[29]. Finally, the shifting demographic profile associated with the 'greying of America' is resulting in growing numbers of adults reaching retirement age, at the

same time that there are proportionately fewer younger adults paying into the Medicare trust fund through employment contributions. When Medicare was enacted in 1965, there were approximately 18.2 older adults for every 100 working age adults. This 'old-age dependency ratio' is projected to climb to 20.9 in 2010, 27.0 in 2020, 34.9 in 2030 and potentially increase to 42.1 older dependents for every 100 workers in 2080[30].

In addition to demographic realities, the predicted insolvency of Medicare is also due to escalating health-care expenditures. Current reform efforts identify regional variations in spending that account for higher costs without better health outcomes. For example, from 1992 to 2006 Medicare spending (adjusted for inflation) grew 3.5% annually. By comparison, spending in Miami, Florida rose by 5%, contrasted with a 2.3% increase in Medicare spending in Salem, Oregon. Similarly, 2007 per capita Medicare spending averaged $12 100 in Manhattan, New York, compared to $6 700 in Minneapolis, Minnesota (31). Higher cost regions are generally associated with fewer primary care physicians, greater numbers of specialists, more spending on discretionary procedures, greater use of intensive care units in the last six months of life and poorer health outcomes[32]. *The Dartmouth Atlas of Healthcare* estimates that reducing annual per capita growth in spending from the current national average of 3.5% to 2.4% would result in a savings of $1.42 trillion, leaving Medicare with a positive balance of $758 billion in 2023 in contrast to the predicted $660 billion deficit[31].

Accountable Care Organizations (health-care systems that are rewarded for high-quality care and lower expenditures) have been proposed in the recently passed health-care reform legislation as one example of a potential model for achieving savings and improving care. However, the structure, financing and role of mental health care in plans for health-care reform will need to be identified to ensure compliance and the delivery of effective care.

Integrated Mental and Physical Health Care and the 'Medical Home'

Conventional mental health services have been organized and financed by 'carving out' care into separate settings, providers and financing that is distinct from general medical care. This separation has been promoted as a means to support the integrity and financing of specialty mental health care. However, it also has been identified as a potential barrier to holistic care that incorporates the interaction of physical and mental health in overall outcomes. Collaborative models of physical and mental health treatment have been proven to result in improved outcomes in primary care[33], home health care[34] and long-term care[35]. Older adults with depression who receive integrated care not only have lower aggregate health-care costs over several years of follow-up[36], but also indicate signs of improved survival, quality of life and patient satisfaction[2]. Studies have also shown that patients with substance abuse related medical conditions who receive integrated care have reduced hospitalizations, inpatient stays, emergency room use and medical costs[37].

A historical barrier to integrating mental and physical healthcare has been the lack of appropriate financing mechanisms. Prior to 1 January 2008, only physicians were permitted to use Current Procedural Terminology (CPT) billing codes that indicated time spent conferring with providers from other disciplines regarding patient care. New CPT codes permit psychologists and other non-physician providers to bill for integrated team conferences[11]. The next step needed in reforming billing is to allow for same-day billing of mental and physical health services 'incident to' a single primary care provider. This change will enable individuals to access physical and mental health care that is integrated, concurrent, co-located and simultaneously addresses the needs and preferences of the whole person.

'Medical home' is a term first coined by the American Academy of Pediatrics in 1967. In a medical home responsibility for care and the coordination of services is in the hands of the patient, family members, a personal medical provider and a medical team. The teams are formed according to patient needs and may include specialists, nurses, social workers, care managers, dieticians, pharmacists, occupational therapists and the community[38]. Key attributes of the medical home include: (a) the use of evidence-based practice and clinical outcome tools to guide joint decision making; (b) an organized process of care coordinated under a single primary care provider that incorporates principles of the Chronic Care Model (CCM); (c) development of an integrated plan of care that connects patients and families to a team of support; and (d) delivery of advanced care through multiple venues including face-to-face, email and telephone communications[38]. Research suggests that medical homes have a significant impact on societal health as they improve medical standards, patient experiences and outcomes[38]. The use of medical homes in the delivery of integrated care may further improve outcomes for older adults with SMI. Policy makers will need to promote greater integration of mental health in primary health care and inclusion of mental health providers in the development of primary care delivery modelled on the concept of a 'medical home'.

The Changing Landscape of Long-Term Care: Home and Community-Based Options

The Olmstead decision enacted by the Supreme Court in 1999 regulated federal policy regarding the inappropriate and unnecessary placement of individuals with disabilities into institutions[39]. States were required to assess thousands of individuals living in psychiatric institutions and nursing homes to conclude whether they could receive care in a community-based setting[40]. However, the lack of community-based residential options for older adults with serious mental disorders is a barrier to complying with the Olmstead mandate[41].

The increasing demand for alternatives to nursing homes is demonstrated by the development of continuing care communities, assisted living facilities, home health-care options and community-based ageing network services. Despite the growing demand for home and community-based services (HCBS), occupancy rates at nursing home facilities have remained constant between 2002–7, and 73% of long-term care Medicaid dollars went to nursing home facilities in 2007[42]. Medicaid spending on HCBS was reported at $17 billion for older and disabled persons while nursing home spending totaled $47 billion. However, the proportion of Medicaid expenditures for HCBS versus nursing homes varies considerably by state. For example, in 2007 New Mexico spent 61% of its Medicaid long-term care budget on HCBS. In contrast Tennessee spent only 1% of the Medicaid long-term care budget on HCBS[42]. Overall, Medicaid spending on HCBS has increased by 68% over the past five years as the number of older and disabled individuals receiving HCBS services has increased to 1.4 million in 2005[42]. The growing demand for HCBS substantially exceeds budgeted resources for home and community-based long-term care alternatives. For example, an estimated 90 000 people were on waitlists for HCBS waiver programmes in 2007[42].

To accommodate the future needs and preferences of older adults, health-care reform will need to shift financial incentives away from supporting nursing homes as preferred long-term care settings to provide incentives for developing an array of HCBS options. In order to be successful these policy initiatives will also need to include financing for integrated mental health services within home and community-based services.

The Ageing of the Population with Serious Mental Illness

The ageing of the population of persons with SMI is challenging state-supported services across the nation to develop and finance an array of services aimed at older adults with schizophrenia, schizoaffective disorder, bipolar disorder and treatment refractory depression. Per capita combined Medicaid and Medicare expenditures for disorders such as schizophrenia in older adults (age 65–74) are over 3.5 times greater than expenditures for dually eligible Medicaid and Medicare beneficiaries receiving services for a medical diagnosis only (without a co-occurring psychiatric disorder)[43]. One of the primary drivers of higher expenditures is the association of SMI with higher rates of institution-based long-term care. Nearly two-thirds of older adults with SMI are hospitalized or admitted to a nursing home annually. Middle-aged and older adults with schizophrenia are three times more likely to be admitted to a nursing home than adults without SMI[44]. Medicaid beneficiaries with schizophrenia are admitted to nursing homes nearly 13 years earlier than other Medicaid beneficiaries (age 65 versus age 78)[45]. Finally, adults with SMI have a 25–30-year shorter lifespan than the general population, presenting a dramatic health disparity associated with the need for improved health care and attention to prevention and health promotion as a core component of quality mental health services[46].

Effective interventions exist for older adults with SMI[47]. A reorganization of the mental health services system must take into account the leading factors attributed to high rates of institutionalization among the SMI population including: poor social skills and supports; high medical co-morbidity; and inadequate independent living skills. Mental health services that include age-appropriate psychosocial rehabilitation combined with physical care are likely to reduce health disparities and address the needs of older adults with SMI[48]. New integrated models of care for older adults with SMI will need to be developed and implemented that attend to the combined need for psychosocial rehabilitation and health care addressing the needs of the 'whole person'[47,49].

Addressing the Workforce Gap in Geriatric Providers

As the population ages, current demographic projections for the number of older adults with mental health problems or cognitive impairment indicate that the system of health care will become increasingly unable to deliver effective services to this population[50]. Conversely, projected declines in health-care providers with expertise in geriatrics will pose a serious challenge. For instance, over half of geriatric psychiatry fellowship slots went unfilled in 2006[51]. Recently, the Institute of Medicine (IOM) released a report that underscores the issue of a serious shortfall in the geriatric health-care provider workforce[2]. The American Association of Geriatric Psychiatry (AAGP) has suggested a follow-up study to advocate for loan forgiveness legislation, funding for the Geriatric Health Professions Program, and reform of Medicare to enhance mental health coverage[50].

Several legislative initiatives have been proposed to begin to address the shortfall in the workforce of geriatric health providers. In March 2009, the 'Geriatricians Loan Forgiveness Act' (H.R. 1457) was referred to the House Committee for review[52]. The Act would classify each year a person is enrolled in a geriatric training programme as a year of obligated service under the National Health Service Corp Loan Repayment Program guidelines. Individuals are entitled to repayment of $35 000 in educational loans. Another loan repayment bill, the 'Caring for an Aging America Act of 2008' (S. 2708) would include loan forgiveness as well as other incentives to attract and retain geriatric care providers into the workforce. At the time of this update both bills are under review.

Bridging the Gap Between Research, Practice and Policy

The gap between what we know regarding effective mental health treatment and the services currently offered by health-care providers constitutes a major challenge in improving the effectiveness and efficiency of health care[53,54]. Although a significant array of evidence-based practices (EBPs) are effective in the prevention and treatment of mental disorders[55,56], research has shown that it takes more than a decade to implement findings into the delivery of care[57].

Current initiatives from the National Institute of Mental Health (NIMH), the Substance Abuse and Mental Health Services Administration (SAMHSA) and the Administration on Aging (AoA) are focused on multiplying the availability and use of EBPs[58]. NIMH and SAMHSA have partnered to promote and support the use of evidence-based services in state mental health systems. These strategies and others must continue to expand in order to reduce barriers to implementing EBPs for older adults. Possible areas of focus include increased emphasis on interventions that are designed for use in real-world settings by real-world providers, development of financing options and incentives, improved educational opportunities for health and social service providers and improved understanding of effective dissemination and implementation strategies.

SUMMARY AND CONCLUSION

This chapter summarizes the major components of the Medicare and Medicaid programmes for older adults in the United States with attention to the delivery of mental health services. The most substantial changes to improving the delivery of mental health care to older adults have occurred through the implementation of recent legislation and programming including: (a) the Wellstone–Domenici Mental Health Parity and Addiction Act of 2008; (b) the Balanced Budget Act of 1997, and the Medicare Prescription Drug, Improvement and Modernization Act of 2003; (c) the implementation of Medicare Part D and the provision of prescription drug coverage to older adults; (d) the provision of coverage to beneficiaries dually eligible for Medicaid and Medicare benefits; and (e) the provision of long-term care to older adults through Medicaid, and 1115(a) waivers and demonstration projects aimed at encouraging novel home and community-based Medicaid services.

While the enactment of legislation and programmes have enhanced Medicare and Medicaid services for older adults with SMI, the system still faces many challenges. In order to improve the mental health services that older adults receive, attention must be paid to addressing: (a) Medicare's impending insolvency; (b) integrated care and the 'medical home'; (c) the changing landscape of long-term care with attention to home and community-based options; (d) the ageing of

older adults with SMI; (e) the workforce gap in geriatric providers; and (f) the gap between research, practice and policy. Timely and thoughtful attention to each of these issues will not only improve the delivery of mental health care that older adults receive, but may also reduce the current administrative and economic burdens associated with the delivery care. Addressing the future challenges of an ageing America will require innovative approaches to organizing, delivering and financing mental health services as a core component of general health care for older adults.

Geriatric Psychiatric Outpatient Care: The Private Practice Model in the USA

Elliott M. Stein[1] and Gary S. Moak[2]

[1]*Jewish Home of San Francisco San Francisco, CA, USA*
[2]*University of Massachusetts Medical School, Worcester, MA, USA*

In the USA, ambulatory or outpatient psychiatric care of individuals in later life is provided in a variety of public and private office settings. These include publicly financed community mental health centres, hospital-sponsored or university-sponsored outpatient clinics or services, the offices of psychiatrists (and other mental health professionals) in private practice, health maintenance organizations (HMOs, both privately and government-funded; the governmentally sponsored ones are now called Medicare Advantage plans) and others. This chapter will focus on practical aspects of providing psychiatric treatment to older Americans in office-based psychiatric private practices. We will not discuss the details of treatment in these settings, but rather the 'mechanics' of the process.

An important focus of community-based psychiatric ambulatory care is the need to create relationships with other community services and providers of care and assistance. This provides both a framework and a means by which many of the services are provided. Some of the barriers and obstacles to care will also be reviewed.

In providing community-based ambulatory care, the psychiatrists must have a comprehensive and patient-centred focus, following the patient to provide whatever psychiatric treatments are needed in whatever setting. While there are some geriatric psychiatrists who limit their activities to specific treatment locations, such as in offices or in-hospital programmes, this type of care may require the patient to be seen and treated sequentially in many places and circumstances.

INFLUENCES ON PRIVATE PRACTICE

For the purposes of this chapter, we will define private practitioners as independently employed or self-employed psychiatrists who work alone or in small groups. These practitioners provide treatment to patients who individually seek their help, and who pay for services received, primarily with Medicare health insurance benefits. Notwithstanding the current and ongoing, large-scale reorganization occurring in the American health care system, private practice remains a widespread model of medical practice in the USA. In many ways it has served as a starting point for the pattern of care provided in the other settings mentioned above. Many of the techniques discussed below are applicable to other models of treatment. Older patients seek care from private practitioners or other mental health providers with varying degrees of utilization and satisfaction[1,2].

Private practices are essentially private businesses, typically started, owned and operated by the individuals providing and/or supervising the clinical services provided. They may be small businesses, comprised of a single individual or several associated people, or they may be larger groupings of multiple people joined together to provide psychiatric/psychological treatment, or be part of a large medical multi-specialty affiliation. Such groups may grow to include dozens, or even hundreds of providers, becoming large businesses in the process. This chapter will focus on the smaller entities which are more typical and more common, although there are market forces which are encouraging practitioners to join together in larger groups to achieve both economies of scale, and to better negotiate with third-party payers of services, and other caregiving entities.

The private practice of medicine in the USA has evolved as a cottage industry within a historically unsystematized, free-enterprise, fee-for-service climate. Changing lifestyle preferences and demographics among young physicians are having some impact on this pattern. From its inception in 1965, the Medicare system had a built-in prejudice against the provision of outpatient psychiatric services. There was a discriminatory 50% patient co-payment requirement for all psychiatric treatment services delivered outside of an acute care hospital setting (unlike all other covered medical services, for which the patient co-payment is 20%)[3]. In 2008, this co-payment requirement was addressed by a new law which will gradually phase out the discrimination over a several year period until 2014, when there will be parity between payments for physical and psychiatric treatment[4]. This limitation on Medicare insurance coverage had constrained provision of these services to the elderly. Over the past 10–15 years, however, much greater influence has been felt from a multitude of other outside forces, at times impeding geriatric psychiatry practice[3,5], but in some cases expanding it. These forces (to list a few) include: efforts by the federal government to rein in Medicare spending[6,7]; the penetration of health maintenance organizations (HMOs) into Medicare; the advent of federal nursing home reform regulations; the growing presence of health care agency accrediting

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

bodies, such as the Joint Commission for the Accreditation of Healthcare Organizations (JCAHO) and the National Council of Quality Assurance (NCQA); the creation by the American Board of Psychiatry and Neurology of subspecialty board examinations in geriatric psychiatry; social attitudes (e.g. public attitudes about medical care and doctors, as well as about mental illness and psychiatric care); the influences of physician attitudes[8] and medical malpractice litigation[9]; the availability of newer psychopharmacologic agents (including their increased acceptance by the public and their increased utilization by primary care physicians); patient finances; and folklore and 'common sense' of both the professional and the general population. Geography also is a factor, as there is significant regional variation among practitioners and communities in different areas of the country, as well as variations in payment rates and public (Medicare/Medicaid) and private (HMOs and other managed care companies) monitoring and regulation. Some geriatric psychiatry practices have adopted the use of physician extenders, such as nurse practitioners or physician assistants, to enhance the scope of treatment options. Adaptation of geriatric assessment and treatment principles has been slow, for the most part, in private general and psychiatric medical practice. Nevertheless, successful practitioners need a working knowledge of these forces in order to function. As a field which is now well into its adolescence in the USA, there are a growing number of examples of psychogeriatric care models that have proven generally applicable. In fact, the fee-for-service system in the USA has thus far been a relative failure in geriatrics, since it has not incorporated many of the accepted principles of geriatric care[10]. Some varying approaches have been tried by practitioners, but most still follow the above-noted model. The incursion of managed care HMOs into the Medicare system held out promise to change this state of affairs. HMOs, in theory, employ methodologies such as integrated delivery systems, screening, prevention and case management that are ideally suited to geriatrics[11]. Their track record has been disappointing, however, and their approach to managing mental health care has been largely ineffective for the elderly. Managed care companies often 'carve out' the management of mental health services by subcontracting it to managed behavioural health care companies with specialized expertise in mental health benefits management[12]. Such companies rarely have any expertise in geriatrics, and do not appreciate its differences from general adult psychiatry[13]. These companies have often ageist attitudes built into their coverage utilization guidelines, and inappropriately limit treatment or completely deny it, especially involving members with Alzheimer's disease, which they do not view as a covered psychiatric disorder. To the extent that managed care has penetrated Medicare, this practice has made the practice of geriatric psychiatry more difficult, as the seniors enrolled in these plans typically may only receive services from health care providers who are contracted with them. This limits their access to care which might otherwise be available.

PRIVATE PRACTICE AS A BUSINESS

Another important factor in discussing this type of psychiatric practice is the previously mentioned idea that geriatric psychiatry is a business. As such, the patients are to be considered as customers. Furthermore, at times, other physicians, and additional referring sources, may also be regarded as customers. As such, it behoves the psychiatrist to organize the practice and to provide services in ways that answer the needs of these customers. The psychiatrist may help the patient to define these needs, provide information about them, alter them or aid them in various ways. The psychiatrist may need to refuse patients' requests when professional judgment dictates this. American consumers, especially the adult children of geriatric patients, are becoming more and more concerned about the availability of health care, its costs, its efficacy and its risks. At the same time they are becoming more educated and aware of health care issues and, due in large measure to the availability of health-related information from the internet, and other mass media sources, more knowledgeable about treatment options and risks, although this knowledge may be of variable accuracy. If the psychiatrist does not do a good job or does not adequately address at least some of the patient's needs (and/or their adult child's needs), the psychiatrist may lose that patient's business. The interaction between them, therefore, has aspects of an exchange of service for payment. Providing a comprehensive service, as mentioned above, is often very satisfying and helpful to patients. At the same time, the business opportunities for income are maximized. In a community-based private practice, people are often referred to the individual doctor, rather than to a hospital, a university or a public clinic where they may be assigned a doctor. Patients may be referred because of the doctor's quality of service, reputation or relationships with the referring party. These qualities therefore become significant aspects of the psychiatrist's success in business as well as clinical practice.

Important factors in satisfying the patient/customer include:

1. Cost: reasonable fees and/or helpfulness and knowledgeability in filling out insurance claims. Acceptance of the patient's insurance coverage in payment for the services.
2. Accessibility: convenient and comfortable office location and surroundings. The psychiatrist may decide to provide more services in more locations.
3. Availability: the availability of the psychiatrist to go to the patient if needed (e.g. to consult at a medical hospital if the patient is admitted by another physician for a physical ailment, or to see the patient at home, in a nursing home, or an assisted living facility) is very important. The convenience of the geriatric psychiatrist going to where the patient lives, rather than the patient coming to the doctor's office, is very attractive to family or caregivers responsible for transportation. Because of the time and effort, as well as the distraction from other activities, the viability of this form of practice, in private practice, depends upon the numbers of people who may need services in that area or location; sometimes arrangements can be made with facilities that ensure an adequate volume of patient visits for each trip to the facility.
4. Scheduling: flexibility to see patients at convenient times without excessively long delays in scheduling appointments. This is crucial, since many frail patients are brought by their adult children, who may work.
5. Communications: the ability to contact the psychiatrist quickly and easily at need (e.g. by telephone by the patient and, when appropriate, by the patient's family). This includes the willingness of the psychiatrist to return such phone calls quickly, and the friendliness and accuracy of the psychiatrist's secretary or answering service. It also includes the ability and willingness of the psychiatrist to speak to the patient (and family) about his/her symptoms, illnesses and treatments in a clear and patient manner.
6. Concern: the feeling that the therapist has a genuine interest and concern for the patient. This feeling of concern extends to the patient's interactions with the office staff. This is an especially vital factor for the older population[14].

7. Confidence: patients and involved family members need to feel that the psychiatrist knows what the patient's problem is and has an idea about what can be done. The doctor does not need to provide definite answers, but must indicate a grasp of the situation and some ideas for an approach to it. This helps to provide a structure to what is often a strange and frightening experience. Empathy with the patient's distress is very helpful in this, as is reassurance to the patient that his/hers is not the worst case the doctor has ever seen (a common fantasy).
8. Understanding: A related skill is being aware of and addressing, when needed, those concerns, preconceptions, prejudices, fears, needs, worries and expectations which may interfere with the provision of services to the identified patient; these can be the patient's feelings or those of the family member(s) involved. They may include fears of being controlled, a bias against doctors, psychiatrists, medications or hospitals, belief that the patient's problematic behaviour is wilful, concerns of financial worries, caregiver stress or the feeling that coming for help is a sign of weakness or failure, the presence of partial information, such as information gleaned from pharmaceutical advertising, news reports about medications, or the neighbour's experience with a particular drug, or the expectation that the doctor has an easy answer to the problem.

There are only limited data available on income and workload for geriatric psychiatrists as a group. For all psychiatrists, 1998 median annual gross income was $171 490 (a 3.5% increase from 1997), and annual net income was $118 630 (a 4.33% increase from 1997). This was the second lowest income of the 20 largest specialties (above general practitioners) surveyed by Medical Economics that year. The rate of inflation in the year 1997–1998 was 1.6%. Comparable 1998 income data for all US physicians show an annual gross income of $256 290 (down 0.7% from 1997) and a net income of $163 940 (up 2.2%); for non-surgical specialties, the gross income was $227 300 (up 1.7%) and the net income was $147 140 (up 2.4%)[15]. When these data are compared to the median annual net income for psychiatrists in the USA in 1989, which was $103 570 (the fourth lowest of 15 office-based specialties surveyed that year; the only doctors who made less were general practitioners, family physicians and paediatricians)[16], we find that the income of psychiatrists had risen 14.5% in that period. The median net income for all fields of medicine rose just under 25% during the same period, while the cumulative inflation rate added up to 35%.

Although most American psychiatrists see few or no geriatric patients, this trend is changing somewhat. There were over 5400 out of the over 36 000 members of the American Psychiatric Association who expressed an interest in geriatrics during their 1997–1998 Professional Activities (Biographical) Survey (unpublished data, courtesy of the American Psychiatric Association, 2000). The membership of the American Association for Geriatric Psychiatry has grown to over 2000 (unpublished data, courtesy of the American Association for Geriatric Psychiatry, 2009), and interest among general psychiatrists continues to increase. In 1991, the American Board of Psychiatry and Neurology first administered a Board Certifying subspecialty examination in geriatric psychiatry. As of December, 2008, there were 2953 individuals who have passed this examination (data courtesy of the American Board of Psychiatry and Neurology, www.abpn.com/cert_statistics.htm, 2009).

In 1996, 18% of American general psychiatrists had geriatric caseloads exceeding 20% of their practices[17]. Overall, in this 1996 survey of 970 responders, an average of 14.0–17.7% of their psychiatric patients were aged 65+, compared to 8.4% found in a 1987 study[18]. When psychiatrists who provide a higher proportion of geriatric services (more than 20% of their case load – HGPs) were compared to those who were low-volume providers with the elderly (less than 20% of their workload – LGPs), it was found that the HGPs spent proportionately less time in their offices (although still spending most of their time there), more time in hospitals and significantly more time in nursing homes, than LGPs[17].

In 2002, the National Survey of Psychiatric Practice[19] found the proportion of HGPs had increased to 26.0% of respondents, and 28.1% of respondent members of the American Psychiatric Association (a 55% increase from the 1996 survey). Of the HGPs, 31% were Board Certified in Geriatric Psychiatry. These geriatric psychiatrists saw approximately three-times as many geriatric patients and five-times as many patients with dementia as the non-HGP generalist psychiatrists. Nonetheless, most did not have exclusive geriatric practices. Of note is the finding of a wide range of annual incomes among the respondents.

The 2008 report of the Institute of Medicine highlighted the existing and future shortfall of geriatric medical care providers, including geriatric psychiatrists[19,20]. At that time there was calculated to be one Board certified geriatric psychiatrist for every 11 372 older Americans, and that, by 2030, if training programmes continued at their current rates, there would be only one for every 20 195 older Americans[21].

A significant impediment to the collection of data on the work done by geriatric psychiatrists and the income generated by this work has been the inability to differentiate those individuals who provide services to the older population from the work of other psychiatrists. The Medicare system has not differentiated general psychiatrists from geriatric specialists. In May, 2009, the Centers for Medicare and Medicaid Services (CMS), the United States federal agency which administers the Medicare programme, approved the creation of a specialty identification code for Geriatric Psychiatry (personal communication, American Association for Geriatric Psychiatry, 2009), as a recognized specialty, beginning in April, 2010. Individuals who choose to do so, may register with Medicare as having a subspecialty in this area. This will allow information to be collected as to the work load, diagnosis and treatment provision and income generated by these practitioners.

There may be changes in the future, but currently there are relatively low numbers of psychiatrists with a specific interest in treating the elderly. When the medical and general communities know that a particular psychiatrist is a geriatric specialist, there is usually no shortage of patients needing these services. However, at the time of this writing, the economic downturn in the United States along with the projections of future medical costs, together with the current governmental motivation to make changes in the nation's health care system, make uncertain the nature and form that medical care, and specifically geriatric psychiatry care, will take.

OFFICE PLANNING AND DESIGN[22,23]

Establishing a practice to treat older patients requires some attention be paid to the setting in which such treatment will occur and to factors that might act as barriers to treatment. Offices that can only be reached by climbing stairs, or those with varying levels into which one must step up or down, are difficult and potentially hazardous. Long corridors that must be traversed are similarly problematic. Chairs should be available that are sturdy and have armrests

and firm seats, high enough for ease in sitting or rising. They should be upholstered with waterproof and stain-resistant fabrics. Adequate lighting, readable signs and patient information literature should be planned with poor vision in mind. Interesting, recent magazines and a television in the waiting areas should be available for patients, and those who accompany and wait for them. Area carpets, spring-hinged doors and other possible hazards should also be considered. Toilet facilities and drinking water should be in reasonable proximity.

Mobility and transportation problems are another potential obstacle to treatment. Selection of an office location in a rural community, or in an area with poor public transportation or poor handicapped access may be factors. Convenient parking, especially in crowded urban areas, is necessary. Treatment may be interrupted during the winter months if the cold interferes with the patients' ability to get to the office. Some communities have senior transportation services, which will take people with limited mobility to physicians if reservations are made 24–48 hours in advance. Some hospitals may transport patients to and from the hospital or to physicians' offices located in adjoined buildings. Offices may also be located in senior retirement buildings or communities. Some senior living facilities will bring people to doctor's offices or medical centres. Clear signage on the exterior of the building and in the lobby areas and corridors will help the older patient find you.

THE BEGINNING OF THE RELATIONSHIP

Older patients seek out, are referred to or are brought to the psychiatrist's office for care. An initial 'gatekeeper' function may occur by means of enquiries (usually by telephone) into the reasons for the request to be seen, the age of the prospective patient, the referring source, the status of insurance coverage or other financial information. Such enquiries may lead a particular practitioner who prefers to specialize in geriatrics to decline to accept an adolescent as a patient, or to suggest that a patient being seen by another psychiatrist first discusses the idea of transferring with the current therapist, or to refer the patient to a geriatric psychiatrist in a geographically more convenient location.

A prospective patient, once given an appointment, should be told about additional information the psychiatrist would like to have available at the time of the first visit (e.g. the names of the patient's other treating physicians, current medications being taken, information about past psychiatrists, psychiatric medications, hospitalizations, past and current medical conditions). If the referring source is a physician, family member or a member of the staff of a senior-living facility, information from them as to the nature of the problem may be requested.

THE RANGE OF SERVICES

Among the most important services a psychogeriatric specialist can provide are diagnostic services. Too often, inadequate or erroneous evaluation leads to inadequate or erroneous treatment. A knowledge of physiology, psychology and the illnesses of late life, a comprehensive approach to history taking, assessment and testing and the ability to formulate an appropriate treatment plan form the basis of a unique contribution by geriatric specialists[24,25]. In fact, the ability to provide such a comprehensive evaluation and treatment perspective may be a primary reason why patients and referral sources seek the assistance of a geriatric psychiatrist.

An important aspect of the coordinated treatment plan is the collection of past information. With the patient's permission, contact is established with the patient's family, other physicians and therapists. To the extent possible, past records, diagnoses, psychological testing reports, doctors' treatments, psychotherapy records, laboratory and radiological reports are requested and reviewed. While not revealing confidential information, these contacts also benefit the patient by making the patient's other physician(s) and support system aware of your activities with the patient. This increases the likelihood that you will be notified of future problems that may occur and that other medical treatments will be coordinated with you by other physicians. In the absence of such relationships, physicians may call a different psychiatrist to provide treatment, due to lack of awareness of your involvement.

As has been reviewed elsewhere[23,26,27], including sections of this volume, older individuals can be suitable candidates for many of the therapeutic modalities provided to younger patients, including individual, group and family psychotherapies, which utilize insight-orientated, cognitive, behavioural and other techniques. Some approaches, such as reminiscence or life-review therapy[28], have more specific applicability to the ageing person. Modification of family therapy may be necessary, for example to address the role of adult children in assisting in the care of a demented or otherwise impaired parent.

Psychopharmacologic treatment of the elderly often requires alteration in the selection, dosing and scheduling of medication because of changes in absorption, distribution, metabolism, receptor sensitivity and excretion[29,30]. Once again, the geriatric psychiatrist may be sought out in recognition of this expertise by the patient and others involved in the patient's care. Pharmacoeconomic trends in the USA create additional conflicts for geriatric psychiatrists in private practice. Pharmaceutical costs are escalating rapidly in the USA compared to many other countries. Patients may have coverage under a Medicare Part D prescription drug plan, a voluntary federal programme begun in 2006. These plans are designed and administered by a number of private corporate entities. There are limitations and restrictions in expenditures and available drugs under these plans[31,32]. For example, benzodiazepines and barbiturates were not covered under the plans. The exclusion of these medications was changed in the 2008 Medicare legislation and will be available for prescription beginning in 2013. Treatment options may be limited by restrictive formularies designed with cost containment in mind, but often with limited consideration of the greater sensitivity of elderly plan members to medication side effects. Nursing homes have also adopted formularies to contain their costs, even in the absence of significant managed care penetration. Consultant pharmacists are employed by the homes to monitor physician prescribing, with respect not only to federal regulations but also to formulary requirements. Psychiatrists in private practice are thus often under pressure to prescribe less costly drugs or to run the risk of receiving fewer referrals from primary care physicians or nursing homes.

Sometimes assistance provided may be primarily educational, such as telling the patient or his/her family about the nature of the ageing process or the symptoms, prognosis and treatment of an illness. Treatment may be primarily informational, directing patients and carers to appropriate senior housing, services for the blind or hearing-impaired, continuing education programmes or volunteer work. At times treatment may be directive, for instance telling a patient to get a physical examination, buy a hearing aid or give up driving, or telling a family member to seek the assistance of respite services to provide some relief in caring for a cognitively impaired person, or to advise that the parent or sibling should no longer live alone. The community-based psychiatrist must develop expert knowledge of the available

community resources, as well as relationships with the providers of them.

The initial psychiatric diagnostic evaluation of the patient also is the time of the patient's actual evaluation of the doctor. The practitioner must address the overt and covert concerns, the anxieties and fantasies about the nature of geriatric psychiatry, the reasons why the patient is there and the treatments that will be instituted. Although these anxieties are not unique to this model, the need to address them is. Unlike treatment limited to one location or modality or situation, this relationship will be multifactorial and ongoing. Furthermore, a privately operating care provider is likely to represent an entry contact point into mental health care. If the patient and the associated significant family members are not put at ease, their questions answered and concerns addressed, the contact may quickly end.

Older patients are often novices regarding mental illness and its treatment. They are often fearful of being thought 'crazy' or of being 'put away'. Structuring the beginning of the initial interview can help relieve their anxiety. You may start with 5–10 minutes of specific questions, such as address, age, date of birth, concrete information on marriages, children, parents, siblings, education, employment, interests and so on. This can also give you a lot of information in a short time, helping to give a more complete picture of the patient. Simultaneously, you are assessing aspects of mental status and memory.

Treatment of the older patient includes the time when the patient is away from the office. The patient is helped when assured of the doctor's continued interest and care. This can often be achieved using relatively simple techniques: (i) providing specific information tells the patient that you know what is going to happen, for example 'This medicine is going to take two to three weeks to build up in your system. You may experience some side effects during that period but you will not experience the benefit for two to three weeks. You need to be patient during that time'; (ii) assuring access and inviting communication, for instance 'My telephone number is a 24-hour number. If you have any problems or need to reach me, you can call any time'. Patients rarely do call outside of office hours after being told this, but they feel very reassured; (iii) specific instructions for behaviour and for contacts; for instance, instead of saying, 'Call me if you have any problems', saying 'Call me next Tuesday' assures the patient that you want to hear from him/her. It also reduces the number of calls he/she might otherwise make before next Tuesday.

FAMILY INVOLVEMENT

Families are often interested and involved in the psychiatric care of elders. Relatives and friends can be important sources of information to the doctor. Interactions may include mediation and other interventions into the family system, reinterpretation and re-framing of past and present events, support, reassurance and education. Attention to family issues is especially important in treatment of patients with dementing disorders[33,34].

Because of the increased interrelationships and involvements some families have in an older patient's status and treatment, it is often vital to maintain contact and a positive rapport with the family. Also, patients will often request this. Conversely, when family members feel unnecessarily excluded or denied access to information, they can influence or disrupt the treatment entirely. This is not to imply that therapeutic confidentiality is not maintained; families generally understand this. They do, however, want to know that appropriate help is being provided. Such reassurance can have a positive therapeutic effect on the patient, as a reflection of the family's confidence in the doctor. It can also have the practical influence/effect of helping to keep the patient in treatment. Differing opinions among relatives may also be a source of potential disruption of the treatment. Patients will often give permission, or even request the doctor to speak to family members. Sometimes family involvement is necessary, such as in ensuring compliance with medications or appointments, or in providing observations of behaviour or of problems which the patient may not report.

In situations where there are no immediate relatives, non-kinship support networks become increasingly important[35]. The therapist may at times utilize the assistance of family surrogates in gathering information and in helping the patient. Where such networks are weak or absent, assisting the patient in their creation can be of great benefit.

RELATIONSHIPS WITH OTHER PHYSICIANS

In the absence of the formalized organization of a university environment or the planned hierarchy of a hospital or corporate structure, the geriatric psychiatrist in private practice must create or seek out relationships with other practitioners. This can be done through involvement in professional societies, participation in the activities of the community's hospitals and through non-medical social contacts. Eventually, further relationships will also be created by patients who seek psychiatric services and request that contact be established with their other treating physicians. Collegial relationships thus created can provide advice and assistance, help in monitoring the status of patients between visits to the psychiatrist and provide sources of referrals for new patients.

As noted previously, private practitioners may also consider other physicians as customers. They are often the ones who initiate, refer or make the appointments for their patients. They do this in the expectation that their patient's needs will be met. They may also feel that, by doing so, they relieve themselves of the burden of caring for that aspect of the patient's condition, therefore making their jobs a little easier.

RELATIONSHIPS WITH OTHER PSYCHIATRISTS

As with other physicians in general, private practitioners must create a network of relationships with other psychiatrists in the area, both near and far. Those at some distance, or whose special areas of interest or expertise differ, can be sources of referrals. Other psychiatrists may receive enquiries or have patients referred to them whom they are unable to treat; they may then direct them to you. Psychiatrists who practice in closer proximity may also be sources of new patient referrals, especially when their treatment interests vary from yours. Furthermore, a certain percentage of patients, especially those with chronic or recurring illness, may be 'doctor-shoppers' and spontaneously, or by referral, change from one practitioner to another over a period of time. Developing good rapport with other local psychiatrists helps in providing better care to these patients by sharing understanding of their needs, pathology and past successful treatments and by helping to avoid duplication of previously attempted unsuccessful treatments.

Formal or informal groupings of private psychiatrists may gather for continuing education and study, to help with supervision, second opinions or 'risk-management' of difficult cases, or to share tasks, such as psychiatric coverage for a local hospital's emergency room. When a private practitioner takes a break, to go on vacation or to a conference, it may be one or more of these local psychiatrists who

may help to provide coverage for patient care, who is asked to be available to take care of emergencies or to provide ongoing services to patients who are hospitalized at the time. Such coverage may be done reciprocally as a courtesy for mutual benefit, or may be by formal arrangement.

RELATIONSHIPS WITH OTHER PROFESSIONALS

Other professional care providers with whom privately practicing geriatric psychiatrists and their patients come into contact include psychologists, social workers, nurses, speech therapists, occupational therapists, private care managers, hospital administrators and the operators of day treatment programmes, and senior activity centres, nursing homes, assisted-living and independent living facilities, and other residential settings where seniors reside. Knowledge of these and other community resources is essential for the geriatric psychiatrist. At times the best treatment offered to a patient may be a referral to one of them. Needless to say, each of these can provide valuable services. As they get to know the geriatric psychiatrist, they can also be valuable resources; for example, they can be excellent sources of information about a patient's status and functioning when the patient is not in the doctor's office. They may allow the psychiatrist to provide more and better service to patients by helping to monitor, care for and carry out treatments with the patient. They can alert the doctor when problems are developing, often earlier than the patient might have, and can assist in the management of a crisis by supporting and reassuring the patient. These individuals are sources of referral to the practitioner. They will also speak to others in the community of their experiences and contacts with the practitioner. This is an important facet of how a professional reputation is made.

PROFESSIONAL ORGANIZATIONS

Working alone or in small group practices can be isolating. Involvement in local, regional, national and international professional organizations is yet another important aspect of private practice. These may be specific psychogeriatric, or psychiatric societies, or they may be medical or interdisciplinary. These associations provide mutual support, education and professional validation, and well as being additional avenues for networking and encouraging referrals of new patients.

RELATIONS WITH HOSPITALS

Each psychiatric programme within a hospital can have its own rules, regulations, standards, patterns of practice and pattern of relations with community-based practitioners. Some hospital facilities employ psychiatrists on staff; others may not. Some programmes are organized more in accord with the direction given by the hospital and the hospital-based staff. Others encourage more involvement in programme planning by the community staff physicians. Some facilities are sites for training programmes and have psychiatric residents and Fellows who provide services. There are some geriatric facilities within free-standing psychiatric hospitals and others that are geriatric units within medical hospitals; some are located in private, for-profit hospitals, or in non-profit or public or charitably funded institutions, or in university-affiliated programmes. While the rules, staffing patterns and required paper forms may vary from hospital to hospital, these variations are, for the most part, not so onerous as to be unworkable or impossible to deal with for the community-based practitioner. In some of these settings, the community-based practitioner may be able to influence the nature of the hospital's policies and treatment programme by participation in psychiatric departmental meetings and activities.

The differences among hospitals require some flexibility on the part of the doctor, but also may allow the possibility of tailoring referrals to the hospital most appropriate to the patient. For a variety of reasons, different hospital units acquire different patient populations and characteristics. Some programmes are age segregated, with specifically designated geriatric psychiatry wards. Others are age integrated, with younger and older patients sharing and participating in the treatment programme together. Some programmes may be more suitable for cognitively intact, physically healthy older people suffering from affective or anxiety disorders or relationship dysfunctions. Others may be more focused on evaluation and treatment of problems associated with dementia or delirium.

THE POSSIBILITY OF INPATIENT HOSPITAL TREATMENT[36]

At the time of the initial visit or at some subsequent time in the course of the treatment of an older patient, the psychiatrist may recommend inpatient hospital treatment. The process begins with an assessment of whether the hospitalization is something that would be beneficial and therapeutic but non-emergent, or is an urgently needed admission due to imminent danger to the patient or others. Immediately after this decision, the psychiatrist must decide whether the patient is capable of consenting to this plan. Depending upon the hospitals and resources available in the community, these assessments may lead to a decision to use a particular inpatient facility. For example, there may be one that can admit people on an involuntary basis, or care for people who are potentially suicidal or aggressive. Similar choices may result from the ability of a specific hospital's psychiatric ward to care for elderly patients who have concurrent severe medical problems, or who are wanderers, or who need the hospital's specific therapeutic approach. Other factors that affect the choice of inpatient service include locations of past hospitalizations, the hospitals used by the patient's other treating physicians, proximity to the patient and the patient's family to allow for visitation and, importantly, whether a particular hospital has a room available for the patient at the time it is needed, and whether the admission can or cannot be delayed until a bed becomes available. In some cases, where room is not available locally or at the time needed or where local facilities are not appropriate, referral for hospitalization may have to be made to a psychiatrist or facility elsewhere.

In the United States, at this time, there are multiple providers of health care insurance for the elderly. These include the Federal and State governments and a variety of private health insurance companies and managed care organizations (MCOs). Some health plans, especially the MCOs, may have contractual agreements with particular hospitals to provide care; this may dictate which hospital may be used for the individual's inpatient care.

ADMISSION TO HOSPITALS

Various hospitals and psychiatric facilities within hospitals may have different procedures for arranging admissions. Typically, the psychiatrist or his staff communicate with a designated person or office to make the reservation for admission. Information that must be provided at this point varies, but usually consists of the patient's

name, age, insurance information and admitting diagnosis. Some facilities may also wish to have information regarding the geriatric patient's ability to function in activities of daily living, mobility, signs and symptoms of the patient that warrant admission, a preliminary treatment plan, or the likelihood of the patient being a danger to self or others.

When the patient is admitted, each hospital's usual procedure begins. Administrators and nurses fill out forms. The patient is shown to a room, belongings are put away and the staff make the patient acquainted with the facility and programme of activities. At about the same time, the private psychiatrist is notified that the patient has arrived. If not already given, initial orders are requested. When the psychiatrist is not available to come to the hospital immediately, orders might be given by telephone to the ward nurse, addressing such needs as diet, monitoring of vital signs, laboratory tests, ward therapies and medications to be started and so on.

IN-HOSPITAL TREATMENT[36,37]

In-hospital treatments for the elderly can include the full spectrum of therapeutic approaches devised for psychiatric patients in general, although these might vary depending upon the resources and philosophy of the facility and the specific instructions of the doctor. The psychiatrist may personally provide individual psychotherapy, family therapy, psychotherapeutic medication management, electroconvulsive therapy, or other treatments, as well as ongoing diagnostic evaluation. At times the community psychiatrist may not provide all of the therapeutic services, and may seek the assistance of other professionals, such as utilizing a psychologist to provide psychotherapies. Many older patients also benefit from group, occupational, recreational and ward milieu therapies, physical therapy, speech therapy or reality-orientation/memory-stimulating techniques. The community psychiatrist may not be directly involved in these treatments; the hospital's staff members provide them as part of the hospital's programme and report back to the doctor regarding the patient's progress. Nurses, social workers and other staff members also inform the psychiatrist about the patient's status, symptoms, behaviour and reactions to treatment as observed during the day. Coordination, mutual understanding of achievable goals, cooperation and respect between the psychiatrist and the hospital administration and staff facilitate the psychiatrist's functioning and the treatment of the patient. It is vital that a good working relationship be achieved. If it is not, the doctor and the treatment can be undermined in numerous ways.

Working in the hospital requires flexibility on the part of doctors and staff. The staff must accommodate to various physicians and their styles of treatment. The doctors must adapt to the hospital and its programme, including its staffing pattern, its treatment approach and its physical plant. Patients may be seen at times under less than ideal conditions, including differing circumstances, locations, times and schedules (e.g. seeing a patient in a semiprivate room, planning hospital rounds to not conflict with group therapy programmes, visiting patients only to find that they are in physical therapy or getting X-rays).

POST-HOSPITAL TREATMENT

Planning for hospital follow-up begins during the hospital stay. The physician can direct the social service worker regarding possible directions and options for such problems as living situation changes, needs for at-home services, assistance or care, possible adult congregate-living facility or nursing home placement[38]. The social worker can investigate these and coordinate planning with the physician, patient and patient's family. Other post-discharge options the doctor can order include visiting nurses, physical therapy and other home health treatments or referral to a senior day centre or a partial hospitalization day programme[39,40]. The patient's needs, desires, finances and therapeutic considerations (including the options for follow-up treatment with the psychiatrist) are important factors in these choices. Similarly, the available, involved members of the family may have opinions or suggestions. They may also direct the psychiatrist's attention towards additional problems or issues they feel are significant.

An important part of discharge planning is the re-engagement of the patient in outpatient treatment in the psychiatrist's office. An appointment can be given at the time of discharge, or the patient may be instructed to make an appointment within a specified period of time. The psychiatrist makes certain that needed hospital records, including discharge summary, list of discharge medications, copies of laboratory and radiograph reports and medical consultation reports, are sent to the office. This enhances completeness and continuity of care. Use of electronic or computerized medical records, where available, can enhance this process.

In addition to other usual psychotherapeutic issues that can be discussed in the post-hospital treatment, it is important to include a review of the patient's reactions to the hospital, the symptoms that necessitated the admission and the patient's progress there. Also, it is important to watch for post-hospital regressions and symptom recurrences, as the patient returns to his/her usual surroundings or to a new environment. Medication compliance and monitoring is another post-discharge task that requires attention, especially if the medication is new, if it is causing some side effects or if it requires special care in its use (e.g. special diet or times of administration).

POST-HOSPITAL TREATMENT IN OTHER SETTINGS

As the American health care system has evolved, many patients who in years past were treated in hospitals for longer periods of time are now felt to have improved sufficiently as to no longer warrant an inpatient level of care, and are therefore discharged back in to the community or to facilities while still in need of some ongoing treatment. Others may be in need of treatment but are deemed suitable for the sub-acute level of care provided in a skilled or long-term nursing facility. This may also be done in an out-patient hospital or partial hospital programme, where the person receives some therapeutic services during the day and returns to his or her usual residence at night.

CONCLUSION

Community-based ambulatory psychiatric care is an evolving treatment area in the USA. Economic, political, medical and demographic forces are all having an impact on the provision of care. While aspects of the treatment of younger adults in the community are being applied to the care of seniors, modifications are important in order to more fully address the special problems and needs of this population.

The Medical Psychiatry Inpatient Unit

Maria I. Lapid and Teresa A. Rummans

Mayo Clinic College of Medicine, Mayo Clinic Rochester, Rochester, USA

Medical psychiatry inpatient units are specialized units designed to provide care to patients with concurrently active psychiatric and medical illnesses. These units focus on the integration of medical and psychiatric care and emphasize a disease model of psychopathology[1]. Two important distinctions of medical psychiatry units from traditional inpatient psychiatric units are: (i) the patient population; and (ii) the capacity to safely manage concurrent medical and psychiatric illnesses that cannot be safely handled on a homogeneous unit alone.

The patient population in a medical psychiatric unit by definition has both active psychiatric and medical illnesses. These co-morbid conditions can co-exist independently, result from a medical illness that causes or contributes to a psychiatric disorder, result from a psychiatric illness that causes or contributes to a medical disorder, or result from a psychiatric illness that requires psychotropic medication with potential to produce medical illnesses[2].

The clinical focus and the organization of medical psychiatry units across the country vary widely. Operations of the units occur either primarily in psychiatric departments or in medical departments, and rarely are they units with combined administrative ownership[3]. However, the existence of a medical psychiatry unit, along with its structural organization and model of care, is based on several factors. Overall institutional need is one factor. Access to medical beds in a general hospital can be impaired by length of stay if patients have co-morbid psychiatric conditions. Transferring these patients to a different specialized environment improves the access for medical patients who do not have psychiatric co-morbidity. Another factor is improving the overall clinical care of patients in the hospital. Patients with acute and/or severe psychiatric conditions can be managed better on a combined unit, rather than leaving patients on medical floors or transferring them to traditional psychiatric units, as medical psychiatry units have greater capability for handling both problems concurrently rather than sequentially. Additionally, many of the medical psychiatry units are more capable of dealing with geriatric issues since there is a growing number of geriatric patients with combined medical illness who also require special environments. As a result, medical psychiatry units that focus on geriatric care will become increasingly important as the United States population ages. This chapter will review the general administrative, clinical, educational and research aspects of medical psychiatry inpatient units. Much of the material is based on our own institutional model of a medical psychiatry inpatient unit within a psychiatric hospital, as empirical published data regarding these units are limited.

ADMINISTRATION

Some medical psychiatry units are based in academic medical centres with full-time faculty, while others are found in private hospitals available to physicians of any specialty (psychiatry, family practice, internal medicine and neurology) with admitting privileges. There are also medical psychiatry units in state hospitals for patients with chronic mental illnesses[4]. There are four types of medical psychiatry units based on level of acuity of medical and psychiatric illness[5]. Type I units primarily provide psychiatric care with a low level of medical acuity. Type II units include general medicine or medical subspecialty units associated with a psychiatric liaison service and provide low levels of psychiatric care to those admitted to the general medical setting. Type III and Type IV units provide care for patients with concurrent and more severe medical and psychiatric problems in a unified setting. Type III units provide care to patients with low to high psychiatric acuity, and medium medical acuity (e.g. a non-compliant, poorly controlled diabetic with borderline personality disorder; a hyponatraemic, agitated schizophrenic patient with primary polydipsia; or a depressed renal failure patient refusing dialysis). Type IV provides care to patients with low to high psychiatric acuity, and medium to high medical acuity (e.g. a patient with chronic factitious disorder/borderline personality disorder who injected him/herself with stool water and is septic; or a delirious patient with a pulmonary embolus; or a ketoacidotic borderline/anorectic/bulimic diabetic patient)[6].

Physical Structure/Layout

The physical environment of a medical psychiatry unit is designed to accommodate patients with medical needs, cognitive impairment, functional impairment and sensory deficits such as hearing or visual impairments. It should also provide safety for those with severe behavioural disturbances in the context of delirium, dementia or other psychiatric illness. Ideally, a medical psychiatry unit is a locked unit, with restricted and secure access for safety and to prevent wandering or elopement. Each bedroom and bathroom should have wall oxygen, an emergency cord and call light. For fall precautions, every bed should have a bed alarm and thin, soft padded strips on the floor to minimize impact of fall and fall-related injuries (these are commercially available). All doors, hallways and the entire unit should be handicap and wheelchair accessible,

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

with handrails, grab bars and safe flooring. A special tub or shower room is designed to keep patients warm, comfortable and safe while showering or bathing. Transfer equipment such as Hoyer lifts enable safe patient transfers with less risk of injury to patients (i.e. falls) and staff (i.e. back injury).

Medical psychiatry units have the capability to access and obtain essential diagnostic work-up required in evaluation of organic causes, including imaging, electroencephalography, electrocardiogram and other laboratories, procedures and tests. Other important distinctions of a medical psychiatry unit from other general psychiatry units include the capability to provide intravenous fluids and drug therapy, nutritional support such as total parenteral nutrition and feeding tubes, surgical wound and drain care, intravenous access and care of peripheral and central lines, oxygen support, dialysis and isolation[1]. Medical complications arising from electroconvulsive therapy (ECT) can also be managed on a medical psychiatry unit.

Overall, a medical psychiatry unit provides an environment that is pleasant and accommodating to a patient population with high levels of psychiatric and medical acuity, but at the same time has the essential elements that facilitate the rendering of appropriate medical and surgical services.

Admission Criteria

The focus of care of each medical psychiatry unit across the country is diverse, including elderly, neuropsychiatric or behaviourally disturbed patients, substance abuse, eating disorders, chronic pain, schizophrenia and even patients as young as 13 years old[4,7,8]. Similarly, there is a wide variation in sources of referral, including the general hospital, long-term care facilities (nursing homes, assisted living facilities, memory care units), emergency rooms, outpatient clinics, direct referral from community providers, and tertiary referrals.

Medical psychiatry units maintain a distinctive patient population by virtue of admission criteria[9]. Admission criteria are necessary to ensure that the specialty of the medical psychiatry unit best matches the medical psychiatric problems that require treatment. Criteria for admission specify age, acuity of psychiatric and medical illness, acuity of nursing care, skilled care needs, and other factors. Patients without any concurrent medical illness, or with medical illnesses that are chronic and stable and do not require active intervention, are commonly excluded. Those whose high acuity level of medical illness that exceed the capacity of a medical psychiatry unit to safely manage them on the unit are best admitted to medical surgical services, with the consultation liaison service providing psychiatric care appropriately. Patients with severe behavioural problems should be excluded if there is no available staffing or if the physical environment is inadequate to handle the behaviours. Admissions for psychosocial reasons, in particular severe dispositional problems unlikely to be resolved even with effective psychiatric treatment, should not be accepted[1]. A waiting list for admission to the unit should be maintained, and priority given to patients from other psychiatric units within the facility, and those from medical and surgical units in the general hospital.

Despite implementation of admission criteria or a priority system, some admission decisions can still be difficult. It is helpful to have a team (typically a physician and/or an advanced level nurse) review all referrals for admission to ensure compliance to admission criteria and to make gatekeeping decisions. Hospital administration should support the medical director's authority to decline inappropriate admissions. Inappropriate admissions are not unexpected, even with admission criteria in place. One study that examined admissions to a medical psychiatry unit that required transfer to medical-surgical units within 48 hours of admission due to acute changes in medical conditions noted that the acute changes occurred after admission and were not foreseeable, although more vigilant screening for pulmonary, cardiovascular, electrolyte and infectious disorders was recommended[10]. When inappropriate admissions do occur, mechanisms should be in place to correct the problem, such as facilitating transfers to a more appropriate unit.

The Multidisciplinary Treatment Team

A medical model of diagnosis and treatment is practised in a medical psychiatry unit, because the patients are not only psychiatrically but also medically ill. A multidisciplinary treatment team is necessary in order to address the complex needs of this patient population. Similar to other psychiatric inpatient settings, a medical psychiatry unit utilizes a multidisciplinary treatment team to directly provide comprehensive care to patients in a biopsychosocial model. However, medical psychiatric treatment teams have more experience and expertise in providing care for medically compromised and elderly patients with psychiatric problems. One possible model would comprise a physician trained in medicine and psychiatry, or another would be two physicians, one being a psychiatrist and one being an internist. If the model is a single physician, this person should be trained with subspecialty in psychosomatic medicine, geriatric psychiatry, neuropsychiatry, or combined internal medicine and psychiatry. If the model involves a second physician, preferably an internist with specialty training in geriatric medicine, that physician is dedicated to the medical psychiatry unit daily to provide initial and follow-up consultations, to help evaluate and manage acute and chronic medical conditions, urgent or emergent situations, and to conduct medical examinations for clearance for ECT or other procedures.

Psychiatrists commonly lead the multidisciplinary treatment team. It is important for the psychiatrist team leader to have sound medical knowledge of the various aspects of psychiatric interventions (psychotherapy, pharmacotherapy, ECT, behaviour modification etc.), efficiently coordinate patients' care, communicate effectively, and successfully handle or resolve conflicts within or outside the team.

The other core members of the treatment team include nurses, social workers, pharmacists, therapists and chaplains. The nursing staff is one of the most important factors in the successful operation of a high-level acuity medical psychiatry unit[5]. Medical psychiatry nurses should have particularly strong medical/surgical nursing skills. In fact, hiring medical/surgical nurses and training them in the care of psychiatric patients is often preferable. Social workers coordinate placement and liaison with community agencies, meet and provide support to family members, conduct family therapy, and perform a thorough psychosocial assessment. Pharmacists assist with proper medication administration, advising the treatment team of drug interactions, monitoring drug levels and medication reconciliation. Recreational therapists organize and coordinate aspects of the clinical programming related to leisure and recreational activities. Physical therapists are available to provide gait assessment, manage deconditioning, conduct exercise regimens for strengthening, and help improve deconditioning and mobility of patients. Occupational therapists serve many functions. They provide relaxation training and stress management training to reduce anxiety. They conduct safety and cognitive evaluations to help determine disposition planning.

They evaluate patients for activities of daily living (ADLs) and help with improvement of ADLs. Chaplains help assess spiritual needs and concerns, provide spiritual support to patients and lead spirituality groups.

While the psychiatric treatment team is the team that provides the primary care, other services and disciplines are consulted as appropriate. Psychologists provide consultation with personality assessment, neurocognitive assessment and recommendations for behavioural therapy. Other medical or surgical services readily provide consultation and assist management of specific problems.

Unit Operations

Teamwork between a physician medical director and nurse manager is essential in successfully operating a medical psychiatry unit. A medical director in a medical psychiatry unit balances the unit's need to fill beds with the need to screen for appropriate admissions, integrates medical psychiatric care, advocates for high quality of care, addresses financial and regulatory issues, and respects psychosocial and biomedical dimensions of care[11]. Both the medical director and the nurse manager lead a multidisciplinary service committee, comprised of representatives from other disciplines in the unit (nurse, social worker, recreational therapist, other allied health staff), which meets regularly to review operations and clinical issues, hear staff input or concerns, review new rules and regulations or systems changes, resolve conflicts between staff, review unit performance and satisfaction surveys, and discuss other administrative and clinical issues pertinent to the unit.

The costs of operating a medical psychiatry unit are high, and financial issues are significant. There are constant pressures to reduce costs and shorten hospital stays, but at the same time taking care of more medically ill patients increases costs and the amount of staffing requirements and nursing time. This in turn has led to patients with more psychiatric and medical acuity that paradoxically increases the cost, making many medical psychiatry units less viable long-term. Therefore, partnerships must exist to underwrite the up-front costs of care of these patients. This will be beneficial in the long term as it will reduce re-admission rates to medical-surgical hospitals and overall expense of care for patients with co-morbid medical and psychiatric problems. Additionally, medical psychiatry units can decrease the cost of care by shortening hospital stays in the medical-surgical hospital, reducing disability in patients by having the psychiatric co-morbidity in medical patients addressed, delivering better aftercare, and ultimately helping patients become more functional.

Clinical Programming

While medical psychiatry patients receive psychopharmacologic and somatic/biological treatment for their psychiatric illnesses, psychotherapeutic interventions are equally important and should be structured and tailored to the needs of the medical psychiatry patient. An example of how clinical programming can be structured during the day in a medical psychiatry unit is shown in Figure 126.1. Group activities are led by non-physicians, typically nursing or allied health staff. All aspects of the clinical programming are flexible to accommodate various levels of cognitive functioning as well as the physical limitations that are common among medical psychiatry patients.

Different types of group therapy are available, including psychotherapeutic (grief, support, problem solving, cognitive behavioural, reminiscence, spirituality) and psychoeducational (mood disorders in particular depression and anxiety, chemical dependence, coping skills, ECT, proper use of medications), as well as other kinds of therapy (occupational therapy: relaxation, stress management, time management, optimization of ADLs; physical therapy: gait assessment, conditioning, strengthening, mobility, transfers; and recreational therapy: crafts, games, socialization, and other recreational or leisure activities). Family members can be included in some activities. Individual therapy or counselling is available as needed. Community organizations such as a National Alliance for the Mentally Ill (NAMI) family group may be available for families to attend within the psychiatric hospital. Other forms of intervention include modified exercise, music therapy, pet therapy, and other sensory activities such as a sensory room available for use for those who need de-stimulation in a quiet and relaxing environment.

Factors that Influence Length of Stay and Re-admissions

Many important factors influence the length of hospital stay and re-admission to a medical psychiatry unit. One study examined factors associated with frequent admissions to a university-based acute geriatric psychiatric inpatient unit by dichotomizing patients into single versus multiple admissions, and found that the majority of re-admissions occurred within the first three months following discharge; and that being single, male and having bipolar disorder were significant predictors of rehospitalization[12]. Another study looking at predictors of psychiatric rehospitalization specifically among elderly patients found that re-admission was more likely for diagnoses of schizophrenia, bipolar disorder, depression and substance abuse[13]. The same study found re-admission to be different for mood disorders and non-mood disorders, with very short hospitalizations being associated with increased risk of rehospitalization among persons with a mood disorder. Often treatments can adversely impact length of stay and re-admission. ECT and many psychopharmacological agents are risk factors for falls in a psychogeriatric unit, increasing the length of stay. A similar but more recent study found several factors associated with longer lengths of stay among geriatric psychiatric units[14]. These factors include ECT and its unavailability on weekends; higher positive symptom scores on brief psychiatric rating scales following psychopharmacology complications; multiple prior psychiatric hospitalizations; court proceedings; consultation delays; and placement issues.

CLINICAL ISSUES

Overlap among the geropsychiatric, general medical psychiatry and neuropsychiatric patient population is more common than not. Geriatric psychiatry inpatient units are dedicated to serving patients who are 65 years and older, who have severe psychiatric illnesses that require psychiatric hospitalization. They may or may not have concurrent medical illnesses or high acuity. General medical psychiatry inpatients are adults of any age who require psychiatric hospitalization for acute psychiatric problems, with concurrent active medical problem or problems that need intensive medical care that cannot be safely managed on a general psychiatric inpatient unit. Neuropsychiatry inpatient units provide acute psychiatric care primarily to patients with dementia or active neurological problems that directly contribute to the psychiatric problem. Patients in a medical psychiatry unit are typically geriatric in age and have both co-morbid medical and neurological conditions (see Figure 126.2).

Common Conditions Treated in a Medical Psychiatry Unit

The conditions common to all three patient populations (i.e. geropsychiatric, neuropsychiatric and medical psychiatric) are organic mental disorders (delirium, dementia), mood disorders (depressive and bipolar disorders) and common chronic medical problems. Psychiatrically, depression is the most common condition seen in a medical psychiatry unit. Depression often complicates medical illnesses through medication interactions, side effects or non-compliance. Often, symptoms of depression mimic medical illness and pose diagnostic challenges. Sorting out these issues is a benefit on a medical psychiatric inpatient treatment unit. Untreated depression results in increasing rates of suicide, which is already a significant problem for the geriatric medically ill population. A study of psychogeriatric inpatient suicides in Australia found that compared to younger inpatient suicides, they are more likely to have depression and more alcohol misuse in pre-admission and intra-admissions suicidal ideation[15].

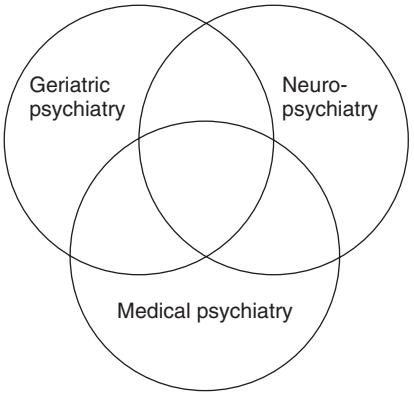

Figure 126.2 Overlap between geriatric psychiatry, medical psychiatry and neuropsychiatry patient populations

A survey of 11 academic medical psychiatry units reported that mood disorders and organic mental disorders were the most common conditions seen[16]. Other psychiatric diagnoses include schizophrenia, personality disorders, anxiety disorders, somatoform disorders, pain syndromes, drug and alcohol abuse/detoxification and eating disorders. These diagnoses are similar to those in traditional psychiatric units. The most common medical concerns were neurological and cardiovascular. However, most medical psychiatry units that treat older patients have a high prevalence of cardiovascular and respiratory issues.

Other medical psychiatry problems managed on medical psychiatry units include delirium, dementia and behavioural complications; psychiatric manifestations of neurological disorders such as stroke, epilepsy, Parkinson's disease and head trauma; medically complicated eating disorders; chronic pain; paroxysmal behavioural disorders of unknown aetiology; factitious illness; somatoform disorders; and physical illness combined with a complex family of psychosocial problems that interfere with the patient's ability to cooperate with necessary medical treatment[1].

Inpatient Evaluation and Management in a Medical Psychiatry Unit

A comprehensive and thorough evaluation of all active psychiatric and medical problems is the goal in the inpatient medical psychiatry setting, which leads to a similarly comprehensive treatment and management of concurrent psychiatric and medical issues in a unified setting. A multidisciplinary approach is essential in order to meet the complex needs of medical psychiatry patients. The highly supervised and structured environment in an inpatient setting allows care providers to closely assess and monitor a person's psychiatric and medical status, including mood, behaviour, thought process, appetite, sleep patterns, level of physical functioning, vitals signs and other physical parameters. It is possible to see fluctuations in any of these areas in such a closely monitored environment. Members of the treatment team have more time to obtain collateral information regarding a patient's history and recent events leading to hospitalization from family members, friends, local physicians or other care providers.

Diagnostic evaluation is efficiently completed, including laboratories, imaging and other appropriate medical and surgical tests. Because of medical co-morbidities in this psychiatric population, baseline electrocardiogram, complete blood count, electrolytes, glucose, liver function tests, renal function tests and thyroid stimulating hormone should be standard. Other tests should be ordered according to a patient's active symptoms. Medical consultations from dedicated internists (details above under 'Multidisciplinary Treatment Team') are standard, and other consultations from medical and surgical specialties are also easily available and accessible. Care conferences, treatment planning and discharge planning are held in the inpatient unit in a coordinated manner with input from all sides, including patients, families and treatment team.

All modalities of psychiatric treatment are available in the inpatient unit, including psychopharmacologic agents, biologic treatments such as ECT and psychotherapeutic interventions. Because of the frequently more complex discharge needs of medical psychiatric and geriatric patients as dictated by their clinical and psychosocial needs, intensive social work involvement is essential for effective discharge and aftercare planning. Family support throughout hospitalization, and even immediately post-discharge, is commonly provided.

EDUCATION

The medical psychiatry unit is a rich training ground for medical students, residents, fellows and students of other specialties and disciplines. From a medical student perspective, rotations in the medical psychiatry unit allow them to grasp the concepts of mind–body connection and also realize that psychiatry is indeed a medical specialty. Psychiatric residents gain competence in the management of patients who are very ill and have very complicated medical and psychiatric co-morbidities. Other students who rotate on medical psychiatry units include fellows in geriatric psychiatry, psychosomatic medicine and geriatric medicine; residents in neurology or internal medicine; and students from other disciplines, such as nursing, pharmacy, chaplain services and recreation therapy.

RESEARCH

Many issues can be explored more comprehensively on a medical psychiatry inpatient unit to allow us to provide a better value of care for such patients with these co-morbid conditions. The three most pressing issues that should be explored on a medical psychiatry inpatient unit are: (i) research on the interface among medicine and psychiatry, neurology and psychiatry, and geriatrics; (ii) research on treatment outcomes in this patient population to determine which treatments work well and which do not; and (iii) research on the cost effectiveness of providing dual treatment concurrent care rather than separate, fragmented sequential care.

SUMMARY

Medical psychiatry units serve a unique role in the care of the complicated patients who have both psychiatric and medical problems. In addition to clinical care, medical psychiatry units educate medical students to recognize the common interactions between these problems and geriatric patients. Residents and other physicians learn to integrate, rather than fragment, care in order to provide the best patient outcomes. Determining how the medical psychiatry unit can improve value and the overall cost of care is essential for viability.

ACKNOWLEDGMENT

The authors gratefully acknowledge Linda K. Smith, RN, our medical psychiatry unit nurse manager who provided valuable information regarding unit operations.

Psychiatric Services in Long-Term Care

Marc E. Agronin[1], Stephen M. Scheinthal[2] and Ashok J. Bharucha[3]

[1]*Miami Jewish Health Systems, Miami, and University of Miami Miller School of Medicine, Miami, FL, USA*

As the percentage of individuals living into their 70s and older continues to increase dramatically across most developed countries in the world, there has been a corresponding increase in the number of individuals living in long-term care (LTC) facilities. In the United States alone there are approximately 1.43 million residents living in nearly 16 000 nursing homes, and over 1 million residents in over 35 000 assisted living facilities (ALFs)[1]. Psychiatric illness represents one major reason for individuals needing the structure and assistance of an LTC facility. Epidemiological surveys indicate that at least two-thirds of all residents suffer from one or more psychiatric conditions, usually dementia, depression, delirium and/or behavioural disturbances[2]. A survey of LTC nursing directors in six states identified not only a pressing need for psychiatric services in general, but also highlighted the need for specific help with non-pharmacological approaches to resident management[3]. All of these figures suggest that competent, skilled provision of mental health services is fundamental to the well-being of these residents. As a result, there is a critical need for geriatric-trained psychiatrists and other mental health specialists to work in these settings. In addition, the myriad regulations that the psychiatrist must understand in caring for patients in a facility is constantly expanding. This chapter will review the potential roles of the geriatric psychiatrist, key clinical issues and the important regulations that guide practice in LTC. Although the regulations cited are specific to the United States, they represent approaches to quality of care that are relevant to international LTC settings.

Table 127.1 The roles of the psychiatrist in LTC settings

- Provide psychiatric evaluation and follow-up for residents
- Provide crisis management for residents (e.g. for suicidal, assaultive, abusive and homicidal behaviours)
- Initiate and oversee voluntary and involuntary hospitalizations
- Provide liaison for relevant mental health issues to administrators, social workers, MDS coordinators, risk managers, and other caregiving staff
- Communicate with family and other caregivers regarding resident mental health issues
- Conduct forensic evaluations of decision-making capacity
- Provide oversight for the use of psychotropic medications
- Maintain adherence to state/federal/national regulations
- Educate staff about psychiatric issues
- Administer or lead a mental health team
- Supervise ancillary mental health trainees and staff
- Participate in facility committees: medical staff, pharmacy and therapeutics, ethics etc.
- Assist the primary medical team in facilitating communication of complex medical, psychosocial, and safety issues with clients and their families
- Assist with end-of-life care decisions
- Conduct research studies
- Manage mental health programmes (group therapy, intensive outpatient programmes, memory centres etc.)

ROLES

The main role of the geriatric-trained psychiatrist in any LTC setting is to provide psychiatric consultations and follow-up care for residents. These consultations are warranted by the presence of psychiatric illness, by regulations that stipulate routine psychiatric surveillance of residents and monitoring of psychotropic medications, and by the need for risk management for situations in which potentially dangerous behaviours present. In addition, the psychiatrist may play roles in administration, education, clinical oversight and research. A summary of all potential roles can be found in Table 127.1.

Although it is rare for a psychiatrist to serve as the actual medical director of a facility, it should be clear from Table 127.1 that his or her multifaceted roles go well beyond being merely a consultant. In fact, the psychiatrist's deep immersion in the LTC milieu is critical to his or her understanding of the day-to-day dynamics of institutional care that impinge upon the well-being of residents.

The psychiatric consultant is also a key player in risk management. From the perspective of any facility, many situations that involve potential threats of harm to residents or that have the potential to incur substantial liability inevitably involve psychiatric conditions or the effects of psychotropic medications. Several of these circumstances are listed in Table 127.2.

One of the most critical roles of the consultant is to provide oversight for the use of psychotropic medications. As will be discussed

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Table 127.2 Psychiatric issues that increase the risk of harm and liability

- Poor safety awareness (wandering off from units, handling inappropriate objects, walking with unsteady gait)
- Suicidal threats, gestures or attempts
- Indirect life-threatening behaviours (e.g. refusing to eat, take medications or submit to life-sustaining tests or treatments)
- Physically aggressive/assaultive behaviours towards other residents and/or staff
- Sexually abusive behaviours
- Homicidal threats
- Risk of falling due to psychotropic medications (e.g. benzodiazepines, antipsychotics, sedative-hypnotics)
- Risk of severe psychotropic medication side effects, especially those related to antipsychotics (e.g. diabetes, severe weight gain, tardive dyskinesia, stroke, cardiac conduction delays and death)

later in the chapter, the use of nearly all psychotropic medications requires clear documentation of the diagnostic indication, implementation of concomitant behavioural strategies, judicious dosing and mandatory attempts at dose reductions for conditions that naturally have symptomatic remission.

Another important role for the psychiatrist is to educate LTC staff about common psychiatric symptoms and diagnoses, and how to initiate referrals and provide clinical data, recognize medication side effects and deal with behavioural disturbances. Any employee of an LTC facility has the potential to recognize psychiatric illness, ranging from nurses, aides, dieticians, therapists and social workers who provide hands-on care, to administrators who deal with complaints and crises, to kitchen and custodial staff who may form bonds with residents and notice early changes in behaviour. Thus, all of these individuals need access to the psychiatrist as well as training in the recognition and management of common psychiatric symptoms.

Communication with family members and other caregivers is one of the most critical and yet often neglected roles of the psychiatric consultant. Not only can these caregivers provide some of the most detailed and accurate clinical information, but they often aide the implementation of treatment plans, from encouraging residents to take medications and participate in activities, to simply providing essential care and companionship[4]. Working in partnership with caregivers helps to reduce caregiver burden that otherwise takes a toll in terms of their mental and physical health[5], and makes the LTC facility feel more like a community and less like an institution[6]. Ideal doctor–caregiver communication also serves a primary role in risk management for the facility, since it can mitigate feelings of anger, alienation and confusion when unfortunate events such as injuries occur – ultimately reducing litigiousness. In fact, such communication can engender realistic expectations of care in the LTC setting and even anticipate certain problems before they erupt. Several ways to optimize education and communication between the psychiatrist, staff and caregivers are listed in Table 127.3.

Table 127.3 Optimizing education and communication

- Staff in-sevices on Alzheimer's disease and other dementia types, depression and suicidality, anxiety disorders, behavioural disturbances, sexuality, sleep disorders, psychotropic medications and non-pharmacological management techniques
- Lectures to family and friends of residents on mental health issues
- Routine phone contact with caregivers regarding resident status
- Write educational articles for LTC facility publications and websites, and for local media
- Speak to community organizations that interface with the facility (e.g. guardianship associations, Alzheimer's Association)
- Sponsor memory and depression screenings at the facility or in the community

CLINICAL ISSUES

The entire spectrum of psychiatric diagnoses seen in geriatric patients is present in LTC settings, and requires the same approaches to diagnosis and treatment as in any other setting. One challenge for the psychiatric consultant is that there does tend to be greater medical and psychiatric co-morbidity in residents suffering from either acute delirium or chronic dementia – or both. There is also a greater concentration of psychiatric disorders including depression, dementia, anxiety disorders and schizophrenia compared to the community (see Table 127.4). Many of the same stigmas that limit adequate psychiatric care for elderly in the community will also apply in LTC, such as viewing depression or cognitive impairment as 'normal' in late life, or assuming that older personalities are more rigid, stubborn and treatment resistant[7]. All of these assumptions are incorrect and can prove discriminatory. Complicating the effects of these ageist views is the shortage of geriatric psychiatrists to consult in LTC settings, and the discriminatory reimbursement rates that have historically penalized psychiatric diagnosis (now being reversed by recent US federal legislation).

Table 127.4 Epidemiology of major psychiatric conditions in nursing homes[a]

Diagnosis	*Community prevalence (%)*	*Nursing home prevalence (%)*
Major depression	2–4	15
Depressive disorders	10–15	30–47
Anxiety disorders	11	20
Anxiety symptoms	20	40
Dementia (all types, ages 65+)	25	50–67
Schizophrenia	< 1	6

[a] Note: these figures are rounded off and based on approximate ranges from four sources[8–11].

On the other hand, individuals with psychiatric impairment living in LTC settings have a much greater chance of being evaluated in a timely manner due to mandated regulations. Medication adherence can be better monitored, and supportive staff and therapeutic activities are all on site. Thus, many of the barriers to treatment in the community, such as lack of transportation or timely access to mental health clinicians, do not exist in LTC settings.

The first and most fundamental trigger of psychiatric decompensation in LTC is the transfer to the facility itself. Whether they are coming from a long-standing home or an inpatient ward at a hospital, most new admissions have faced a recent medical or psychiatric stress or crisis and are no longer able to live alone. The psychological impact of the reason for admission and the unfamiliarity of the setting and its rules can be upsetting, especially for individuals who do not like living with others or have set routines that are now being disrupted. The psychiatric consultant must be attuned to the symptomatic manifestations of this stress, found in anxious and depressed moods, anger, agitation, resistance to care, disruptions in sleep and

Table 127.5 Recognition and treatment of adjustment reactions to LTC placement

STEP 1	Review profile and history of resident prior to arrival to anticipate unique needs and challenges (e.g. resident has complicated psychotropic regimen that should be reviewed and monitored from the moment of arrival)
STEP 2	Educate staff to recognize manifestations of difficult adjustment: nervousness, anger, sadness, social withdrawal, agitation, insomnia, anorexia, exaggerated physical complaints, resistance to care, poor rehabilitation
STEP 3	Develop admission procedures for social workers and nursing staff to collect basic psychiatric history as well as to screen for cognitive impairment and depression in order to identify individuals who need early intervention. Staff should be proactive about talking to primary care physicians or the medical director to write orders for psychiatric consultations
STEP 4	Obtain information about residents' interests and needs in order to best provide care and therapeutic activities. Ask family members to provide photos, room decorations, radios, televisions etc. in order to make the new room feel familiar and comfortable
STEP 5	Provide individual and group counselling for adjustment issues
STEP 6	Promote early and aggressive intervention for new psychiatric symptoms or the exacerbation of previous disorders

appetite, exaggerated somatic complaints, poor rehabilitation, and even failure to thrive. Although previous psychiatric history may be a key guide to diagnosis and treatment, the adjustment reaction itself must be addressed. Several ways to recognize and ameliorate this adjustment are listed in Table 127.5.

In general, the diagnosis and treatment of psychiatric disorders in older patients will be similar regardless of whether they live in the community or in an LTC setting. There are, however, a number of clinical features that are unique to LTC settings, summarized in Table 127.6.

The psychiatric consultant often has to work with family members and other caregivers who may be dealing with their own emotional issues over having a loved one in the facility. Strong feelings of guilt, grief and anger are sometimes displaced onto staff members, resulting in conflicts over care issues. Often these conflicts stem from unrealistic expectations of what institutions can provide and how quickly they can do it. In other situations the family or caregivers themselves suffer from psychiatric disorders that limit or distort their interactions with staff. A general rule of thumb is for the consultant to identify the next-of-kin or legally authorized representative of the patient and then communicate early on in order to obtain history and discuss the diagnosis and treatment plan. A team approach can help to optimize care and provide a consistent approach with difficult caregivers. Consultants need to avoid engaging in defensive or passive–aggressive approaches with these caregivers, such as not answering phone calls or arguing over treatment issues, since they will only worsen the situation and lead to further conflict.

In thinking about the provision of psychiatric services in LTC, an obvious question is: what is known about the models of mental health services delivery and the relative effectiveness of such models? A seminal review of the literature by Bartels, Moak and Dums (2002)[12] identified three relatively distinct models that merit mention: (i) a psychiatrist-centred model, (ii) a psychiatric-nurse-centred model, and (iii) a multidisciplinary team-based approach. The approximately 20 reports that examined these three models, however, were noted to suffer from serious methodological limitations, including (in the vast majority of cases) non-experimental designs, small sample sizes, lack of control groups and outcome measures that may not have been ideally situated to capture the model's effectiveness. Nonetheless, a few broad pragmatic themes emerged that appear to be relevant to clinical practice in LTC settings. Firstly, preliminary evidence indicates that nursing home personnel prefer regularly scheduled psychiatric visits with timely (and medically necessary) maintenance treatment follow-up[3]. Secondly, interdisciplinary, multidimensional approaches appear to be favoured over solo consultations. And finally, innovative approaches that integrate education and training with consultation, and offer hands-on advice about behavioural management in addition to neuropsychiatric diagnostic work-up and treatment planning are considered optimal.

REGULATIONS

For the last two decades, psychiatric care in LTC settings has been under increasing scrutiny from US state and federal governments. This scrutiny began in the 1980s when concern about the inappropriate use of psychotropic medications and physical restraints resulted in the adoption of Nursing Home Reform Amendments in the 1987 US Federal Budget Act, known as the Omnibus Budget Reconciliation Act of 1987 or OBRA '87. Final OBRA regulations came into effect in 1991[13]. OBRA '87 represented the biggest change in Medicare regulations since the programme was created in 1965. One mandate was the reduction and/or elimination of both physical and chemical restraints in nursing homes. Much of the drive to reduce the use of psychotropic medications came from the realization that many of them have potentially serious adverse effects, particularly extrapyramidal symptoms, tardive dyskinesia and neuroleptic malignant syndrome associated with antipsychotic agents.

The philosophy of OBRA is that judicious dosing and frequent attempts at dose reduction will prevent unnecessary use, reduce the frequency and intensity of adverse effects, and promote better surveillance and safety in LTC settings. The implementation of OBRA guidelines and their enforcement through routine surveys has resulted over time in up to a 50% overall decrease in chemical and physical restraints accompanied by a significant increase in the use of behavioural interventions[14,15]. Despite the enactment of these guidelines, however, documented physical restraint usage remains as high as 61% in some facilities[16]. Psychiatrists who work in LTC settings in the USA must understand OBRA guidelines in their entirety and be able to ensure their maintenance in order to optimize psychiatric care and avoid citations from routine surveys. A summary of these responsibilities can be found in Table 127.7.

Prior to an admission to a nursing home in the United States, state licensing agencies (under the authority of the OBRA regulations) must conduct a Preadmission Screening and Annual Resident Reviews or PASARR in order to prevent admission of people with developmental disabilities or severe, chronic mental illness. The PASARR regulation was set in motion in January of 1993. The PASARR screen needs to be conducted independently of a facility, and should be completed annually. To date, however, outcome studies of the PASARR programme have documented poor compliance

Table 127.6 Common psychiatric diagnoses and issues relevant to LTC settings

Diagnosis	*Relevant issues*
Major depression and depressive disorders	• Suicidal behaviours (may be indirect life-threatening behaviours) • Apathy that interferes with daily functioning • Failure to thrive (with weight loss, malnutrition, dehydration, and complication of co-morbid medical issues)
Alzheimer's disease and other dementias	• Disruptive and/or dangerous behaviours • Psychosis (delusions, hallucinations) • Postural and gait instability and risk of falls • Bladder and bowel incontinence • Risk of aspiration and pneumonia • Sensitivity to centrally active medications
Anxiety disorders	• Phobia of falling may limit ambulation and participation in physical therapy • Compulsive behaviours are frustrated by institutional schedules and lack of privacy • Panic attacks may involve physical and verbal agitation
Schizophrenia and other psychotic disorders	• Disruptive and/or dangerous behaviours based on paranoid,grandiose or bizarre delusions • Suicidality • Risks of antipsychotic side effects • Health and safety risks from excess tobacco use • Lack of appropriately structured therapeutic activities
Personality disorders	• Staff and family burnout due to excess demands and emotional and behavioural crises • Suicidal and homicidal behaviours • Loss of functioning and deconditioning due to excess dependency needs • Non-adherence with institutional rules, medications, and other treatments • Litigiousness

Table 127.7 A summary of the psychiatrist's responsibilities under OBRA '87 Interpretive Guidelines (USA only)

- Become familiar with OBRA Guidelines, including the use of the MDS and RAPs
- Be familiar with Beers criteria which list medications to be avoided since they involve a high potential for adverse outcomes
- Promptly provide comprehensive psychiatric evaluation for requested individuals in order to document: (i) current symptoms, (ii) diagnosis, (iii) potential causes, (iv) use of behavioural interventions, (v) justification for psychotropic and/or physical restraint usage
- Document required diagnoses and stay within OBRA designated dosing ranges when prescribing benzodiazepines, other sedative-hypnotics and antipsychotic agents (unless the rationale for higher doses is documented)
- For sleeping pills, daily use should be for less than 10 days unless a gradual dose reduction has been unsuccessful (and attempted at least 3 times within a 6-month period)
- For antipsychotics, benzodiazepines and sedative-hypnotics, consider and document a gradual dose reduction at least twice within a year (approximately every 6 months)
- For antidepressant medications, document appropriate diagnosis and attempts at gradual dose reduction if there is complete lack of efficacy or long-term symptomatic stability
- Attend regular psychotropic medication meetings at the facility with nursing staff and the consulting pharmacist to review psychotropic drug use and adherence to OBRA guidelines

with recommendations for alternative placement as well as with the implementation of new mental health services[15,17]. These findings highlight yet again the critical role of the psychiatrist in identifying residents in need of mental health services, as well as investigating (both from a clinical as well as research standpoint) care processes that may facilitate implementation of the PASARR mandate.

Upon admission, nursing homes must conduct a comprehensive assessment of each resident's needs and functional capacity and then repeat this yearly using a standardized instrument called the Resident Assessment Instrument (RAI). Two major parts of the RAI include the minimum data set (MDS), which collects a spectrum of relevant resident-specific information on needs and function, and resident assessment protocols (RAPs) which are triggered by certain MDS data, and help clinical staff conduct more detailed evaluations of problems such as mood and behavioural disturbances. Quality indicators (QIs) and Quality measures (QMs) are derived from MDS

data and used as rough grading measures for the nursing home (and are even posted for public review on the website of the Center for Medicare and Medicaid Services or CMS). QIs specific to psychiatric care include items that report the prevalence of behavioural symptoms affecting others, symptoms of depression (especially without antidepressant therapy), cognitive impairment, the use of other psychotropic medications, and restraint usage. It is worth noting that the greatest unresolved controversies regarding the validity of the MDS items centres upon the behavioural symptoms, suggesting a need for expert psychiatric evaluation, rather than relying upon clinical assessment by routine staff alone[18].

Psychiatric Consultation

The psychiatric consultant needs to be acutely aware when practicing in LTC facilities (and to a lesser extent in ALFs) that these are highly regulated environments with regular surveys by state, federal and other accreditation organizations. In his or her varied roles, the consultant contributes critical services and oversight that can maintain adherence to key regulations, such as OBRA, and prevent citations for not meeting state regulations. In addition, the consultant must be able to work closely with the medical director, administrator, director of nursing, risk manager, social workers and unit managers to ensure that everyone is 'on the same page' and functioning as a team. These interactions become particularly critical when working with residents with severe behavioural disturbances that pose a risk of harm to self or others, and help to ensure that proper channels of communication are maintained with distressed families.

CMS regulations are very strict as to who may provide psychiatric care in a nursing home. In addition to psychiatrists, clinical nurse specialists with psychiatric training are also allowed to use psychiatric consultative codes and psychotherapy codes, but the regulations for geriatric nurse practitioners are more restrictive. A consult must have a signed order by a physician, typically the primary provider, and the need should be supported by nursing notes. The order should then reflect the specific reason and not simply state 'psychiatric consult requested'. Pre-printed orders and family requests are not sufficient for a consultation because they do not necessarily support medical necessity. Verbal orders are permitted but should be the exception and not the rule. In addition, there should be documentation in the physician's notes as to why a consult is required. The bottom line is that a psychiatric consultation is neither automatic nor at the discretion of non-clinical staff, but must have a specific, documented justification and order.

Psychotropic Drug Reviews

As noted above and in Table 127.1, a primary role of the psychiatrist in LTC facilities is to prescribe and monitor psychotropic medications. The need for clear documentation on diagnosis, rationale for

Table 127.8 OBRA Interpretive Guidelines for specific psychotropics[13]

Short and long-acting benzodiazepines and other anxiolytic/sedative drugs

- Other possible reasons for resident's distress have been considered and ruled out
- The resident meets criteria for one of the following DSM-IV diagnoses: generalized anxiety disorder, organic mental syndrome (delirium, dementia, or amnesic and other cognitive disorders), panic disorder, symptomatic anxiety due to another disorder
- Use is equal to or less than the maximum recommended daily dose
- Daily use at any dose is less than 4 consecutive months, unless an attempt at gradual dose reduction is unsuccessful
- A gradual dose reduction should be attempted at least twice within 1 year
- Long-acting benzodiazepines should only used after an attempt to use a short-acting agent has failed
- Exceptions to the rule for long-acting benzodiazepines: withdrawal from short-acting agent, diazepam for neuromuscular syndromes, clonazepam for bipolar disorder, tardive dyskinesia, nocturnal myoclonus, or seizure disorders

Drugs used for sleep induction

- Other possible reasons for resident's insomnia have been considered and ruled out
- Use is equal to or less than the maximum recommended daily dose
- Daily use at any dose is less than 10 consecutive days, unless an attempt at dose reduction is unsuccessful
- A gradual dose reduction should be attempted at least 3 times within a 6-month period

Antipsychotic drugs

- The resident meets criteria for one of the following DSM-IV diagnoses: schizophrenia or other acute or chronic psychotic disorder, Tourette's disorder, Huntington's disease, organic mental syndromes (delirium and dementia) with associated psychotic and/or agitated behaviours that are documented and that pose a risk of harm to self or others or interfere with staff's ability to provide care
- Use is equal to or less than the maximum recommended daily dose
- prn use discouraged unless a quick taper is being conducted
- A gradual dose reduction should be attempted at least twice within 1 year
- Close monitoring for tardive dyskinesia, postural hypotension, cognitive and behavioural impairment, akathisia, parkinsonism and metabolic disturbances (weight gain, hyperlipidaemia, hyperglycaemia)
- Inappropriate indications: wandering, fidgeting/restlessness/nervousness, insomnia, anxiety, uncooperativeness, unsociability, impaired memory, depression, poor self-care and agitation that does not pose a danger to self and others
- Exceptions to the rule for attempted dose reductions are for chronic psychotic disorders and bipolar disorder

Table 127.9 Drugs and drug–diagnosis combinations with high potential for adverse outcomes based on Beers criteria

- Tricyclic antidepressants (amitriptyline and doxepin)
- Use of tricyclic antidepressants in residents with cardiac arrhythmias
- Use of sedative-hypnotics in residents with chronic obstructive pulmonary disease
- Use of antidepressants with anticholinergic properties in residents with benign prostatic hypertrophy

use, appropriate dosing, behavioural management and attempts at gradual dose reduction has been emphasized. The failure to provide this documentation can not only lead to citations for the facility, but on a broader level can create jeopardy for the psychiatrist in terms of reimbursement for services. Lack of compliance with CMS regulation in terms of medical necessity of the visit and the use of the correct procedural code can lead to hefty fines.

In terms of actual prescribing, OBRA guidelines provide specific lists of regulated medications, conditions that justify their use, and maximum recommended daily doses. Although all of these details are too numerous to list, a condensed list can be found in Table 127.8.

Original OBRA '87 guidelines covered benzodiazepines, other sedative-hypnotic medications and antipsychotic agents. More recent revisions by CMS under Guideline F-329 consider *any* drug as unnecessary if it is being given under any of the following conditions: (i) excessive dose, (ii) duplicate therapy, (iii) a prolonged period of time without justification, (iv) without adequate monitoring, (v) without adequate indications, or (vi) in the presence of adverse consequences. Although each of these requirements seems rooted in common sense and is associated with good clinical practice, their implications are perhaps greatest with respect to the widespread use of antidepressants, antipsychotics, and mood stabilizers in LTC. Whereas in the past a psychiatrist might have routinely considered antipsychotic tapers while maintaining long-standing use of antidepressants, now both classes of medication might be in line for gradual dose reductions (GDRs) if the clinical need for prolonged use is not documented and justified.

Another important set of regulations first promulgated by the geriatrician Mark Beers, and later incorporated into OBRA guidelines, is known as the *Beers criteria*, and is composed of a list of drugs and drug–diagnosis combinations that incur a high risk of adverse outcomes in individuals over the age of 65 years[19,20]. In general, these high-risk situations should be avoided or only used with explicit justification and close monitoring. Beers criteria most relevant to psychiatric practice are listed in Table 127.9.

Geriatric Psychiatry Care in the Private Psychiatric Hospital Setting

Brent P. Forester[1], Robert Kohn[2], Susan Kim[1] and Thomas Idiculla[1]

INTRODUCTION

The private psychiatric hospital offers an opportunity to deliver specialized treatment to geriatric patients across a continuum of care. The types of psychiatric services offered in these hospitals vary, but may include a dedicated geriatric psychiatry inpatient unit, partial hospital programmes that can accommodate the needs of older patients transitioning out of the acute psychiatric setting or requiring more intensive outpatient treatment, and outpatient services that include memory diagnostic clinics. Private psychiatric hospitals offer unique challenges to providing the appropriate medical care often needed for older adults with complex neuropsychiatric disorders. Most private psychiatric hospitals are not geographically proximate or integrated into the general medical hospital setting. Consequently, they are more limited in the acuity of medical care provided. This chapter will review models of geriatric psychiatry care in the private psychiatric hospital setting, examine the limited literature available on this topic, and describe an analysis of diagnosis and treatment trends over the past 15 years in two private psychiatric hospitals: McLean Hospital and Butler Hospital.

INPATIENT GERIATRIC PSYCHIATRY TREATMENT IN THE PRIVATE PSYCHIATRIC HOSPITAL

Most of the literature describing inpatient geriatric psychiatric treatment does not specifically examine inpatient units in private psychiatric hospitals. However, a review of what we know about inpatient geriatric psychiatry treatment will help provide a useful background for more specific diagnosis and treatment trends in the private hospital setting. Research conducted in New Zealand has shown that treatment in an acute geriatric psychiatry inpatient unit is effective and beneficial. This outcome study found that those with 'functional disorders' showed improvement in behaviour and symptoms, while those with 'organic disorders' had improvement in functional impairment, behaviour and symptoms[1]. Furthermore, there are clinical advantages to having a sub-specialized geriatric psychiatry unit. A retrospective chart review revealed that the specialized geriatric psychiatry unit offered more thorough and dedicated care to their geriatric patients compared to the general psychiatry unit[2]. This study revealed that significantly greater percentages of older inpatients treated on the geriatric psychiatry unit received 'complete organic medical workups, structured cognitive assessment, ageing-sensitive aftercare referral, and monitoring of psychopharmacological side effects and blood levels' than patients on a general psychiatry unit.

Physical Structure of the Inpatient Unit

The physical structure of the geriatric unit is designed to accommodate both the emotional and physical needs of the patients. These units are designed to provide a therapeutic milieu that limits restrictions on the geriatric patient. Adaptations that may not be appropriate or considered safe for a general psychiatric unit (e.g. handrails and grab bars) are made for a specialized geriatric psychiatric unit. Other adaptations include: low beds and over-bed tables, walk out showers, whirlpool tubs, enlarged signs and posters, appropriate furniture (such as seating with arms that enhances independent standing), call lights, personal alarms, non-slip and cushioned flooring, large day rooms with space to wander safely, a designated area for those who yell to limit the disruption of the rest of the unit, wheelchair and walker accessibility, bright lighting, calendars in rooms, and large clocks in rooms. These units may even have fish tanks and other visually stimulating additions. Light and pet therapy, which has been shown to improve 'psychopathological status' and 'perception of quality of life' in cognitively unimpaired elderly subjects[3], may be readily available.

Sub-specialized geriatric units might offer amenities that are specific to the unique needs of geriatric patients such as large signs, colour coordination and enlarged room numbers which aid patients in confronting problems with loss of orientation[4]. Private geriatric psychiatry units may create a home-like ambiance which is associated with 'improved intellectual and emotional well-being, enhanced social interaction, reduced agitation, reduced trespassing and exit seeking and improved functionality of older adults with dementia and other mental illnesses'[4].

Specialized Dementia Units

Private psychiatric hospitals that do offer designated dementia units are able to address needs specific to patients with dementia. For

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

example, such units may utilize decreased auditory and visual stimulation, which has been shown to reduce agitation and aggression levels among demented patients[5]. A number of studies support the efficacy of environmental interventions to successfully manage the prevalent behavioural complications of dementia[4]. Factors to consider include providing patients with dementia-appropriate sensory stimulation and safety measures. Sensory overstimulation may exacerbate problems with distraction, agitation, concentration and confusion[4]. Alternatively, deprivation of sensory stimulation may have negative effects on patients with dementia[4].

Designing a separate unit for patients with dementia may also afford the opportunity to create group treatment programming that is more specific to the needs of cognitively impaired individuals. Although some hospitals may offer a distinct dementia unit for those who are cognitively intact, many units include both those with cognitive disorders and primary affective or psychotic disorders. This requires that the treatment team be versatile in addressing the needs of the unit as the population mix changes.

The Multidisciplinary Team

The inpatient geriatric psychiatry unit utilizes a multidisciplinary team that focuses on respecting the patient and their culture. This team includes the geriatric psychiatrist, the nurses, mental health workers or clinical nurse assistants, an internist preferably specialized in geriatric medicine, a clinical pharmacist, neuropsychologist, social worker, occupational and physical therapists and activity support staff. The geriatric psychiatrist is often the treatment team leader and the medical director, with administrative responsibilities that may include screening admission referrals, managing length of stay and handling personnel training and supervision. The geriatric psychiatrist initiates the appropriate neuropsychiatric work-up, including referral to subspecialists in neurology, geriatric medicine, neuropsychology, physical medicine and rehabilitation, and physical and occupational therapy. The geriatric psychiatry inpatient unit nurse must be comfortable with patients who may require total ADL (activity of daily living) care. The nurse needs to demonstrate flexible skills that enable her to assume the role of a medical nurse while providing traditional psychiatric nursing interventions, including supportive therapy for those who are cognitively intact. The neuropsychologist conducts neurocognitive testing to assist with differential diagnosis of cognitive disorders for patients referred by the geriatric psychiatrist. In addition, the neuropsychologist may assist in developing behavioural treatment recommendations, including implementation of individualized behavioural plans.

Managing Medical Co-morbidity in the Free-Standing, Private Psychiatric Hospital

Any inpatient unit in a private psychiatry hospital (and non-general medical hospital) setting is limited in the management of individuals who are severely medically compromised. Many of these units have a dedicated internal medicine specialist who is an integral member of the treatment team and will round daily and monitor individual medical issues including hydration status, treatment of co-morbid infectious disease (pneumonia, UTI, diarrhoea) and management of chronic medical issues such as diabetes and hypertension. Daily laboratory monitoring or the use of intravenous fluids or antibiotics may be required. The coordination of care with the medical team is essential to allow for a rapid and appropriate assessment of the patient with a suspected delirium. One of the most challenging aspects of this coordination of care is being able to differentiate the medical issues that can be effectively managed on-site and those that require a transfer-out to a local general medical hospital setting for diagnosis and management. In general, the development of a diagnosis of delirium in a hospitalized older adult is a medical emergency, and underlying causes need to be determined and treated in a timely manner. If the aetiology of the delirium is unknown or if there are changes in an individual's vital signs or EKG, a referral to a general medical hospital setting is initiated for further acute medical work-up and treatment.

The Role of the Social Worker

The social worker on a geriatric psychiatry unit has an expanded, multilayered role, but primarily serves to educate families and coordinate post-discharge care with families and community referral sources. The social worker often provides supportive therapy directly to the patient or family. Focused interventions include helping families recognize and manage caregiver stress, feelings of grief related to illness in loved ones, and guilty preoccupation regarding decisions of long-term care placement. Some of the social worker's responsibilities include: advocating for the family while planning for assisted living or nursing home placements, assisting families in arranging financial planning, and managing legal issues related to substituted decision making and guardianship. Social workers will also advocate for and coordinate hospice care after discharge when medically appropriate. The social worker must also be intimately familiar and liaise with community agencies, homecare and nursing agencies and protective services, as well as guardians and attorneys. Although the primary goal of the social worker on the geriatric psychiatry unit is to ascertain that each patient is placed at the appropriate level of care, this must be completed under increasingly time-pressured circumstances in which hospital administration goals and family wishes are often in direct conflict.

The Occupational Therapist

The occupational therapist works with patients on the unit to continuously assess physical and cognitive needs. The occupational therapist examines gait, mobility, motor skills, use of adaptive equipment, and independence with activities of daily living (ADLs), including transfers. These assessments are performed throughout the hospitalization, as medications and inactivity may adversely affect gait. Functional independence may be assessed with the structured Occupational Therapy Evaluation of Performance and Support (OTEPS)[6] or the Kohlman Evaluation of Living Skills (KELS)[7], which evaluate mobility, self-care, instrumental ADLs, safety, medication management, financial management, and meal planning and preparation. The occupational therapist functional assessment assists in providing an appropriate disposition for the patients based on their level of function. Furthermore, the occupational therapist will try to create an atmosphere on the inpatient unit that permits inclusiveness of all patients, adjusted for their cognitive level.

The Clinical Neuropsychologist

Neuropsychologists also play a critical role on the geriatric psychiatry inpatient unit, assisting with cognitive assessment, diagnosis and

coordinated treatment planning. Examining the relative degree of change in cognitive performance from previous visits can be a very useful guide in understanding the aetiology of cognitive dysfunction and developing discharge planning options. Neuropsychologists may help guide implementation of appropriate group therapy activities with the cognitively impaired patient, and assist caregivers with decisions regarding the level of restriction that should be allotted to a patient. Decisions may also involve matters regarding administration of medication and discharge location[8].

Inpatient Group Therapy Interventions

The daily schedule on the geriatric psychiatry unit is structured with activities planned throughout the day. Patients will be evaluated individually with the psychiatrist and may receive individualized and family therapy with the psychiatrist, nursing staff and/or social worker. Patients are encouraged to participate in group activities regardless of cognitive capacity. Examples of group activities include task-oriented groups or craft activity groups involving patient-centred tasks, groups focusing on spiritual needs of patients, and sensory-oriented groups designed to examine gross motor activities in an environment to help calm patients (e.g. music). An end-of-the-day focus group may include relaxation exercises designed to teach the more cognitively intact patients about sleep hygiene, muscle relaxation and deep breathing.

The geriatric inpatient unit may also have distinct groups modified to address certain needs that are specific to patients with dementia. Memory groups are not only effective in addressing cognitive issues, but also the agitation and aggressive behavioural components that accompany memory loss in dementia. An individual inpatient treatment programme for geriatric patients with dementia and dysfunctional behaviours was found to be effective in improving the agitation and aggressive behaviours of patients with dementia while 'preserving or enhancing cognitive and functional abilities'[5]. Distinct dementia groups may provide therapies, such as morning bright light therapy, which has been shown to be effective in normalizing irregular sleeping behaviours among demented patients by increasing total nocturnal sleep and reducing sleep time in the afternoon[9].

Multi-sensory Behavioural Therapy

'Snoezelen' units, originating in the Netherlands in the 1970s, were developed to provide a multi-sensory experience that promotes the stimulation of all senses and does not rely on verbal interaction. Individuals may choose specific aromas, sounds, colours, tactile experiences and tastes, all of which promote relaxation. 'Snoezelen' units can be large enough to permit sufficient space for individuals who like to wander, thereby reducing intrusion into another patient's personal space. Some units promote stimulation of the senses by being connected to an outdoor area where patients may freely walk within a fenced-in space when the season is appropriate.

Multi-sensory behavioural therapy in single-blinded studies showed a modest reduction in agitation and apathy, and improved ADLs compared with standard psychiatric inpatient treatment alone[10]. Other studies with dementia patients carried out in nursing homes have been negative[11,12], or showed modest improvement in mood and well-being.

The Geriatric Neuropsychiatry Unit at McLean Hospital works exclusively with the dementia population. The unit has a dedicated sensory stimulation room with equipment such as a sound machine, a soft-toned lamp, a weighted blanket, a sand tray and a lighted ball which may be used with supervision in an effort to reduce levels of stress and agitation. A recent pilot study demonstrated the efficacy of a sensory-based intervention for individuals with dementia and associated behavioural disturbances. Interestingly, psychotropic drug administration did not improve the response to this intervention[13].

The Patient Population

Data from Medicare inpatient hospitalizations from 1990 to 1991 found that 19% of patients with a primary psychiatric diagnosis were treated in the psychiatric hospital compared to general hospital psychiatric units or general hospital non-psychiatric units[14]. Those with schizophrenia, bipolar disorder and major depression were most likely to receive inpatient treatment in a psychiatric hospital, while those with anxiety and substance-related disorders were less likely to be treated in a psychiatric hospital. However, the population mix in geriatric psychiatric inpatient units has been changing over the past several decades. One study examining admissions data from 1988 through 1998 found that recent admissions were more likely to have a primary diagnosis of dementia and to present with agitation or psychosis[15]. In 1988, over 60% of admissions had a diagnosis of affective disorder, which was reduced to 34% by 1998. Over this 10-year time period, the admitted patients were older, took more medications on discharge, had shorter lengths of stay, and were less likely to be discharged home.

Several studies have examined factors that result in re-hospitalization among elderly psychiatric patients. These studies have suggested that co-morbid depression and dementia, substance dependence, short lengths of stays, social isolation, maladaptive family systems, being single, co-morbid physical and mental health problems, male gender and bipolar disorder are all potential factors that may increase the risk of re-hospitalization[16].

Length of Stay

Length of stay (LOS) is frequently longer for geriatric patients compared to younger hospitalized individuals. A study conducted at the Institute of Living, where the average length of stay in 2001 was 14.1 days, revealed that 12% of the patients had a length of stay of over 26 days[17]. Factors contributing to an increased length of stay included receiving electroconvulsive therapy (ECT), not performing electroconvulsive therapy on weekends, being more impaired based on the Brief Psychiatric Rating Scale positive symptom scale, falling, pharmacological complications, multiple prior psychiatric hospitalizations, requiring court proceedings to continue treatment, and delays in consultations. Diagnosis and demographic factors did not appear to play a role in length of stay.

In a review of the determinants of LOS on the Geriatric Neuropsychiatry Inpatient Unit at McLean Hospital in 2007, factors associated with an increased length of stay included older age, aggressive or sexual behaviour, need for guardianship and ECT treatment. Furthermore, neither diagnosis on admission nor discharge location contributed to LOS.

The length of stay is longer in the private psychiatric hospital setting, as compared to the general hospital psychiatric unit for elderly patients[14]. Interestingly, the cost for care in the private psychiatric hospital may be lower possibly due to less medical co-morbidity[14].

GERIATRIC PSYCHIATRY INPATIENT ADMISSION PATTERNS: BUTLER HOSPITAL AND MCLEAN HOSPITAL, 1994–2008

We examined admission patterns for 1994–2008 to geriatric psychiatry inpatient units at two private psychiatric hospitals, Butler Hospital in Providence, Rhode Island and McLean Hospital in Belmont, Massachusetts. Butler and McLean Hospitals had a similar age distribution of patients: ages 65–75 (45.1%, 38.9%), 76–85 (39.9%, 44.6%), and over the age of 85 (15.0%, 16.5%). Since 1995 there has been a decline in admitting individuals between the ages of 65 and 75 years, and a steady rise in the other two age groups (Figure 128.1). The decline in those aged 65–75 was more dramatic for Butler Hospital, possibly due to McLean Hospital also having a dedicated dementia unit. Overall, more women than men are hospitalized: 67.8% and 64.4% were females, for Butler Hospital and McLean Hospital, respectively. The female-to-male ratio increased with age for both hospitals, with the 65–75 age group averaging 64.8% and 63.4% women; the 75–85 group averaging 69.7% and 63.0%, and the over 85 group averaging 71.7% and 70.4%. The most common discharge diagnosis for Butler Hospital across all age groups was dementia, followed by substance use disorder and depressive disorders; while for McLean Hospital the most common discharge diagnoses across all groups were dementia, depressive disorders and bipolar disorder. However, diagnosis varied by age group (Table 128.1).

The average length of stay from 1994 to 2008 was 13.4 days; 13.7 days for females and 12.8 days for males for Butler Hospital. McLean Hospital had a longer length of stay: 20.1 days; 20.6 days for females and 19.3 days for males. For Butler Hospital there was little evidence of a significant decrease in length of stay over time. At McLean Hospital there was an overall decrease in length of stay. However, this decrease in the length of stay was not dramatic. For instance, in 1994 the length of stay was 19.4 days and in 2008 it was 17.7 days; there was a peak in 2000 of 25.7 days.

Overall, 37.5% of patients at Butler Hospital and 33.7% of patients at McLean Hospital are discharged from the inpatient unit to a nursing facility, with increasing age related to more frequent nursing home placement. A quarter (24.1% and 25.5%) of those aged 65–75 are discharged to a nursing facility; while 44.6% and 36.3% of those aged 76–85, and 58.8% and 45.8% of those over 85 are sent to a nursing home from Butler Hospital's and McLean Hospital's geriatric psychiatry units, respectively.

GERIATRIC PARTIAL HOSPITAL PROGRAMMES

The private psychiatric hospital offers an opportunity to have a continuum of care for elderly patients from the inpatient programme to partial or day hospital and outpatient services. One goal for providing geriatric patients with intensive outpatient services is to reduce readmission rates, thereby reducing total costs incurred for the patient and the hospital. Whether such programmes achieve such fiscal savings remains unknown. Private psychiatric hospitals struggle with the conflicting tension between keeping the inpatient census full while also making efforts to reduce inpatient LOS. Older adults with mood and psychotic disorders generally experience recurrent acute exacerbations, which require more intensive interventions. The partial hospital programme may serve to avoid or delay inpatient admission and allow for a more successful transition back to independent community living. Partial hospital programmes may be designed specifically for the geriatric patient or have tracks within the adult partial programme that would be appropriate for the older patient depending on their cognitive capabilities. These programmes typically are Monday through Friday for one or two weeks, and act as a bridge to outpatient care.

Such a programme would have geriatric patients with limited cognitive impairment participating in a general programme that may emphasize cognitive therapy, group therapy, problem-solving therapy and psychoeducation. Problem-solving therapy has demonstrated effectiveness in reducing severity of depression in older patients as measured by the Geriatric Depression Scale and the Hamilton Rating Scale for Depression[18].

However, those who cannot benefit from groups that demand a greater degree of cognitive functioning are best served in a more support-oriented track. Such a track typically has a shorter day and consists of smaller groups, less detailed psychoeducation and more concrete activities such as art therapy, an occupation therapy task group and nutrition teaching. Group therapy in the cognitively compromised track would focus more on daily goals and planning pleasurable activities.

The elderly patient who is cognitively intact would participate in higher-functioning groups such as cognitive behavioural therapy, mindfulness, assertiveness, psychoeducation and behavioural

activation groups. Table 128.2 illustrates a typical partial hospital schedule using various tracts depending on the level of functioning of the patient. A cognitively impaired partial hospital track may be appropriate for those with mild cognitive impairment or dementia, but adult day care in the community setting may be more helpful for individuals with moderate to severe dementia.

There are a number of financial issues specific to the United States that must be considered when developing a partial hospital programme for the elderly. Medicare requires careful documentation of medical necessity for the initiation and continuation of group therapy interventions in partial hospital programmes. In addition, medications are not covered in partial hospital programmes under Medicare; therefore, the patient is responsible for purchasing and bringing daytime medication to the programme. Importantly, transportation is not covered by insurance and may be a limiting factor.

The partial hospital programme is appropriate for those who can benefit from structure and support. The programme allows for family education and interventions for dealing with conflicts, while also providing support and an opportunity for intensive psychopharmacological management. The partial hospital programme also permits the staff to observe an individual's daily functioning and diurnal changes in behaviour.

Examining data from Butler Hospital and McLean Hospital provides an illustration of the types of patients treated in a partial hospital programme. Between the years 1994 and 2008, the Butler Hospital partial hospital programme had 887 admissions for patients aged 65 and older. The McLean partial hospital programme is considerably larger and had 2702 admissions during that period of time. The majority (77.6% Butler Hospital; 58.0% McLean Hospital) of individuals were between the ages of 65 and 75, while

[a] Geriatric patients in this track arrive later at the partial hospital programme than those in the traditional cognitive behavioural tracks. For those who are not cognitively able to manage specific groups, as noted in the schedule task groups are provided as an alternative.

only 2.1% and 6.0% of the admissions were over the age of 85, respectively. The majority of those in the partial hospital programme were females: 62.5% Butler Hospital and 74.8% McLean Hospital. The most common discharge diagnoses for Butler Hospital were depressive disorders, 23.6%; anxiety disorders, 22.8%; substance use disorders, 17.6%; and dementia, 12.2%; whereas McLean Hospital's programme was more focused on depressive disorders, specifically, accounting for 81.9% of discharge diagnoses compared with only 5.7% for bipolar disorder, 8.2% for non-affective psychosis, 8.3% for mild cognitive impairment and 2.7% for dementia.

A cross between the time-limited partial hospital and the outpatient geriatric psychiatry clinic where patients are seen for 15 minutes to an hour on an as-needed basis, is the enhanced outpatient treatment programme. McLean Hospital provides an example of such a programme that was initiated in 2008. The SAGE (or Seniors Aging Gracefully Everyday) programme is now utilized as a step down from inpatient care, or used to prevent the need for hospitalization. The SAGE programme is geared toward those with major depression, bipolar disorder, anxiety disorders and psychotic disorders. Patients attend the programme two to five days weekly for about four hours per day. Individual and group psychotherapy along with psychopharmacological assessment and management are available services. Such a programme typically offers cognitive behavioural therapy, illness education, coping skills, family counselling and community-resource need assessment.

SPECIALTY GERIATRIC PSYCHIATRY PROGRAMMES

The private psychiatric hospitals often have substance abuse treatment programmes, which may offer an opportunity to provide treatment specific for the geriatric population. For instance, Butler Hospital has a weekly group therapy session open to the elderly population. The rationale for this group is that a number of geriatric patients feel intimidated among younger substance users in Alcoholics Anonymous, and an age-specific group provides them with a more secure environment to promote abstinence.

Memory disorders clinics, directed by either a geriatric psychiatrist or a behavioural neurologist, are also common in the private psychiatric hospital setting. These clinics often are multidisciplinary and include neuropsychology and occupational therapy. The memory clinic primarily focuses on providing diagnostic services and consultation to referring medical professionals. The clinic also provides treatment and follow-up services including the use of medications, counselling for patients and families, and assistance with locating and using community-based resources. Most of these clinics also actively conduct research and may offer patients an opportunity to participate in trials with commercially unavailable medications.

CONCLUSION

There are both challenges and opportunities for the care of older adults with neuropsychiatric disorders in the private psychiatric hospital setting. Foremost among the opportunities is a vertical system of care that integrates traditional inpatient geriatric psychiatry treatment with a range of outpatient services including partial hospital programming and specialty mood and memory disorders clinics. Multidisciplinary teams help provide inpatients with a full range of specialty medical and psychiatric, neurological, neuropsychological, physical and occupational therapy and social work services. Over the past 15 years, trends at two prominent private psychiatric hospitals indicate a shorter inpatient length of stay for both centres, and varying prevalence rates of dementia, affective and psychotic disorders. In addition to the financial hurdles associated with providing geriatric psychiatry care in the private psychiatric hospital setting, are the challenges of managing medically complex inpatients with both neuropsychiatric conditions and medical co-morbidities. Nevertheless, private psychiatric hospitals in the United States remain an important resource for older individuals and their families struggling with

mood disturbances, psychosis, behavioural disinhibition syndromes and cognitive impairment.

Liaison with Medical and Surgical Teams

David N. Anderson

Mersey Care NHS Trust, Older People's Mental Health Services, Sir Douglas Crawford Unit, Mossley Hill Hospital, Liverpool, UK

'My own experience suggests that the proportion of geriatric referrals is growing and that a liaison psychiatrist increasingly acts as a part-time geropsychiatrist, yet one without the benefit of appropriate training and expertise'[1].

This was said by one of the founding fathers of liaison (general hospital) psychiatry. It demonstrates how the mental health needs of older people admitted to general hospitals is increasing and has been for some time. Global demographic change is becoming a major challenge for all nations of the world. Because ageing is associated with increased health problems and multi-morbidity[2], this will be reflected in hospital populations. Because physical morbidity increases the chance of psychiatric morbidity, this will be reflected in greater need for liaison psychiatry services with expertise in older people's problems.

In most parts of the world, mental health of older people is not a distinct speciality. In the UK, where older people's mental health has become a separate speciality, there had been no consideration of the needs of older people admitted to general hospitals until the Royal College of Psychiatrists published the first national guideline on the development of specialist older people's liaison services[3]. This has stimulated great interest, and these services are now recommended in national guidance from government and professional bodies[4–6].

In the UK, two-thirds of National Health Service beds are occupied by people over the age of 64 years[7], and up to 60% of this age group admitted to general hospitals may have or acquire a mental disorder during an admission[3]. Furthermore, this mental disorder will be an independent predictor of poor outcome by increasing mortality, length of hospital stay and loss of independent function, and reducing the prospect of a return to independent living[3]. This morbidity has been shown to increase subsequent health care utilization and cost[8] and readmission to hospital[9].

This adverse effect remains apparent some time after hospital discharge, with increased mortality being evident two years later[10], nine years later for depression[11] and still doubled three years later with delirium[12].

In the UK, liaison psychiatry has been a developed speciality for adults under age 65, but older people received mental health attention by the inferior process of consultation[13]. Consultation is a reactive process where patients are seen on a case-by-case basis, frequently by inexperienced medical staff working independently of the general care team; a single opinion is given and the patient referred again if problems fail to resolve. Liaison is proactive, integrated with general hospital care and based on collaborative working (Table 129.1). The superiority of liaison has been shown in controlled trials and by systematic review (Table 129.2).

The desire by clinicians to move to a liaison approach is clear[14]. This change is supported by accumulating evidence that addressing older people's mental health in general hospitals improves the outcome for patients and the efficiency and effectiveness of general hospitals. How this can be achieved for the more common conditions is briefly discussed in this chapter.

PREVALENCE AND INCIDENCE

Systematic review of the literature finds that the most common disorders are dementia, delirium and depression, which together will account for about 80% of the psychiatric morbidity (Table 129.3). All three are substantially more common in general hospitals than found in the community, and all conditions combined are 3–4-times more common. Rates vary with hospital departments, being particularly high in medical and orthopaedics. There is very little known about rates in emergency departments.

Each of the three major disorders creates different problems and a different focus of approach, discussed later.

DETECTION

Despite mental disorder being so common, detection by general care teams is poor. The diagnosis of delirium is missed in 32–67% of cases[15], and cognitive impairment in over half[16]. A meta-analysis of older medical admissions reported a median detection rate for depression of 10%[17]. In England, a national report found that only 41% of people with dementia had any form of mental assessment recorded[18].

General care teams have difficulty understanding the concept of syndromes, and their response to mental disturbance is, predominantly, a reaction to symptoms. Consequently, crying, not eating, and thoughts of death are synonymous with depression, and any cognitive errors with dementia. Jackson and Baldwin[19] reported how nurses on medical wards recognize symptoms of depression rather than the syndrome. A small qualitative study in the USA found that 75% of general nurses could not distinguish dementia from delirium, despite 75% saying that they had received formal education on the subject or had attended a conference about confusion in the elderly[20].

Table 129.1 Characteristics of liaison and consultation services

Consultation	*Liaison*
Reactive	Proactive
Limited resources	More labour intensive
Isolated input	Collaborative
Low priority	High priority
Little impact	Developmental
	Education and training
Slow response	Rapid response
Little review	Frequent review
	Improve quality of referrals
	Improve adherence of recommendations
	Change practice and attitudes
Mental health separate from general services	Mental health integrated with general services
Mental health physically distant from acute care	Mental health physically part of acute care

Table 129.2 Benefits of liaison compared to consultation

Quicker response
Increase referrals and quality of referral
Increased specialist assessments
Improved diagnostic concordance between referrer and assessment
Better adherence with treatment recommendations
Reduced length of admission
More return to independent living
Reduced readmission
Reduced health care utilization
Reduced cost
High patient satisfaction

Table 129.3 Average period prevalence of psychiatric morbidity (%)

Dementia	31
Depression	29
Delirium	20 (50% incident)
Cognitive impairment	22
Anxiety	8
Schizophrenia	0.4
Alcoholism	3

A further example, and one which emphasizes the importance of syndrome diagnosis, is a report on older people referred to a liaison service with depression when 40% were found to be suffering from delirium[21]. Depressive symptoms were as common in the delirious patients as those diagnosed with depression, 50% expressing a wish to die, 25% suicidal thoughts and the majority thoughts of worthlessness and guilt.

But, detection in an acute hospital with serious physical comorbidity can be difficult. Particularly so for depression, when key biological symptoms like fatigue, loss of appetite, weight and sleep can arise from physical or psychological illness, and evaluating loss of motivation and worry in people seriously physically ill is difficult.

A diagnostic approach to depression based on DSM-III-R[22] criteria, counting all symptoms regardless of their origin (inclusive) or excluding any symptom that could arise from physical illness (exclusive), produces a variation in prevalence of 27 to 46%[23]. The exclusive approach had high specificity for severe and persistent major depression, but missed 49% of major depressions identified by the high-sensitivity inclusive approach, almost 60% of whom continued to experience symptoms of depression weeks after discharge. Furthermore, these findings are based on structured psychiatric interviews, and unstructured clinical impressions are less reliable.

Interpreting cognitive function can be similarly difficult. Is a person's cognitive performance poor simply because they feel ill or too tired to attend? What is the significance of disorientation to day and date when a person has spent weeks or months in hospital or has been very ill?

It is partly for these reasons that mental health liaison teams are needed to develop expertise working in this environment. Assessment and diagnostic instruments do not solve this problem as they also need to be interpreted and few are validated for use with physically ill people. In untrained hands these tools can be dangerous, lead to false conclusions and the mistaken belief that a quick tick-box approach can replace the history and mental state examination.

Routine screening for cognitive impairment and depression has been suggested, but the benefit and method remain uncertain. A screening instrument would need high sensitivity (like the inclusive approach for depression described above) but would yield false positives, while a diagnostic instrument would require high specificity (like the exclusive approach for depression above), but risks missing many people with the disorder who would benefit from treatment.

A systematic review of screening for depression and anxiety in non-psychiatric settings concluded that the routine administration of psychiatric questionnaires with feedback to clinicians does not improve the detection of emotional disorders or patient outcome; although, those with high scores may benefit[24]. Studies of the systematic detection and multidisciplinary treatment of delirium or depression in medical inpatients have, so far, been unable to demonstrate superiority over usual medical care[25,26]. The systematic detection and treatment of delirium has shown small benefits for older surgical patients[27].

The exception is the use of clinical prediction rules to identify older people at risk of developing delirium, and this is discussed later under delirium.

EDUCATION AND TRAINING

The limitations of general care teams discussed above highlights the need for education and training, and suggest that whatever training is currently employed seems to have little effect. Teaching and training is core business for liaison teams and there is evidence that the introduction of liaison services into general hospitals is associated with changes in referral that might be taken to indicate a more informed change of behaviour[28]. And so, it is likely that their presence, in itself and by clinical contacts, has an educative effect.

However, the best way to deliver more formal training to general care teams remains uncertain. Principles of adult learning which may be usefully incorporated into educational programmes include timely and relevant information based on participant identification of learning needs and integration of new information into existing knowledge base(s) with time for consolidation and appropriate non-judgemental feedback to the individual[29].

Case-based discussions that bring immediate relevance, supervision that reinforces knowledge and skills, and audit to evaluate

change will be important to effective education. Care pathways can be helpful. This might suggest that an approach which focuses on the needs of specific departments and specialities involving complete clinical teams could be more effective than random teaching sessions for hospital staff and particular professional groups. The circumstances and subject matter should dictate the approach.

Whatever the approach, training time must be built into job plans and the resourcing of liaison teams. The time needed is always underestimated, and when clinical staff are under pressure, training will be relegated to low priority. In one audit of a nurse-led liaison service, 7.5% of time was spent directly on formal education and 33% giving guidance, advice and making recommendations to ward staff[30].

Delivery to large hospitals, including night staff, with staff who move through in training, is difficult and a perpetual process. Incorporating mental health into established teaching programmes will give it credence and importance. The presence of liaison teams in general hospitals offers the prospect of mental health being absorbed into the culture of the hospital and not seen as a separate activity just provided by mental health services. The importance of improving the mental health knowledge and skills of general care teams cannot be overestimated because the vast majority of older people admitted to general hospitals with mental health needs will not be seen by specialist liaison teams. The management of non-referred cases will be the ultimate measure of how successfully liaison services have changed the general hospital's response to mental health.

INTERVENTIONS

Delirium

Delirium is the most common non-specific presentation of physical illness among older people and the most common new condition in the hospitalized elderly. It will complicate 5–10% of routine surgery. Delirium present at the time of admission is referred to as prevalent delirium, and that beginning in hospital as incident delirium. The distinction is important when discussing prevention, as 30–40% of incident delirium may be hospital acquired and preventable. Rates of delirium will vary between hospital departments, being highest with the most ill patients (Intensive Care), higher with emergency than elective surgery and higher with more complex conditions.

It is a cause of death, prolonged admission, loss of independent function, high cost and is associated with an increased risk of hospital-acquired complications including incontinence, falls, pressure sores and infection. Estimates from the USA suggest that it affects more than 2.3 million older people each year, is responsible for more than 17.5 million inpatient days and costs over $4 billion (1994 dollars) each year[31].

Furthermore, it is now clear that not all delirium resolves, and cognitive impairment persists 12 months after a medical admission when 15% still meet the diagnostic criteria for delirium[32]. Patients developing delirium during a medical admission are twice as likely to have died, and six-times more likely to have acquired a diagnosis of dementia three years later[12]. Reversibility seems crucial for outcome. A prospective study of older medical patients found that the 6 and 12 month outcome for delirious people who survive and recover was no different to no-delirium groups in relation to cognition, function or institutional status[33].

Once established, the treatment is that of the underlying condition, with supportive care and management of behavioural and psychotic symptoms[34]. There is a theoretical basis to developing pharmacological prophylaxis and treatment with cholinesterase inhibitors[35,36] and manipulation of the immune system[37], but small controlled trials of the former have failed to demonstrate efficacy.

There is compelling evidence for interventions which prevent incident delirium that is closely linked to processes of care. Clinical prediction rules have been described for medical, non-cardiac thoracic surgery and elective orthopaedic populations[38–40]. These enable people at risk to be identified on admission to hospital and preventative care strategies employed to reduce delirium risk. Because delirium mostly develops within the first seven days of admission or surgery, this approach can concentrate on that period[41].

The most developed prevention approach arose from studies of older medical patients, identifying the strongest independent predisposing and precipitating factors that predict incident delirium[42,43]. These large studies found the relative risk was 9.5-times greater for people with a high-risk predisposing profile, and 8.9-times greater for those with a high-risk precipitant profile, than those with low risk.

This formed the basis of a controlled trial of a preventative intervention involving 852 older medical inpatients, employing a multi-component intervention strategy (The Elder Life Program). The subjects were identified on admission as being intermediate or high risk, and in the intervention arm the incidence of delirium was 34% lower than usual care. The intervention group experienced significantly lower total days with delirium, lower total number of episodes, improved cognitive function in those already cognitively impaired and lower use of sleep medications[44].

This intervention was shown to be cost effective for intermediate risk (72% of subjects) but not high risk. Cost of the intervention was offset by savings accrued from treatment intensity, including nursing and diagnostic procedures[31].

A randomized controlled trial of 126 older people admitted with hip fracture employed a similar structured prevention strategy of proactive geriatric consultation and protocol of care. The incidence of delirium was 36% lower in the intervention group, with 58% less severe delirium. Number needed to treat was 5.6[45]. Reducing the severity of delirium is important, as increased severity is associated with increased mortality, loss of function and institutionalization[46,47]. Sub-syndromal delirium is also associated with worse outcome compared to no delirium, and equivalent to mild delirium[47].

Though the protocols were different in the medical and surgical studies, they were essentially proactive high-quality medical and nursing care. It has been said that incident delirium is a sign of hospitals failing older people[48].

Dementia

Dementia increases the risk of delirium five-fold, and recognizing delirium superimposed on dementia is particularly difficult[20]. It is, however, very important because delirium is a common presentation of acute physical illness in people with dementia, with no localizing signs. As a general rule, any person with dementia in hospital who shows a sudden change of behaviour, function or mental state should trigger the possibility of delirium. There is no evidence, at present, to indicate any particular approach to the treatment of delirium in those with chronic cognitive impairment, and standard protocols of care apply[49].

People with dementia are highly susceptible to environmental change. Lying in bed, not given the opportunity to maintain their personal care skills, and disruption of familiar routines exposes them to a loss of independent function quickly. They take longer to recover, and cognitive impairment hampers their ability to benefit from rehabilitation.

A cross-sectional regional audit in England found that people with dementia were more likely to be in acute hospitals than any other health care beds, and 68% of those no longer required acute hospital care[18]. In a study of elderly hip fractures, over 70% of cases had not been diagnosed before admission[50].

Consequently, there are multiple reasons why the presence of dementia has to be identified at the time of admission, and general care teams need to recognize the significance this has for management and eventual discharge. Care plans have to take account of the effect of their cognitive impairment and the added risks it creates. All too often, it is only when a person is considered medically fit for discharge that any thought is given to their cognitive function and planning that should have occurred much earlier. A person with dementia is five-times more likely to develop delirium and then suffer the consequential effects on outcome[27].

A randomized, controlled trial of intensive multidisciplinary rehabilitation after hip fracture surgery achieved a reduced length of stay for those with mild or moderate dementia in the intervention arm. Those with mild dementia were as successful returning to independent living as those without dementia[51]. There was no benefit for length of stay or independent living for people with severe dementia, and the mild or moderate group from the intervention arm were more likely to be living independently three months after discharge.

The National Institute for Health and Clinical Excellence[5] recommend that every suspected case of dementia in general hospitals has a specialist assessment and there should be specialist older people's liaison teams available for treatment and training.

Depression

All forms of depression are seen in a general hospital, where presentations are more varied and more difficult to diagnose. Preoperative anxiety and depression are associated with an increased risk of postoperative complications, and usually linked to worries about surgery or the disease. These often resolve following successful surgery. Unfortunately, depression accompanying a medical admission has a poor prognosis[17].

Physical illness and disability increase the risk of depression greatly. Depression in older age increases mortality from natural causes[52] and independently increases six-month readmission after discharge[9]. Up to 50% of people with depression in the general hospital have a disorder present before admission. The course of depression after discharge from a medical admission remains very stable, and a 12-month prospective study of older medical patients failed to find any effect of antidepressants[53]. The more severe course was predicted by higher initial Hamilton Depression Rating Scale score, depressive core symptoms lasting six months, and female sex.

The evidence base for effective treatment is poor in general, and with important co-morbidities. Antidepressants, in general, are better than placebo or usual care in the presence of physical illness, with very respectable number needed to treat or harm; although, this Cochrane review included all adult ages[54]. Antidepressants are also effective for depression in older people, but this Cochrane review comments on how few trials include people with physical illness[55].

Large, placebo-controlled trials have shown the superiority of selective serotonin re-uptake inhibitors after myocardial infarction for severe or recurrent depression, and confirm their safety[56]. This class of antidepressant may reduce the risk of further fatal and non-fatal ischaemic events, possibly by virtue of an effect on platelet coagulability[57].

The evidence for treatment effectiveness in Parkinson's disease, stroke or with chronic obstructive pulmonary disease (COPD) is largely absent[58–61]. There is emerging evidence that older people with COPD may be particularly difficult to engage in antidepressant treatment, but case management with a problem-solving behavioural approach is promising[60]. The differing nature of presentation and outcome of depression with these co-morbidities creates challenging questions about the very nature of these disorders and whether they represent the same condition.

The only randomized, placebo-controlled trial of antidepressants in older people in a general hospital involved medical patients who were quite seriously ill[62]. The protocol purposefully kept exclusion criteria to a minimum, but the study was underpowered. Fluoxetine was superior to placebo, though not a statistically significant difference, and side effects no more likely with active treatment. Despite evidence supporting the safety of selective serotonin re-uptake inhibitors, and some benefit, less than 50% of depressed medical patients and 25% of depressed older hip fracture patients receive antidepressants[17,45].

One controlled study has shown the superiority of interpersonal counselling for older people with mild depression six months after a medical admission[63]. Two prospective randomized controlled trials of older people depressed during a medical admission employed the intervention of an older people's liaison nurse. Though improvement was not statistically significant, possibly due to being underpowered, both showed more symptom improvement with intervention than usual care[64,65], and improved quality of life[65].

Self Harm

Self harm is much more common among younger adults and only 2–3% of cases presenting to general hospitals will involve older people. However, with older people the risk of completed suicide is higher; older people show greater suicidal intent than younger people, and the profile of older people who self harm is similar to that of older people who die by suicide, with 60–90% depressed[66,67]. In a small study of consecutive older medical admissions, 36% expressed suicidal ideas, with 19% still having these thoughts six months later[68]. About one-third of older people with self harm presenting to a general hospital will have a history of previous self harm[69].

Following self harm there is a 66-fold increased risk of suicide in the first year, which increases with age[67], and over 20 years a 49-fold increase of suicide and 33-times increase of open verdicts with older people[70].

Suicide in people with dementia is relatively uncommon, but risk may be difficult to detect. A study of nine years of recorded suicides to the National Confidential Inquiry into Suicide and Homicide by People with Mental Illness found only 1% associated with dementia[71]. This only reports suicides occurring within 12 months of contact with mental health services in England and Wales. It found younger people with dementia over represented (over 20%) and fewer of the typical risk factors for suicide; particularly: history of self harm, psychiatric admissions or noted psychiatric symptoms, and more likely to have a diagnosis in excess of 12 months.

All older people presenting with self harm or suicidal thinking must be assessed by a specialist service.

Somatoform Disorder

This includes somatization and hypochondriasis and is now often referred to as medically unexplained symptoms. These presentations

of physical symptoms thought to have psychological origins are common in medical and surgical departments, though much less common with older people. In addition, the development of a mental disorder, particularly depression in later life, may cause exacerbation of symptoms from a long-term condition. If late onset, this last is more common, and most patients will have physical illness or disability even when attribution of the physical symptoms to the known disorders may be difficult.

There is little information about these conditions in general hospital populations and only a limited amount from studies in other health care settings. These conditions can lead to costly investigations and interventions and impair quality of life[72].

In a prospective study of elderly primary care attenders, somatization was found in 5% and associated with depression, physical illness and low perceived social support[73]. It was commonly transient, even though 13.6% had a somatizing attributional style which was quite stable. Frequent attenders were characterized by high rates of depression (28.3%), psychological distress associated with physical symptoms and perceived lack of social support (40%).

Antidepressants and cognitive behaviour therapy have been shown to be effective[74]. Improving perceived social support is likely to be helpful. Treatment should only follow thorough medical investigation.

LIAISON SERVICES

Working in a general hospital environment creates different problems and questions for mental health practitioners than outpatient or community practice. Mental health practitioners will need greater knowledge of acute physical illness and how this changes the meaning of mental disturbance. General hospitals are not designed to cater for mental disorder, and the environment can contribute to the problem and will limit the way in which mental health is both assessed and managed. To acquire the necessary expertise requires that the liaison specialist's time is committed to working in this field. This is discussed by Anderson and Ooman[75].

Though the development of these services for older people is relatively new, there is accumulating evidence of their value and effectiveness. The principle functions are to work collaboratively with general care teams, provide a rapid response, manage complex conditions, improve the detection and understanding of mental health, and deliver training to general care teams that will improve their skills in mental health assessment and management[3].

By improving the treatment of mental disorder they contribute to greater efficiency of general hospitals. A systematic review has shown that the introduction of a specialist liaison service has a significant benefit on health savings[76]. A summary of benefits reported from controlled trails is shown in Table 129.2.

It also seems to be the case that admission to a general hospital is a common first presentation of mental disorder for older people. Holmes[50] found that over 70% of older people with dementia admitted with hip fracture were not previously diagnosed. An analysis of 2760 referrals to a specialist liaison service for older people in the UK showed that 68.2% were not under the care of mental health services, though 20% had been, and 62% of mood disorder cases represented a new-onset disorder (unpublished data: Anderson D, Nortcliffe M, Dechenne S *et al*. Characteristics of a nurse-led liaison mental health service for older people: the Liverpool Dataset Project).

Several models of service delivery have been described[3] but the essential elements for a service to be most effective are:

- multidisciplinary team
- based in the general hospital
- dedicated to hospital liaison
- strong links with mental health services
- good information system.

Psychiatric morbidity varies between departments, being generally higher in medical and orthopaedic wards. Complex medical co-morbidity, the acute presentation of physical illness and the strong association between cognitive impairment and falls characterise these populations. A liaison service would expect 70% of referrals to come from medical specialities and the referral rate per admitted case is higher from medicine than surgery. The composition of the hospital and presence of very specialist departments will impact on the work of liaison services. Surprisingly little is known about the morbidity in accident and emergency departments. There is evidence that the rate of referral of older people and the average age of those referred has been increasing for at least three decades.

A large series of referrals over a five-year period found the most common reasons for referral to be cognitive assessment (42.8%), depression or anxiety (19.3%) and behaviour disorder (6%) (unpublished data: Anderson D, Nortcliffe M, Dechenne S *et al*. Characteristics of a nurse-led liaison mental health service for older people: the Liverpool Dataset Project). This generally accords with findings from smaller studies. The most common diagnoses from this series, as expected, were dementia (35%), mood disorder (17%) and delirium (11%). Dementia was more likely to be of vascular type than reported in community services, and 43% of delirium occurred in the context of dementia.

About half the referrals only required a single assessment, and the most common recommendations were for behaviour management (30%), further investigation or assessment (27.1%), medication prescribing (14%) and discharge planning (12.6%). In this series, 66.3% were discharged to their original place of residence and 19.4% to care homes; 8.4% required transfer to a mental health inpatient unit and 8.6% to a community outpatient mental health service.

CONCLUSION

The psychiatric co-morbidity of older people admitted to general hospitals is high, and admission is a common means by which mental disorder of older people comes to the attention of the health care system. General care teams have serious limitations in their ability to detect, diagnose and manage mental disorder. Two-thirds of this morbidity is mild and uncomplicated and will need to be recognized and managed more effectively by general care teams.

The development of specialist liaison services for older people brings an opportunity to improve the outcome for patients and the efficiency of general hospitals. These teams bring the skill and expertise necessary to manage complex co-morbidity, and provide training and education that general care teams require. This developing subspeciality will become increasingly important in ageing populations and is a vehicle for improving the quality of care.

Rehabilitation

Rob Jones

Mental Health Services for Older People Directorate and Nottingham University Section of Old Age Psychiatry, Queen's Medical Centre, Nottingham, UK

INTRODUCTION

In one sense the broad principles of rehabilitation seem well and securely established. But in another sense they seem to be rediscovered anew by succeeding generations, with sometimes wise old concepts seeming to come newly dressed as fresh approaches. In England up to 70% of acute hospital beds are occupied by older people, a theme familiar to most ageing societies, focusing attention on how to promote recovery more rapidly and ensure it can be sustained, not least with older people with mental health problems.

Rehabilitation of the older person with psychiatric disorder means restoring and maintaining the highest possible level of psychological, physical and social function despite the disabling effects of illness. More broadly it also means preventing unnecessary handicap associated with illness, preventing unnecessary handicap secondary to maladaptive responses to illness and combating the deadening effects of low expectations for older people among professionals, patients, families and society in general. Managing chronic disease and disability is the greatest challenge to modern medicine. Within this, rehabilitation of many older people with psychiatric disorder looms large – although, of course, many old people with psychiatric disorder respond well to 'curative' therapy and require little rehabilitation.

In fact, rehabilitation has always been a fundamental and inseparable part of old age psychiatry (as of all psychiatry). Perhaps for this reason, as with rehabilitation in geriatric medicine[1,2], little writing in the way of conclusive evaluation or substantial trials has addressed the topic specifically. Some particular techniques, such as psychological approaches with the cognitively impaired, have been well described[3,4], but little evaluated[5], and evaluative research is much needed here.

SPECIAL PROBLEMS WITH PSYCHIATRIC DISORDER IN THE OLDER PERSON

'Old age' may span 40 years or more, posing quite different rehabilitation problems; but the most major challenge is the very frail, the old old. In this group multiple disability is prominent, easily complicated by polypharmacy, and physical and mental ill health interact in complex ways. With this vulnerable population, disentangling the respective influences of ageing, previous personality and current ill health can be exacting. Two thirds of the UK's disabled population are older people and the true extent of handicap due to psychiatric disorder is probably still not established.

With depression especially there may be restriction of physical activity, threatening physical capacity and health. Depression associated with stroke disorder[6] or with Parkinson's disease[7] particularly illustrates both the connection between physical and psychiatric problems and the importance of physiotherapy and occupational therapy in psychiatric rehabilitation.

Physical factors are frequently of great importance in dementia. A quiescent individual may become delirious and disturbed at night through heart failure, obstructive airways disease or even the uncomfortable effects of severe constipation. Settling such problems may transform the reality of care for a carer and seeking out such therapeutic opportunities is an important part of rehabilitation. Similarly, in dementia physiotherapy and occupational therapy to promote and maintain the best possible physical capacity are key elements. Advice and practical aid to carers, such as with lifting and handling the physically disabled person with dementia, can be crucial.

A judicious mixture of the 'therapeutic' (curative) and the 'prosthetic' (supportive) approaches, sagely described over two decades ago by an eminent wise voice in geriatric medicine[8,9], is very necessary in old age psychiatry. While much functional psychiatric disorder and delirium can be 'cured', and this must be the aim, most older people with dementia need some degree of supportive care at some stage. The poor financial and housing state of many older people, together with the lack of children or spouses to help as carers for many of the old old, are further complicating factors. Maximizing 'participation' despite psychiatric disorder needs to be a major goal: maintaining as far as possible a role in the family, social contact, a range of activities and minimization of loss of autonomy or institutionalization. This requires an approach which embraces psychiatric, medical, rehabilitation, nursing and social perspectives. Vigorously pursing active prevention of disability or of reduced participation as a consequence of psychiatric disorder is a vital part of rehabilitation.

SPECIAL PRINCIPLES IN REHABILITATION OF THE OLDER PERSON WITH PSYCHIATRIC DISORDER

Table 130.1 summarizes the principles. The home must be the focus of attention. This is where problems have arisen and where they

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

Table 130.1 Principles of rehabilitation for the older person with psychiatric disorder

Focus on the home
Ensure comprehensive assessment
Encourage normal function
Treat the treatable
Analyse disabilities and chart progress
Clarify team goals with patient and carers early
Clarify team goals with support workers early
Teach what can be relearned
Adapt the adaptable
Coordinate support and follow-up
Promote flexibility and ingenuity
Promote realistic optimism
Promote participation and autonomy

will need to be overcome. Planning for rehabilitation should begin at the earliest moment; an initial assessment at home by a senior psychiatrist, or other experienced team member, is invaluable – even if 'home' by now is an institution in the community. Home is also where the carers, and often any social services support staff involved, may readily be found. It is where they will need to work with solutions. This contrasts with standard medical rehabilitation where traditionally often no such opportunities for outreach have existed.

Frequently, further assessment by, say, an occupational therapist, physiotherapist or another specialist team member may be necessary – and this can perhaps also be arranged at home. But avoiding disruptive admission should not be at the cost of really meeting assessment needs. The day hospital or a community-based therapy resource centre and their teams may often be useful to complete such assessments. They (or a day centre specially supported with outreach expertise) may be settings where important rehabilitation efforts can be made.

Effectively supporting the carers with people at home is essential for rehabilitation. In the UK, Admiral Nurses are a good example – specially trained mental health nurses who work all the time in the community with people with dementia and their carers.

Poor function or morbidity should never be accepted as immutable, and, still less, as normal. Assessment should aim at a thorough understanding of social, physical and psychological function as well as the previous pattern of personality and lifestyle. From this, diagnoses and specific treatment for the treatable should follow. But also analysis should show the extent of disability, how it is mediated and how it may be overcome. Problems should be clearly recorded, with proposed solutions and with regular review of progress, and with this it is useful to use standardized assessments, such as the Bristol Activities of Daily Living Scale (BADL)[10], and a standardized framework, such as the International Classification of Functioning, Disability and Health (ICF)[11]. From the earliest moment, independent function and improvement should be sensitively encouraged, especially with hospitalized patients.

As early as possible, the agreed goals of rehabilitative efforts need to be clarified with the patient, with the relatives/carers, with the whole rehabilitation team and with any support workers needed in the community. Education, guidance and a rehabilitative 'demonstration' may well be necessary to resolve conflicting views on the prospects for progress. Carers may need therapy or rehabilitation in their own right. Almost always the support of carers is essential, though some stoutly independent patients manage well without this.

A prognosis-based plan is useful. This means assessing: what are the problems and what are their causes? Prognostication will follow: will these get better or worse? To what degree? Over how long a period? From this a plan can flow consistent with what seem the most major likely developments of a problematic nature, over a foreseeable time scale and taking account of what is most remediable.

Sometimes disability strongly distorts the previously stable power and dominance pattern in the family, first noted in classic work[12] but reiterated in evolving family therapy work[13], so that, for instance, a forceful mother becomes dependent on a passive daughter. Relationships are always important and such phenomena can strongly influence outcome. They need to be understood and often complex ambivalence worked through[14]. Such factors are frequently important when carers seem reluctant to resume caring[14,15] and need to be carefully teased out when juggling with the various elements of risk and risk minimization involved in supporting a vulnerable person at home[15]. The patient's 'crutch is not made of wood but of some other person's tolerance or patience'[16].

An agreed balance should be sought between the needs of carers and the patient's right and desire for continued comparative independence despite significant disability – bearing in mind the team's prime responsibility to the patient.

In effect, carers should be 'recruited' as rehabilitation therapists' 'aids'. But often they will need practical help and advice on rehabilitation techniques, and, always, the reassurance of the services' continuing availability for support and sensitive expert response. This is less easy both to offer and in practice as services increasingly become, as in recent years, driven towards short-term involvement and a short-term perspective.

Similar considerations apply with any support staff necessary to help the patient at home – principally social services staff in the UK. Their early involvement and integration into the assessment and rehabilitation process can be logistically difficult but generally is most effective. Again, a longer term perspective and continuity are invaluable.

Good teamwork is of the essence. Clarity and consistency within the multidisciplinary specialist team are essential. Nurses and therapists, for instance, must communicate well, each complementing and enhancing the other's approach.

Specialist and general practitioner must be in accord. The specialist team must carry the confidence of those who will work with the patient outside hospital. (Table 130.2 lists many of the team members and resources requiring coordination for rehabilitation – inevitably there is great overlap.)

Clear goals should be set, in accord with those of the patient and carers, and clearly understood by all[15,17–20]. This is much easier said than done with the vulnerable frail older person; but vitally important is good communication.

Patients are taught what they can learn or relearn but often only modification of domestic equipment, provision of aids or modifications of the home will overcome their disability. More often still problems are only overcome through support services – home-delivered meals or a home help/community care assistant – coming into the home. Ingenuity and diplomacy may be needed with an old person reluctant to accept such necessary support. The great majority of support is provided by relatives/carers and supporting the supporters is the main task. This may require a day hospital or community venue for therapy, day care centre or respite admissions. Maintaining confidence that there will be reliable and appropriate care interventions and responses by the service is vital. Such confidence and such a reality become harder to maintain as there

Table 130.2 People and facilities to aid rehabilitation of the older person with psychiatric disorder

	Specialist psychiatric team	*Social services and local authority services*	*Primary care team*
People	Psychiatrists	Social workers	General practitioners
	Hospital specialist nurses	Domiciliary services manager	Practice nurse
	Community psychiatric nurses/Admiral nurses	Home help/community care assistants	District nurse
	Physiotherapist	Meals on wheels	Health visitor
	Occupational therapist (OT)	Community OT	Specialist community nurse
	Clinical psychologist	Support to voluntary sector	Specialist community health support teams
	Social worker	Sitter services	
	Ready access to geriatricians	Carers groups	
	(Speech therapist – sometimes)	Preferably multiagency specialist home support team	
	(Dietician – sometimes)		
	Carers groups		
Facilities	Assessment ward	Luncheon club (often voluntary)	Health centre
	Nursing home	Day centres (often voluntary)	
	Day hospital	Long stay and short stay residential care and nursing homes	
	Outpatients	Housing adaptation	
	Longer stay and respite care facilities	Sheltered and super-sheltered housing	

is more pressure on services to be short term in their outlook and activity.

At some stage with hospital patients, except in the most grossly deteriorated person, a home assessment is advisable with an occupational therapist or physiotherapist, or both, and perhaps with other team members.

Hospital-based staff can be too pessimistic and, allowed to function in her familiar environment, even a person with quite significant dementia can sometimes perform surprisingly well. Often serial home assessments are helpful with increasing challenge, leading to overnight stays. Also, failure initially to manage satisfactorily should not preclude the possibility of later improvement with further therapy or support.

A model of how a person-centred multi-agency specialist home support team for people with dementia and their carers works to achieve valued results has been quoted in the National Dementia Strategy[20] and evaluated in pilot form[21]. This highlights many of the issues arising when striving for a more bespoke, individual approach.

Above all, rehabilitation with older people requires flexibility allied to a realistic but constructively optimistic approach. Innovation and ingenuity are frequently necessary. The complex interaction between physical, social and psychological factors in older patients is further complicated by the likelihood that circumstances, especially perhaps physical health, may change dramatically; this demands a flexible response. The solution, carefully constructed and successful on one day, may need major change on the next as the situation radically alters. For this reason rehabilitation with older people is rarely completely finished, and 'maintenance' measures are often necessary. Careful planning of continuing care, follow-up and continuing availability as problems arise are essential features. The strength and determination of patients, relatives and support staff are considerably bolstered by the knowledge that this approach is backing them up[15,20,21].

REHABILITATION AND LONG STAY CARE

Many patients, especially among those with dementia, despite support end up requiring long-term care but rehabilitation must remain a strong theme. Eventually, multiply disabled people, particularly with dementia, are likely to require 24-hour care. They may often exhibit both difficult, disturbed behaviour and the need for heavy physical care. Providing the best quality of life, given often quite limited resources, is the aim and a major strategy is preventing unnecessary dependency and promoting the maximum retention of function. With descriptions[22–25] of the care of such patients in various settings, a frequent theme has been the availability of skilled and expert staff from the multidisciplinary team to help maintain good function. Evaluation of such long-term care programmes has proved complex and difficult[22,23].

Earlier concerns expressed in the UK that such disabled patients would be excluded from hospital long stay care, largely seemingly for funding reasons, in favour of publicly funded and means-tested placements in private residential or nursing home care[26–28] have been superseded by this reality. In the USA (and many other countries) long-term care of older people has long been provided largely in the private or charitable sector. But in the USA the Omnibus Budget Reconciliation Act (OBRA Act)[29] requires nursing homes to ascertain and meet any needs for therapy and treatment. In the UK the fear is that the drive previously striven for in the best hospital care to provide a good quality of life can be replaced in private and independent care homes by a desire for a quiet life, leading to residents showing unwarranted passivity and dependency, possibly resulting from unnecessary

tranquillizing medication[30–32]. Financial constraints could make this more acceptable than the patient's exercise of individuality, movement and self-expression.

Reports of high levels of depression in homes for older people[33–35] emphasize the worry about effective rehabilitation and care for older people with chronic psychiatric disorder. Any institution providing shelter is at risk of providing a relatively impoverished environment[16,22,23] and undue restriction of independence.

Bennett[16] called unnecessary social inactivity and dependence the psychiatric equivalent of contractures. Hospitals (and social services) and care home settings have provided much good practice. Accounts of good long stay care for people with dementia emphasize the invaluable input of occupational therapy, physiotherapy and person-centred approaches[2,36,37]. Sensibly ensuring activity in a structured day and enriching the environment with, for example, music therapy, art therapy, drama therapy or other stimulatory approaches[20] are important wherever the setting (p. 58). Emerging innovative work in Nottingham, logged as commissioned research[38], is usefully looking at the ethnography of the nursing teams in various health settings providing care for people with dementia and how this relates to staff well-being as they strive to deliver quality person-centred care. Preliminary results very much support the theme of the National Dementia Strategy[20].

Community Psychiatric Nurse (CPN) support (indeed, availability of all the specialist team to give support) to such homes is both feasible and helpful, and should be developed[39]. But concern remains about how to monitor effectively and maintain standards in private and all long stay care, especially with people with dementia, epitomized by Objective 10 of the National Dementia Strategy[20]. Ultimately good care here depends on the commitment of sufficient appropriately trained staff to help disabled old people experience to the full their remaining scope for independence and capacity for joy.

NEUROREHABILITATION AND COGNITIVE STIMULATION APPROACHES WITH PEOPLE WITH DEMENTIA

Considerable focus has been placed in recent years on psychological and individual training approaches that help to maximize or maintain function in older people, especially those with dementia, despite the challenge of pathological ageing[4]. Cognitive stimulation therapy has shown promise and much can be achieved by practical and individual approaches exploiting the older person's continuing good function and tendency to adapt most successfully to coping in his/her own individual environment. While work in this area has been promising and should be encouraged[40], the Cochrane Database shows a limited evidence base[5].

DEVELOPING THEMES WITH REHABILITATION IN THE OLDER PERSON

A dominating theme is the need for a more person-centred, individual, bespoke approach, particularly to the older person with dementia, especially when working to support individuals with dementia and their carers at home. Each person with dementia/carer dyad has its own specific problems requiring a bespoke individually tailored solution[21]. Task-centred care, one size fits all, designed to suit the needs of the service provider, will not do.

The emphasis with support of this clientele at home needs to be different from the normal rehabilitation aim of restoration of function. Here rehabilitation instead seeks to maintain maximum autonomy and participation by the individual despite deterioration. This means flexibly and individually working to promote continuing participatory activity in some form, rather than simply restoring function (no longer possible) or replacing function[41]. Supporting individuals in participating in making cups of tea is preferable to doing it for them when they can no longer relearn this skill. There is considerable challenge here to the standard rehabilitation approach, which focuses on recovering or relearning lost function. The standard rehabilitation approach fits ill with supporting chronic neurodegenerative disease.

Considerable attention in various health fields, including in psychiatry, especially in general adult psychiatry, has focused over the past decade on early and concentrated intervention into the home, often via special teams to give special support[42]. The hospital at home scheme in geriatric medicine has been an example in one area, and assertive outreach schemes, perhaps in tandem with crisis resolution teams, have been another. One emphasis here has been prevention of hospitalization but necessarily emphasis has also been needed on promoting recovery and good function. Linked to this has been promoting earlier discharge from hospital, either with a move to a less acute facility but with an intensive rehabilitative input and/or intensive rehabilitative input into the home following earlier discharge. In the UK intermediate care, with this short intensive input, has been the name applied to this approach. Such approaches and teams have been defined as very short term in their intervention (usually a maximum of six weeks)[43–46]. While the supportive rehabilitative effort has been welcome, there has been a danger of lack of overall coordination and continuity of care for patients and families. Compartmentalized services can fail to link optimally for the patient's benefit across the divides between teams. In the UK such tendencies have arguably been exacerbated by short-termism in funding with performance target management requiring quick discharge. Chronic and degenerative health problems (especially mental health problems in older people) can be especially sensitive to perverse incentives here. They do not fit in well with such short-term approaches. With hospital discharge the fear has been expressed that the target of recovery may have been replaced with 'fit for discharge to a care home'. Again, such difficulties would be avoided more easily by having the dominant focus on individual bespoke outcomes and person-centred care, respecting autonomy[21,41].

With such major interaction in this population between physical health and mental health (and with each commonly interacting with other issues), there is a great need for collaboration between geriatric medicine and old age psychiatry. The area of liaison between these specialties is a prominent theme. More broadly, there is a need for spreading of the knowledge and expertise of old age psychiatry into all physical health care settings that may deal with older people with mental health problems[47]. The area of how older people with medical crises and mental health problems fare in the general hospital is a major issue and concern in the UK. Particular dissatisfaction with this area has been expressed especially by the carers of people with dementia, meriting highlighting in the UK government's National Dementia Strategy[20] and by NICE/SCIE[19]. It is clear that improved collaboration and improved working by such services could impact beneficially in a considerable way on such rehabilitation here.

In terms of service organization, in the UK there seems to have been quite a restriction on and even a move away from the use of old age psychiatry day hospitals with older people. This seems potentially detrimental to rehabilitation approaches. Some of this has been accompanied by spreading mental health expertise more widely into day centres but the main emphasis appears, unfortunately, to have

been on cost cutting in specialist services. Good, expert, readily and locally accessible assessment and therapeutic ambulatory facilities on a day or sessional basis remain an essential component necessary for proper rehabilitation approaches with this patient population.

Another service area concerns people termed 'graduates' in the UK – these are people who have developed mental health problems earlier in life and with whom these have endured into old age, beyond 65 years. Many of these people need considerable psychiatric rehabilitation expertise and support. Arguments arise as to who should care for them. The answer is that there should be no age discrimination[48] and that people of any age should receive the service and expertise they need regardless of their age. This may mean them staying with services which predominately deal with younger people or may mean an older person with dementia receiving help from an old age service[49]. It is essential that services plan and agree together the appropriate care for the individuals concerned, so that people do not fall between the 'gap'.

Antidementia drugs (cholinesterase inhibitors) merit mention and should be a part of a broader rehabilitative approach. There is great hope, and some accumulating evidence, that these will have a prophylactic and preventative effect with mild cognitive impairment, such that 'conversion' to Alzheimer's disease is delayed or prevented, with encouraging evidence also in mild/moderate Alzheimer's[50,51]. Neurorehabilitation may usefully come into play with this approach.

The UK National Dementia Strategy[20] emphasizes 'living well with dementia', advocating that with proper information, support and attitudes people with dementia can experience a good quality of life. It lays great emphasis on changing attitudes more positively, educating widely with accurate information and thereby raising expectations so that a good quality of life becomes both expected and the norm. In a tacit way, perhaps, this plays into the rehabilitation approach of maintaining participation and autonomy despite the threat of cognitive decline.

In the UK a new strongly pursued theme in social care involves individuals managing and commissioning their own supportive social services. Known as self-directed care[52], and well used in the USA, this process directly awards individual budgets to clients who have been appropriately assessed, to purchase services as they wish, within some limits. This is being piloted also now in some health care settings. Clearly this is relevant to rehabilitation work and the scheme has been seemingly well demonstrated with younger physically disabled people. Again, a rehabilitation approach focusing on individual answers, promoting participation and autonomy, seems relevant. However, older, frailer, multiply disabled people with mental health problems and possibly inadequate mental capacity may be more vulnerable to exploitation with such a system or unable or just disinclined properly to grapple with it. Such fears arise more prominently with a multi-provider, private provider and market dominated system, towards which the UK has moved significantly, especially with a perceived weakening of the regulating inspecting systems, as exemplified by concerns in the case of the Mid-Staffordshire NHS Foundation Trust[53]. Good advice, availability of brokers and strong, effective regulation are greatly needed with such an approach.

The theme of supporting vulnerable older people at home, particularly people with dementia, raises consideration of the use of 'extra care housing' and the usefulness of assistive technology approaches[54,55]. Both, especially perhaps the latter, must increasingly loom large in most societies around the world in rehabilitation and support approaches for the rising population of older people with mental health problems.

Living at home, with such helpful support, contrasts, particularly for people with dementia, with the experience of living in an institutional care home, which is less good. The UK Alzheimer's Society[25] sadly reported people there having 'little to do' with 'little interaction' and very limited time devoted to them individually by staff. Another study[37] in a similar vein found very uncomfortable depersonalized experiences for people living in such care homes.

ATTITUDES

Adverse feelings about older people have been noted by many[37,56,57]. Commentators have addressed helpful and unhelpful attitudes in health professionals of all kinds, including especially doctors[58–60]. Modern medical education is inculcating a better knowledge base for tomorrow's doctors and also better attitudes[61]. The educational potential of old age psychiatry services, not least exploiting the educational opportunity afforded by rehabilitation (and other concerns) with the most disabled, has been described and remains valid[62]. Not only medical students[57], but all varieties of medical and other professional staff concerned with older people with mental health problems, and also carers and lay audiences, benefit from this educational effort. Public education especially is vital in engendering constructive attitudes in society, on which ultimately will depend all efforts towards care in the community and the political will to provide decent services. These efforts and seeking better intergenerational empathy and understanding should never cease.

CONCLUSIONS

Rehabilitation of older people with psychiatric disorder means restoring/maintaining the best level of psychological, physical and social function despite the disabling effects of illness: preventing unnecessary handicap accompanying illness, unnecessary handicap secondary to maladaptive responses to illness and combating the deadening effects of low expectations with older people. Managing chronic disease and disability is the greatest challenge to modern medicine, within which rehabilitation of many older people with psychiatric disorder looms large – a fundamental and inseparable part of old age psychiatry using a judicious mixture of the 'therapeutic' (curative) and the 'prosthetic' (supportive) approaches.

In summary:

- focus on home
- ensure comprehensive multidisciplinary assessment
- encourage normal function
- treat the treatable
- analyse disabilities, chart progress
- clarify team goals with patient and carers early
- clarify team goals with support workers early
- promote realistic relearning
- adapt the adaptable
- coordinate support and follow-up
- encourage flexibility and ingenuity
- promote realistic optimism, participation and autonomy.

Anaesthetics and Mental State

Andrew Moore Severn[1] and David Gwyn Seymour[2]

[1]*Royal Lancaster Infirmary, Lancaster, UK*
[2]*Medicine for the Elderly, University of Aberdeen, Aberdeen, UK*

INTRODUCTION

Modern surgery and anaesthesia have transformed the lives of millions of older people. However, while the great majority of these will emerge without any long-term cognitive sequelae, absolute guarantees cannot be given. Anaesthesia is a complicated process in which many drugs are administered synchronously in combinations that allow for considerable individual preferences. It is not surprising that unravelling the mental state side effects is a complicated task. The task of assessing which drugs may contribute to a specific change in mental state is also complicated by the physiological response to surgery, and the 'stress', physical and mental, experienced by an elderly patient undergoing elective or emergency surgery.

It is over 50 years since Bedford[1] wrote about 18 elderly patients who had 'never been the same' after surgery and anaesthesia, and concluded that 'operations on elderly people should be confined to unequivocally necessary cases'. While there have been major advances in our understanding of postoperative cognitive dysfunction and the methodology used to investigate it, many questions remain to be answered. Although new drugs and monitoring techniques have supplanted those used in Bedford's day, much of the practice and process of modern general anaesthesia would be recognizable to him. Indeed, the birth of modern anaesthesia was heralded by the introduction of curare, a skeletal muscle relaxant, some 13 years before the Bedford paper.

General anaesthesia requires hypnosis and suppression of motor and autonomic reflexes: until 1942 this was achieved by using a single agent, such as diethyl ether, in high concentrations. Modern anaesthesia, by contrast, involves combinations of agents, in smaller doses, and the use of specific agents to suppress reflex activity, so called 'balanced anaesthesia'. In this way the complications associated with large doses of single agents, such as cardiovascular depression and prolonged coma, are avoided. There has also been a realization of the potential and social acceptability of local anaesthesia. 'Balanced anaesthesia' in today's anaesthetic practice may include a combination of an epidural infusion of local anaesthetic with opioids to provide segmental reflex suppression and a 'light' general anaesthetic to provide a suitably controlled environment for the theatre team and patient.

Local anaesthesia without the concurrent use of general anaesthesia, whether by peripheral nerve block, or by a more substantial spinal or epidural block (collectively referred to as 'regional anaesthesia') is not the panacea for prevention of mental state changes that some might suppose. While it is true that the great 'unknown' – the reversible coma – of general anaesthesia is avoided, the metabolic consequences of all but the simplest of operations outlast the duration of the block and exert a humoral effect on the brain. Furthermore, an operation performed under regional anaesthetic may be conducted under sedation, which in itself may have consequences for postoperative mental state changes.

Admission to hospital for major surgery can be considered a 'major life event', accompanied as such events are by anxiety and other changes in mental health status. The factors that contribute to delirium in older patients in hospital are well known[2] but acute surgical wards rarely provide the environment in which these factors can be managed. For example, devices such as urinary catheters and bed restraints, known to be factors that exacerbate delirium, are used as part of routine surgical practice on many wards, arguably as much for the convenience of hospital staff as for the individual benefit to patients.

In an attempt to bring some structure to the complexity of the subject, it will be considered under the following headings:

- The state of current knowledge of the clinical syndromes of delirium and postoperative cognitive dysfunction
- Mechanisms of anaesthesia and possible interactions with neural pathways involved in higher cortical functions.

In regard to the second heading, mention will also be made of the hypothesis that, in conditions of limited 'cerebral reserve', anaesthetic agents might act on the fragile brains of older patients to accelerate or unmask latent changes of dementia.

DELIRIUM

Classic descriptions of the mental changes that can follow general anaesthesia describe 'emergence delirium' (on immediate awakening from anaesthesia) and 'interval delirium' (occurring in the first few postoperative days). Modern anaesthesia, with its attention to matters such as intensive supervision and pain control by specialist staff in the immediate postoperative period, has almost entirely consigned emergence delirium to history in the case of adults, although publications continue to appear in the field of paediatric anaesthesia. It

Emergence delirium aside, postoperative delirium remains a problem. The causes of postoperative delirium, as in delirium in other settings, include acute illness, drugs and drug withdrawal[2–5]. Estimates of the incidence of postoperative delirium in the over-65s range between 7% and 50%, depending on the definitions used and the clinical circumstances[2–5]. The incidence tends to rise with age, the urgency of surgery, the use of sedative and anticholinergic drugs and the degree of preoperative cognitive impairment. Factors (such as sepsis) that favour the development of delirium in a non-surgical situation may also be of relevance postoperatively. Inouye and co-workers have made a major contribution to our understanding of delirium in both medical and surgical situations, by introducing the concept of an interplay between one or more *predisposing* factors (such as age, dementia, co-morbidity and multisensory impairment) and one or more *precipitating* factors (such as acute sepsis, hypoxia, metabolic derangement, or sedating or anticholinergic drugs)[6]. Thus patients who are highly vulnerable because of significant predisposing factors such as dementia or physical frailty might need only a minor precipitating factor to develop delirium, whereas a more robust patient with few or no predisposing factors would require a more major precipitant. O'Keeffe and Chonchubhair[4] concluded that, in at least 90% of cases of delirium following general surgery, it is postoperative medical or surgical complications that are to blame, which implies that the appearance of delirium should lead to a diligent search for underlying physical medical problems. The increased incidence of postoperative delirium with age is likely to be due to age-associated predisposing and precipitating factors rather than direct pharmacological effects arising from age-related differences in the actions of anaesthetic agents[7].

Recent advances in the study of postoperative delirium have included attempts to standardize definitions[4] and a large study in the USA by Marcantonio *et al*.[5], which aimed to develop a clinical prediction rule based on the outcome of 1 341 patients aged 50 and over having major non-cardiac surgery. The latter authors found seven preoperative factors (see Table 131.1) that had an independent relationship with postoperative delirium. When the anaesthetic records of patients who had become delirious were compared with those of patients who had not, certain drugs, notably pethidine and long-acting benzodiazepines, appeared to confer an increased risk of delirium[7].

POSTOPERATIVE COGNITIVE DYSFUNCTION

The widest interpretation of a 'changed mental state' following surgery and/or anaesthesia could embrace many conditions, ranging from mild subjective alterations in concentration or mood at one extreme to major psychosis or coma at the other. For purposes of detailed study, it is helpful to consider a much narrower definition of postoperative cognitive dysfunction (POCD). Indeed, such has been the influence of the work of Moller, Cluitmans, Rasmussen and other colleagues in the International Study of Postoperative Cognitive Dysfunction (ISPOCD) Group[8] that their definition has monopolized the use of the term POCD. A key feature of ISPOCD studies has been the use of the European psychometric test battery (EUPT battery; see Table 131.2), which has been designed as a sensitive and standardized research tool for the detection of postoperative neuropsychological deficits and which can be administered over a 45-minute period. The definition of POCD has been reached by comparing changes in the normalized (Z) scores of individual patients with age-matched controls who were not undergoing surgery, who were studied at the same time intervals[8,9]. Such an approach has allowed sound epidemiological evidence to be gathered and hypothetical risk factors to be investigated and it has also given us useful information about the time course of mental state changes. However, studies to date have told us little about the precise mechanisms of cognitive decline or the determinants of severity in individual cases, and have largely been confined to those with normal cognitive function prior to surgery.

The first ISPOCD study (ISCPOD1) collected data between 1994 and 1996 on 1 218 patients aged 60+ who were undergoing major non-cardiac surgery in 13 hospitals in 8 European countries and the USA[8]. This was a major undertaking, which was intended to answer many of the questions about early and late postoperative cognitive dysfunction in older people that had been raised in the literature over the previous 30 years. As summarized in Table 131.3 and described below, this landmark study has spawned a series of important follow-up studies using the same methodology.

ISPOCD1[8] was particularly concerned to test the hypothesis that hypoxaemia and/or hypotension were causative factors in POCD. Accordingly, oxygen saturation was measured by continuous pulse oximetry before surgery, throughout the day of surgery, and for the next three nights. Similarly, blood pressure was recorded by oscillometry during the operation and every 30 min for the rest of the operative day and night. Patients received general anaesthesia but no restriction was placed on the type of anaesthetic or surgical technique, which conformed to local practice in the study centres. In order to avoid the cerebral vasoconstrictor effects of hypocapnia, normocapnia (as assessed by extrapolation from analysis of the end-tidal CO_2 concentration of the exhaled gas mixture) was a requirement.

Analysis of the data from ISPOCD1 showed that 25.8% of patients had POCD seven days after surgery and that 9.9% of all patients still had evidence of POCD on the repeat neuropsychological tests carried out at three months (corresponding values for controls were 3.4% and

Table 131.3 Studies that have used methods developed by the ISPOCD group to define post-operative cognitive dysfunction following non-cardiac surgery. All studies used pre- and postoperative cognitive testing with a standard test battery (see text and Table 131.2). Standardized (Z) scores were constructed and POCD was defined as described in the text and reference[9]. Most studies also included measures of depression, self-assessed cognitive function and activities of daily living. All patients underwent major surgery, except for those in Canet *et al.*[10]. Postoperative cognitive testing was carried out at approximately 1 week and 3 months in all studies, but Abildstrom *et al.*[11] also followed a subset of the ISPOCD1 patients for 1 to 2 years. Exclusions (see ISPOCD1) include a Mini-Mental State test of 23 or less, certain medications, and a number of medical conditions

Reference	*Age; no. of subjects; other details of study*	*Cognitive findings in subjects (S) and controls (C) (95% confidence intervals in brackets)*		*Other comments and conclusions*
		At 1 week or hospital discharge	*At 3 months, unless specified*	
ISPOCD1 (Moller *et al.*[8])	Age 60+ $N = 1\,218$ Controls: age-matched non-operated UK volunteers ($N = 176$)	S: 25.8% (23.1–28.5) C: 3.4% (1.3–7.8) $P < 0.0001$	S: 9.9% (8.1–12.0) C: 2.8% (0.9–6.5) $P = 0.0037$	The only major risk factor for POCD at 3 months was age. At 3 months, 39 out of 532 patients (7%) aged 60–69 and 52 out of 378 patients (14%) aged 70 and over had POCD; hypoxia, hypotension and depression were *not* correlated with POCD at 1 week or at 3 months
Abildstrom *et al.*[11]	Age 60–86 $N = 376$ (47 controls) 1–2 year follow-up of subset from ISPOCD1		**NB: 1–2 year follow-up** S: 10.4% (7.2–13.7) C: 10.6% (1.8–19.4) $P =$ not significant	Differences in POCD between subjects and controls could not be demonstrated after 1–2 years (but note wide confidence intervals due to small numbers of controls)
Johnson *et al.*[12]	Age 40–60 (i.e. middle-aged) N = 508 (183 controls)	S: 19.2% (15.7–23.1) C: 4.0% (1.6–8.0) $P = 0.001$	S: 6.2% (4.1–8.9) C: 4.1% (1.7–8.4) $P = 0.33$	While one in five middle-aged patients had evidence of POCD at week 1, by 3 months their rate of POCD was not significantly different from that of non-operated controls. Note that 29% of patients at 3 months reported *subjective* symptoms of impaired cognitive function but this was associated with markers of depression rather than with the objective criteria for POCD
Rasmussen *et al.*[13]	Age 61 – 87 $N = 428$ randomized to GA or RA	GA: 19.7% (14.3–26.1) RA: 12.5% (8.0–18.3) $P = 0.06$	GA: 14.3% (9.5–20.4) RA: 13.9% (9.0–20.2) $P = 0.93$	Results for GA vs. RA were reported on an 'intention to treat' basis, but 10–15% of subjects did not receive the allocated method of anaesthesia. A *per protocol* analysis showed no difference at 3 months, but at 1 week $P = 0.04$
Canet *et al.*[10]	Age 61–80 $N = 372$ *Minor* surgery cases only	S: 6.8% (4.3–10.1) (cf. 25.8% for major surgery and 3.4% for controls in ISPOCD1) $P =$ N.S. between S and C	S: 6.6% (4.1–10.0) (cf. 9.9% for major surgery and 2.8% for controls in ISPOCD1) $P =$ N.S. between S and C	On logistic regression, age over 70 and inpatient (vs. outpatient) treatment were predictive of POCD at 1 week but not at 3 months

Table 131.3 (*continued*)

Reference	*Age; no. of subjects; other details of study*	*Cognitive findings in subjects (S) and controls (C) (95% confidence intervals in brackets)*		*Other comments and conclusions*
		At 1 week or hospital discharge	*At 3 months, unless specified*	
Monk *et al.*[14]	Three age groups: 'young', 18 – 39 $N = 331$ (64 controls) 'middle-aged', 40–59 $N = 378$ (62 controls) 'elderly', 60+ $N = 355$ (56 controls)	Age 18–39: S: 36.6% (31.3–41.8) C: 4.1% (0.9–11.5) Age 40–59: S: 30.4% (25.7–37.1) C: 2.8% (0.3–9.6) Age 60+: S: 41.4% (36.2–46.7) C: 5.1% (1.1–14.2) *Statistical tests* $P = 0.01$ for elderly S vs. middle-aged S $P < 0.001$ for S vs. C, in all three age groups	Age 18–39: S: 5.7% (3.0–8.5) C: 6.3% (1.7–15.2) Age 40–59: S: 5.6% (3.2–8.1) C: 4.8% (1.0–13.5) Age 60+: S: 12.7% (8.9–16.4) C: 1.8% (0.0–9.6) *Statistical tests* $P = 0.001$ for elderly S vs. other two groups $P < 0.001$ for S vs. C, in elderly group only	Independent risk factors for POCD at 3 months were age, lower educational level, a history of previous cerebral vascular accident with no residual impairment, and POCD at 1 week. Deaths within a year of surgery: patients who had POCD at both 1 week and 3 months were more likely to die in the first year after surgery ($P = 0.02$)

GA, general anaesthesia; RA, regional anaesthesia; N.S., not significant.

2.8%). Contrary to expectations, no relationship was found between perioperative hypoxaemia and/or hypotension and the development of 'early' (one week after surgery) or 'late' (three months after surgery) POCD. Indeed, despite analyses of the effects of more than 25 other clinical parameters, only age showed a statistically significant correlation with late POCD. Age was also positively correlated with early POCD, as were duration of anaesthesia, a lesser level of education, a second operation, postoperative infections and respiratory complications. The overall conclusion of the ISPOCD1 investigators was that their study had demonstrated a measurable degree of postoperative cognitive change in a minority of older patients three months after surgery (in about 10% of patients vs. about 3% of non-operated controls) and that the risk increased with age. However, the expected relationship between hypoxaemia and/or hypotension and POCD did not emerge. It was also disappointing that, despite a large number of statistical analyses, the study failed to find any specific risk factors for late POCD that were amenable to therapeutic or preventive intervention. In addition, the hope that the study would give better insight into the pathophysiology of POCD was not fulfilled.

Several well-designed 'ISPOCD2' studies using the basic ISPOCD1 design (Table 131.3) have also failed to identify the major factors contributing to POCD. For example, Rasmussen and colleagues[13] were unable to demonstrate any long-term cognitive benefit of regional anaesthesia over general anaesthesia for major surgery, thus apparently exonerating the drugs and processes of general anaesthesia in the development of the syndrome. As to whether there are any markers of brain damage that might correlate with the appearance of POCD, the answer is inconclusive: markers such as neuron specific enolase (NSE) and S-100 protein fail to correlate with severity of the syndrome. However, for cardiac surgery, different pathological mechanisms may apply as the brain is subjected to a different sort of insult from the process of cardiopulmonary bypass. Rasmussen *et al.*[16] noted that for a cohort of patients undergoing cardiac surgery the incidence of POCD at 1 week and 23 months was 38.7% and 13.8%, respectively, but found that some 10% of the original sample were so confused that they could not be tested at 1 week, and a further 15% dropped out of subsequent testing. Rises in plasma concentrations of NSE correlated with the syndrome of POCD. Significantly, the largest single rise in the series was noted in one of the patients who was too confused to be tested at 7 days.

A major practical disadvantage of the ISPOCD methodology is that it requires a baseline preoperative assessment, which limits its application to elective surgical procedures. However, the advantage of the approach over earlier studies that simply looked at postoperative cognitive status is that it is not open to the suggestion that some or all of the cognitive impairment observed postoperatively had been present but unobserved preoperatively. For reasons of space, Table 131.3 is limited to studies that have used the ISPOCD technique, but a list of influential 'pre-ISPOCD' studies was given in the previous edition of the present textbook[17].

By design, the ISPOCD studies to date have excluded patients with preoperative Mini-Mental State Examination (MMSE) scores of 23 or less. This was a pragmatic decision because such patients were thought likely to have difficultly in completing the preoperative cognitive test battery. However, this means that a systematic study using ISPOCD techniques in patients who were cognitively impaired prior to surgery has not been carried out, even though theoretical considerations and the clinical experience of anaesthetists and others would suggest that it is this group of patients who are likely to have the highest incidence of short- and long-term POCD[2]. Silverstein *et al.*[18] reanalysed some of the earlier ISPOCD data by dividing patients into a lower (1.5 SD below controls on the ISPOCD battery) and a higher cognitive group but, as stated above, all patients had MMSEs of 24 or more. They found no evidence that those in the

lower cognitive group preoperatively had an increased incidence of POCD.

While it is good clinical practice for a simple cognitive test to be recorded in all older people prior to surgery, tests such as the MMSE are blunt instruments that may miss minor degrees of cognitive impairment. The question then has to be asked whether the detection of an unexplained POCD represents a new disease or an unmasking of a previously latent problem. We do not have accurate data about the incidence of long-term cognitive decline in patients who already have a degree of preoperative impairment. If the ISPOCD battery is too complicated a tool to assess such patients then perhaps a simplified battery needs to be employed. However, there would be additional problems of gaining informed consent for studies that set out to study the effects of surgery and anaesthesia in patients with a degree of preoperative dementia. At the other end of the spectrum, some individuals who *subjectively* report impaired concentration after surgery may not be classified as having POCD by the standard ISPOCD method, which might indicate that it is insufficiently sensitive in some situations.

It is not easy to summarize the evidence from Table 131.3 and other literature into a form that can give guidance to individual older people who fear subtle changes in postoperative cognitive function. In a recent Commentary[15] we have attempted to stimulate discussion on this topic with a fictitious scenario of a cognitively well-preserved patient of 75 who is considering whether or not to undergo elective hip surgery for osteoarthritis. We drew three broad conclusions from the data contained in the studies in Table 131.3:

1. If we accept the ISPOCD criteria, POCD one week after major non-cardiac surgery carried out under general anaesthesia is surprisingly common in all age groups. While the incidence in the over-60s was estimated at 19.7–41.4% compared with 3–5% in controls[8,13,14], similar incidences were reported in the 40–60 age group[12,14], and even in those aged 18–39[14].
2. Unlike the situation for POCD at one week, the incidence of POCD at three months appears to be positively associated with advanced age. Thus, in the under-60s, the incidence of POCD three months after surgery was around 5% in both patients and controls[12,14]. However, in the over-60s, POCD incidence at three months was 9.9–14.3%[8,13,14], which was significantly higher than the 1.8–2.8% rates found in controls. Very elderly patients are under-represented in the ISPOCD studies, but in ISPOCD1 those aged 70–79 had twice the rate of POCD of those aged 60–69 (14% vs. 7%)[8].
3. Our ability to draw firm conclusions about POCD beyond three months is limited by lack of long-term follow-up data. However, using a subset of ISPOCD1, Abildstrom *et al*.[11] reported that 10.4% of the over-60s fulfilled the criteria for POCD 1–2 years after surgery. While this was the same as the rate found in non-operated controls (10.6%), only 47 of the latter were available, so confidence intervals were wide. The link between POCD and death has also been mentioned by two studies. Monk *et al*.[14] reported an association between POCD at three months and mortality at one year. Steinmetz *et al*.[19] followed up a cohort of ISPOCD patients for a median of 8.5 years and linked the presence of POCD at three months with increased rates of mortality: the hazard ratio (adjusted for age, gender and cancer) was 1.63 ($p < 0.01$). Visual inspection of the survival curves[19] suggests that the main difference between the mortality rates in the two groups occurred between two and four years after surgery and anaesthesia.

The above three conclusions come with the caveat that some patients who report *subjective* cognitive impairment three months after surgery are classified as normal under the standardized POCD definition used in the above studies. A possible explanation is that some of these patients are depressed rather than cognitively impaired[12], but there is also the possibility that subtle cognitive effects are being missed by the ISPOCD psychometric battery. For example, Hanning[20] cited a case of a patient who needed to take early retirement despite being classified as 'normal' on ISPOCD criteria. It should also be noted that the extent of individual disability and distress caused by different levels of POCD has so far attracted little research attention, although Price *et al*.[21] have recently explored the effects of impaired memory and/or executive function on activities of daily living. One of the most interesting conclusions from the ISPOCD work relates to the difference between outpatient (day stay) and inpatient minor surgery and appears to support the practice of day stay surgery in the over-70s as a way of reducing POCD at one week[10].

MECHANISMS OF ANAESTHESIA AND POSSIBLE INTERACTIONS WITH NEURAL PATHWAYS INVOLVED IN HIGHER CORTICAL FUNCTIONS

Xie *et al*.[22] and Inouye[2] have explored the hypothesis that the same mechanisms might cause postoperative delirium and dementia and that anaesthetic agents might sometimes be involved in such mechanisms. The popular scientific press has reported this hypothesis under the alarming headline 'Alzheimer's alert over anaesthetics'[23], although Xie *et al*. have been quick to point out that sweeping clinical conclusions should not been drawn from 'test tube' studies[24]. Indeed, in their refutation of the more extreme extrapolations, Xie and colleagues have stated, 'The available epidemiological evidence shows no association between Alzheimer's disease and previous surgery requiring anaesthesia. If elderly patients put off necessary surgery for fear that the anaesthetic will harm them, they may place themselves at higher risk of disease or death than any small cognitive effect caused by surgery and anaesthesia'.

The tenets of the hypothetical arguments of Inouye and Xie *et al*.[2,22] are:

1. There may be common mechanisms underlying delirium (a common postoperative complication) and dementia, as they share several pathophysiological features such as decreased cerebral metabolism, cholinergic deficiency and inflammation. However, a causal relationship has yet to be proved.
2. The two characteristic histological features of Alzheimer's disease are plaques (containing amyloid) and neurofibrillary tangles (containing tau protein). Certain anaesthetic agents can trigger changes of oligomerization of beta-amyloid protein (Abeta) and apoptosis in animal models and cell culture[25]. The halogenated ether isoflurane can induce apoptosis in cell culture, a process which can be inhibited by Congo Red, an agent which is known to inhibit Abeta production[22]. Halothane, a halogenated hydrocarbon has been shown to increase the oligomerization of Abeta amyloid peptide *in vitro*[26].
3. Cholinergic mechanisms are known to play a part in delirium and dementia. It is of considerable interest, though not surprising given the importance of the cholinergic system in maintaining consciousness, that the cholinergic system is a site of binding of

anaesthetic drugs. Thus, Fodale *et al*.[27] describe nicotinic receptor binding and inhibition by the three volatile inhalational agents in current use in the developed world (isoflurane, sevoflurane and desflurane), and muscarinic blockade by intravenous barbiturates. A discussion of the role of the cholinergic system in the pathophysiology of dementing diseases is outside the scope of this chapter. However, as the types of receptors that mediate anaesthesia appear very similar to the types of receptors that decline in patients with Alzheimer's disease, then it is conceivable that anaesthesia might worsen or hasten the dementing process or unmask latent dementia. In finishing this discussion it is worth noting that acetyl-cholinesterase inhibitors, administered to patients without dementia, do not reduce the incidence of delirium after elective hip replacement[28].

The review by Culley *et al*.[25] summarized the field up to 2007 and included more laboratory evidence that anaesthetics could alter the metabolism of amyloid protein. It also mentioned the theoretical possibility that tau proteins, contained in the neurofibrillary tangles of the brains of people with Alzheimer's disease, might also be affected. Two recent papers have indeed reported the effects of anaesthesia on tau proteins in animal experiments[29,30] although the study of Planel *et al*.[29] in mice described the process as being associated with a severe hypothermia occurring under anaesthesia, rather than being specific to any particular anaesthetic (and was avoidable with proper attention to temperature control). The degree of hypothermia observed by Planel *et al*.[29] was far more than the hypothermia occurring in ordinary anaesthetic practice, with the notable exception of cardiopulmonary bypass. This is of interest as cardiac surgery tends to have higher rates of cognitive impairment than non-cardiac surgery. While this difference has usually been attributed entirely to the direct physical effects of the cardiopulmonary bypass apparatus, the cognitive effects of hypothermia should perhaps be considered as a possible confounder in future studies, with particular attention to the effect of the process on tau production.

As far as patients, relatives and health care personnel are concerned, the major unanswered question is whether the various phenomena discussed in the previous three paragraphs are of clinical relevance. Do certain anaesthetic agents have the potential of triggering the process that leads to the evolution of a degenerative brain disease?

When one considers the history of the development of anaesthetic drugs, the possibility of an uncommon but potentially serious side effect involving long-term cognitive function cannot be dismissed out of hand. The number of potential anaesthetic drugs is enormous – there are huge numbers of variants and isomers of organic compounds such as ethers and alkanes. Volatile inhalational anaesthetics evolved from 1846 by a matter of trial and error with the emphasis, naturally, being on their immediate anaesthetic properties and the lack of any short-term side effects. While many compounds were rejected early on for reasons of toxicity, more subtle toxic effects continued to bedevil clinical experience with these drugs for years after their introduction. Today's volatile inhalational anaesthetic agents, the halogenated ethers sevoflurane, desflurane and isoflurane, derive historically from the original discovery of the anaesthetic properties of diethyl ether. Another class, obsolete in the developed world, comprises the halogenated hydrocarbons. Halothane was the most prominent example of this class, and it was a major advance when introduced in 1950, because of its inert properties, but the association with an idiosyncratic reaction leading to hepatotoxicity led to its obsolescence. An early halogenated ether, enflurane, became obsolete because of fluoride-induced nephrotoxicity.

Conventional classic models of the mechanism of action of general anaesthetics considered that all the inhalational agents worked in a similar way by a purely physical mechanism, the potency of agents correlating with the physical property known as the oil/water partition coefficient. Techniques such as magnetic resonance spectroscopy demonstrated that lipid-soluble molecules with anaesthetic properties interpose themselves into the cell membrane, increasing fluidity of the membrane and interfering with ion channel function. Given the clear correlation between potency and lipid solubility, the key strategy in pharmaceutical development has been finding a molecule whose effects, in terms of rapid changes of anaesthetic depth, could be most easily manipulated by the anaesthetist. For this purpose the physical property of blood/gas solubility coefficient has consistently been shown to be *the* property determining clinical usefulness. Modern anaesthesia is more predictable and safer because of this development, and older patients have benefited at least as much as the young in this respect. Patients regain consciousness and regain protective reflexes within minutes and can go home within hours. As a consequence they are spared prolonged hypoxia, hypotension and hostile ward environments – factors that we know predispose to delirium. Physical models also give the impression that changes induced by the addition of an agent, in this case an anaesthetic agent, are completely reversible. But the classic physical models of action fail to explain the significant pharmacodynamic differences between volatile agents. To explain these, mechanisms such as differential ion channel blockade are useful. For example, for a given depth of anaesthesia, isoflurane causes more vasodilatation than halothane, and this is an important clinical difference. It is against this background of action – specific ion channel or receptor blockade – that theories on the comparative neurotoxicity of general anaesthetics are being tested.

The link between the *in vitro* studies mentioned above, the theory of interference with the cholinergic system, and the possibility of a dementing process being triggered by a single exposure to anaesthesia in clinically relevant concentrations, is of course tenuous. The Food and Drug Administration (FDA) in the US has judged that it is inappropriate at the present time to make any recommendations about specific anaesthetic agents[25] but this remains a very emotive area, as any search of the internet using the keywords 'anesthesia' (or anaesthesia) and 'dementia' will testify. Suffice for the moment to notice that there is fundamental clinical and laboratory work still to be done, and that this is an area where collaboration between anaesthetists and mental health specialists should be particularly rewarding.

Nutritional State

David N. Anderson[1] and Mohammed T. Abou-Saleh[2]

[1]*Mossley Hill Hospital, Liverpool, UK*
[2]*Division of Mental Health, St George's University of London, London, UK*

Dietary surveys of elderly people in several countries over the past three decades have shown that a substantial proportion of subjects had intake below recommended standards. Two US National Health and Nutrition surveys showed that 50% of the populations, especially the elderly, were deficient in one or more nutrients. In 1979, a Department of Health and Social Security survey in the UK suggested that 7% of those aged 65 years or more may be undernourished and twice this proportion of those aged 80 years or greater[1]. In Sidney, Australia deficiency in the intake of nutrients by older people was similar to that found in the UK at that time[2].

There is little evidence that the situation has improved. The National Dietary and Nutrition Survey in the UK has reported since 1992 and, while most older people seem to receive adequate nutritional intake, the most recent survey has drawn attention to greater risk in particular groups of older people, including those who have lost their own teeth, those in institutions, the older age groups and those with low socioeconomic status[3]. A study of people aged 65 years or greater, using a validated malnutrition screening tool, identified more than 10% at medium or high risk of malnutrition[4–7]. Single nutrient deficiency is much more common than malnutrition, and in people in this age group, 29% of those who were independent and 35% of those in institutions were found to be folate deficient and 14% and 40%, respectively, deficient in vitamin C[3].

Of great concern is clear and consistent evidence that the highest rates of malnutrition reported in developed countries are those older people in hospital or care homes. In these populations malnutrition has been reported in 10–60% depending on age and medical conditions[4–7]. These populations will have high proportions of people with physical and mental illness. Inevitably, malnutrition is a common cause and consequence of illness but the number of undernourished people leaving National Health Service hospitals in England rose by almost 85% in the 10 years up to 2006, reaching almost 140 000 in 2006–7[8]; and 70–80% of malnourished people enter and leave hospital without a diagnosis or treatment[9,10].

Those older people at most risk include the housebound, those with cognitive impairment, a history of depression or long-term conditions, and the oldest old. Poor dentition, swallowing difficulties and not having regular cooked meals are further factors placing people at risk of malnutrition (Table 132.1).

The prevalence of malnutrition is certainly higher in older people where countries report this data. Poor financial reserves, isolation, physical handicap, dental problems and mental disorder all contribute, and the effects of disease, disability and ageing can combine to change a marginally sufficient diet into a grossly deficient one. Higher proportions of older people in these circumstances live in relative poverty and have greater prevalence of disease. The diet of lower socioeconomic groups provides cheap energy and is lower in essential nutrients like calcium, iron, magnesium, folate and other vitamins[11].

Malnutrition is a state in which a deficiency of energy, protein and/or other nutrients causes measurable adverse effects on tissue/body form, composition, function or clinical outcome[6]. It has significant implications for people at risk, causing increased vulnerability to infection by compromising the immune system, delayed wound healing, impairing function of heart and lungs, muscle weakness and depression and, in the extreme, death[12].

It increases rates of medical attendance, admission to hospital, length of hospital admissions and mortality. People with malnutrition have two to three times more complications following surgery[13]. Furthermore, the consequences of malnutrition include depression, apathy, decline of social interaction and confusion, which will conspire to produce a spiralling decline of nutritional status[7]. Malnutrition is a significant predisposing factor for the development of delirium in older people admitted to hospital medical wards[14]. Finally, malnutrition will affect the way the body handles prescribed medications.

Despite this information 30–40% of malnourished people do not receive care according to present scientific evidence and 20–25% receive care that is not needed or is potentially harmful[15]. Though single nutritional deficiencies are more common than malnutrition they commonly co-exist[7].

But the most common nutritional problem in developed countries is obesity. This has direct relevance to mental health as it contributes significantly to vascular risk and the metabolic syndrome. It is now clear that vascular risk is not only important for the development of vascular brain disease, which may manifest as dementia, depression or psychosis in later life, but also as a risk factor for the development of Alzheimer's disease. Obesity can impair independent function and ambulation, add to the burden on arthritic joints or impaired cardiopulmonary function and exacerbate other long-term conditions, creating a situation where older people can then become depressed.

While ageing is usually accompanied by weight loss, some older people will become vulnerable to weight gain if their lives become more sedentary and their diet unbalanced. Of course, obesity may also be associated with single deficiencies and people who are obese can

• Low body mass index
• Unintentional weight loss
• Poor absorptive capacity
• Increased nutrient loss
• Catabolic states

become malnourished. Drugs used for the treatment of mental illness often carry the risk of weight gain and the metabolic syndrome.

Those most at risk of malnutrition or who may need nutritional support are summarized in Table 132.1.

ASSESSMENT AND DIAGNOSIS

Part of the problem is difficulty diagnosing malnutrition and agreeing diagnostic criteria. The assessment of nutritional state is complex and any single measure seems inadequate. However, anthropometric measurements, including body mass index (BMI), are the foundation but this needs to be done by professionals with expertise who understand the clinical context. Biochemical markers are often unreliable, particularly with people who are ill, as these are affected by acute phase responses. People most at risk of being malnourished are those who are thin or with recent unintentional weight loss, including people who are obese[6,7,16]. Other clinical circumstances will further identify people at risk of becoming malnourished, for example, people with dysphagia or excessive nutrient loss[13].

Routine screening of people on admission to hospital or care homes is now recommended and identification of those likely to need nutritional support based on a combination of BMI, unintentional weight loss and clinical contexts placing people at risk[13]. Screening instruments like the Malnutrition Universal Screening Tool can be useful, easy to use and require little training[6]. Screening is considered cost effective for older people admitted to hospital[13]. While over 95% of malnutrition is in the community (including care homes), most malnutrition-related expenditure occurs in hospitals[17,18].

MENTAL HEALTH

Malnutrition and nutrient deficiencies are more likely to be a consequence rather than a cause of mental illness in older people. Classical single deficiency states as cause of mental illness are rare in developed countries though there is a strong suspicion that suboptimal nutrition often contributes to ill health in old age. The immediate significance of single deficiency states is confined to a few specific circumstances, for example, thiamine deficiency and the Wernicke–Korsakoff syndrome; B12 and folate with cognitive impairment, dementia and depressive states[19]. In most instances, the import of nutritional status on mental function is less direct and more subtle.

Certainly, the consequences of malnutrition will complicate treatment of mental illness and impair prospects for recovery. In addition, effects on physical strength, organ function and the immune system increase the risk of falls, fractures, pressure sores, infection, hospital admission and mortality. These risks will need to be addressed in care plans and will substantially increase the hazards associated with prescribing psychotropic drugs to older people.

Under-nutrition may arise from quantitative and qualitative dietary inadequacy, and a number of problems facing older people and the mentally ill place them at particular risk. Social isolation, loneliness, poor socioeconomic position, physical and sensory disability and co-morbid long-term conditions are common accompaniments of mental health problems in later life. Depression and dementia, in particular, are associated with reduced appetite, weight loss and poor attention to diet resulting from apathy, loss of interest and cognitive difficulties. Furthermore, effects of nutrient deficiency, including apathy, depression and cognitive impairment, will compound an already difficult situation and may lead to a spiral of decline.

PREVENTION

The overwhelming priority in the management of under-nutrition among elderly populations is prevention. A major impetus must ultimately come from changes in public policy that improve the older person's social, material and financial position in society, address inequalities and ensure the efficient provision of services to those in need.

The market-led approach to nutrition that operates in many food-rich countries has been found to increase the disparity between the nutrition and health of the rich and poor[20]. The provision of domiciliary care services is inequitably distributed, often inefficiently organized and frequently determined by demand rather than need[21]. In the UK a younger person with equivalent need to an older person has much greater access to social care and mental health services[22,23].

In the modern era food suppliers are often large impersonal stores sited some distance from communities, making shopping difficult for physically and mentally disabled people. Low income with disability not only restricts ability to afford a protective diet but also limits access to retailers where healthy food can be purchased more cheaply. Local shops in developed countries are less prevalent and can be significantly more expensive than distantly sited supermarkets[24].

Often the presentation and supervision of meals is poor. This is particularly evident in hospitals and care homes. A leading charity for older people in the UK[25] has drawn attention to the problem in hospitals and this report along with other national guidelines recommends a number of changes to practice that could address this need[13,26]. The National Diet and Nutrition Survey in the UK found the food supply in care homes to be sufficient but biochemical measures revealed poor vitamin and mineral status[3]. While the explanation of this is not clear it may be the result of poor intake and absorption due to poor presentation and timing of food, need for more assistance with eating or changes in absorption and the general medical condition.

Simple measures like providing meals in a form that is appealing and easily edible, at a time when appetite is greatest or when people

are most motivated, providing assistance and allowing enough time for meals to be eaten are often all that is required yet all too often not part of the regimes of hospitals or care homes. Some people, particularly people with dementia, will take food from family or friends and not care staff or from certain care staff, and these institutions need to provide greater flexibility of approach and ensure that areas catering for older people and people with dementia have sufficient number of staff. The ready availability of fresh produce, particularly fruit and vegetables, is lacking. Modern catering is not always sensitive to the needs and preferences of older people.

Diet is a poor source of vitamin D, which depends on exposure to ultraviolet light for its formation. More exposure to natural sunlight is the most important preventive measure but for those older people at risk of little exposure, calcium and vitamin D supplements are recommended[27].

Easy access to health and dental care is important. People with long-term conditions and poor dentition are at particular risk of dietary deficiency. Dental care is especially overlooked yet a study of hospitalized people aged 61–99 years found 60% to have disease of the oral soft tissue[28]. For those living in the community, preventive dental and health care with early recognition and treatment of illness is needed.

The elderly population may benefit from greater education and advice about healthy and affordable eating, issues normally targeted at younger people. The judicious use of fruit juice, frozen foods and some convenience foods might ease the burden of food preparation in those at risk of neglecting their diet. Occupational therapy assessments can find practical solutions to problems arising from visual impairment, arthritic joints and disability or the need for someone to help with shopping and food preparation. The teaching of culinary skills may be particularly helpful to the older bereaved man who never cooked while his wife was alive.

Diet is connected with lifestyle and opportunity and so moderate alcohol consumption is associated with better health and less risk of developing depression but also with a more active and sociable lifestyle, better self-rated health status[29] and higher intake of various nutrients[30]. Whether these variables are independent is not clear but the evidence would suggest that older people who can remain active, exercise and remain socially connected seem to take a better diet and protect themselves from some of the mental health problems occurring in later life.

In a prospective study of relatively healthy and active European men aged 70–89 years, low cholesterol but not dietary factors was associated with increased risk of developing depression[31]. The relationship of cholesterol levels to mental health in later life remains confusing as, while raised levels might suggest increased vascular risk, high levels may reduce risk of dementia, with declining levels reported before incident dementia[32].

TREATMENT

Recommendations for the treatment of malnutrition and the maintenance of optimal nutrition are available[13]. But assessment and treatment require considerable expertise as there are dangers. If correction is too rapid there is the risk of precipitating re-feeding syndrome or Wernicke–Korsakoff syndrome. The former seems to arise from the body's adaptation to malnourishment when rapid change precipitates micronutrient deficiency and dangerous change in fluid and electrolyte balance. This may lead to cardiac failure, pulmonary oedema, cardiac dysthymia, fluid overload or depletion, low levels of phosphate, potassium and magnesium, and raised glucose. People with alcohol problems, in particular, are at risk of rapid re-feeding, causing increased thiamine demand and the Wernicke–Korsakoff syndrome.

The preferred approach is always to improve dietary intake by natural means. Guidance on the risk benefits and approaches to artificial nutrition are available though studies have rarely involved older people with mental illness[13].

Where single nutrient deficiencies are found it is usually better to replace them though there is little evidence to demonstrate that this has clinically detectable effects on mental health other than in exceptional circumstances. Thiamine replacement in Wernicke's encephalopathy is curative. Thiamine supplementation in people with serious alcohol misuse or undergoing detoxification and correction of B12 and folate deficiency in cognitive impairment or dementia may protect or enhance cognitive function. Because single deficiencies often co-exist with more general under-nutrition or the risk of developing malnutrition they should prompt a more detailed assessment of nutritional status. If it clearly arises as a consequence of mental disorder the imperative is to treat that and address the disability or need underlying dietary neglect.

There are a large number of heterogeneous randomized controlled trials of nutritional supplements of mixed quality and results that, in general, show benefits of producing weight gain with fewer complications and mortality and they are acceptable to patients[13]. Similarly, studies of vitamin and mineral supplements produce conflicting results and, although of uncertain benefit, are thought to be beneficial for older people where there is concern about their food intake[13]. These studies rarely consider the effects on mental state.

In extreme circumstances assisted enteral or parenteral methods, including surgical procedures like percutaneous endoscopic gastrostomy (PEG), are considered to sustain nutrition with clear evidence-based guidelines for their use[13].

DEMENTIA

Particular concerns arise about decisions on feeding for people with dementia. While all general principles apply, dementia raises issues rather different from the rest of mental health due to the combination of people who lack capacity to make decisions and who are also suffering a terminal illness.

There are a number of reasons why people with dementia have difficulty sustaining nutrition. Dietary intake may be reduced due to a natural decline of appetite and hunger, difficulty with the feeding process or food preparation due to cognitive deficits, and problems swallowing.

Furthermore, weight loss is a recognized consequence of dementia, regardless of diet, which may develop before the diagnosis is made. A 32-year prospective study showed increasing difference in BMI between people with and without dementia during the 6-year period before the diagnosis was made[33]. Though the reasons are not entirely clear, a number of possibilities are proposed, not least that this is part of the neurodegenerative process[34].

If people with dementia suddenly lose appetite or weight the possibility of other causes must be considered. New physical illness, pain, oral and dental problems, newly prescribed medication, constipation or impaction, and depression may present this way and can be difficult to recognize in more severe dementia when the person's ability to communicate symptoms is compromised. This situation requires a more detailed examination of physical and mental function followed by appropriate investigation.

Many of the essential approaches to facilitating dietary intake and maintaining nutrition have been covered and the prevailing view, when these begin to fail, is to continue with a conservative, palliative care approach rather than take recourse to more invasive and artificial procedures. In advanced disease there is no good evidence that tube feeding prevents aspiration pneumonia (paradoxically the most common adverse association), malnutrition, pressure ulcers or infection, or improves survival, function or comfort[35]. Similar lack of benefit and adverse consequences has been found with PEG[36].

However, this is a difficult situation because while the evidence for tube feeding or PEG fails to provide convincing evidence of benefit in people with dementia, and does demonstrate significant risks, these studies have been conducted on frail people with advanced disease and there is an absence of evidence for people with earlier disease at risk of nutritional deficiency[37].

All commentators emphasize the need for clarity about the purpose of artificial nutrition in this situation, recognizing that there are occasions when such procedures may be warranted; for example, when the problem is reversible and not a direct result of the dementia[38].

Ultimately, decisions will need to be made on an individual basis, acknowledging the evidence base and considering what is in the best interest of a particular individual should they be unable to express their own wishes or have not made that clear through an advance statement.

CONCLUSION

A great deal more needs to be known about the relationship between diet, nutrition and mental health in older people – not only understanding how nutritional deficiency might exert effects on mental function but also identifying people who may be predisposed to develop mental disorder where modification of diet and lifestyle could afford protection[39]. There is no doubt that lifestyle characteristics affect health; improving diet would be expected to improve general health and, thereby, reduce the risk of certain mental health problems in later life. For example, intake of fruit and vegetables is an independent risk factor for stroke[40], a physical health problem with significant psychiatric morbidity.

At present nutritional deficiencies and malnutrition are far more likely to be a consequence than a direct cause of mental illness though in less developed parts of the world they may have greater relevance to the causation of mental disturbance. What is very clear is that older people, people in isolation with long-term conditions and those who are socioeconomically disadvantaged are at greater risk of malnutrition and these are groups also at greater risk of mental illness.

Despite many countries having national policies on nutrition and there being many guidelines and recommendations from professional bodies, the problem of malnutrition continues to be significant. Public policy will also have to address the serious inequalities that exist for older people in many parts of the world. Training for doctors, nurses and medical students on nutrition will need to improve[8,41–43] and rates of malnutrition are highest in hospitals and care homes, where guidance does not seem to be changing practice. Stronger enforcement of this guidance, including routine screening, is probably necessary[8].

The evidence connecting nutrition and morbidity that impairs function, and increases risk and mortality makes this an essential area of knowledge for all professionals working with older people. There is a good case for a specialist practitioner able to provide nutritional assessment and advice to be available to mental health teams working with older people, and these assessments should now be routine for all people admitted to hospital and care homes. The consequences of malnutrition will have significant impact on the treatment of mental illness, risk and recovery.

Further exploration of the relationship between dietary constituents and the course of mental illness may yet yield significant information relevant to the management of mental illness in later life. The chicken and egg question is difficult to unravel, and large prospective studies that control for a substantial number of variables will be needed to address this intriguing association. What is certainly the case at present is that the fundamental need for a nutritious diet to maintain optimal health is still missing in the lives of many older people and its importance overlooked or ignored by health and social care services.

Caregiver Support

Kathleen C. Buckwalter, Mary Ellen Stolder, Charlene S. Aaron and Catherine Messinger

University of Iowa College of Nursing, Iowa City, IA, USA

INTRODUCTION

Alzheimer's disease and related dementias (ADRD) are neurodegenerative, progressive, chronic illnesses with an unpredictable clinical course. Compounding this tragedy is that caregivers' mental and physical well-being suffers, and their activities and social relationships are disrupted, leading them to discontinue home care. This chapter highlights the vital caregiver role, and the costs to and support for home caregivers and those in the process of relocating a patient to an institutional setting. We review the positive and negative effects of caregiving, the psychosocial and physiological outcomes, and variables that mediate the stressors inherent in caregiving.

THE CAREGIVER ROLE

Of the estimated 5.3 million Americans with ADRD, over 80% are cared for by family members and friends, typically spouses[1–3]. Most families want to forestall or avert institutionalization of those with ADRD, so the aging US population presents a significant societal challenge.

Who are Family Caregivers?

Caregiving typically falls to women, who provide 72% of care: 29% are adult daughters and 43% are wives[4]. Nonetheless, both men and women caregivers of persons with dementia (PwDs) devote a similar amount of time to caregiving service and, more importantly, perceive similar levels of stress. Most stress arises from dealing with behavioural problems. This stress is a common precipitant of institutionalization[5,6].

Public Policy and Cost Implications of Caregiving

Policy makers recognize that families are the mainstay of caregiving and that such care comes at considerable cost (i.e. home modifications, assistive devices, special food, high utility costs and lost wages[7–9]). Conservative estimates indicate that family caregivers of PwDs saved the US health care system $350 billion in 2006[10]. With the population ageing, this estimate will increase. Although family caregiving greatly relieves costs to society, it concentrates financial burdens onto caregiving families. Moreover, monetary estimates in no way reflect the human costs of this devastating disease. Indeed, caregiving correlates with other adverse consequences, such as poor health[11–13].

CAREGIVER STRESS AND BURDEN AND ITS IMPACT ON CAREGIVER WELL-BEING

The concept of caregiver burden is used as an all-encompassing term referring to the financial, social, physical and emotional effects of caregiving. Numerous studies have examined the burden and stress of caring for a PwD, the effects on mental and physical health, and the use of a variety of interventions to relieve caregiving burden.

Family caregivers of persons with ADRD experience stressors that affect their health and well-being, and precipitate institutionalization of the care recipient. Hence, 'stress' has emerged as an important concept, with the words 'stress', 'burden', and 'distress' often used interchangeably. Spouses may be at greatest risk, as they are often elderly themselves[14]. In a common pattern, the distress and depression caregivers experience precipitates physiological changes and poor health habits, leading to illness[15].

Models of Caregiver Stress

Several theoretical frameworks have guided studies of PwDs, their family caregivers and how interventions affect both[16]. Stress models, in particular, have guided much of this research, showing that the care recipient's level of impairment is not a linear predictor of caregiver stress[17,18]; instead, caregiver stress is moderated by many factors, including the caregiver's physical health, social support, financial assets, coping abilities and personality. For example, Vitaliano *et al*.[19,20] stratified resources and vulnerability variables of both the caregiver and care recipient, to pinpoint relationships among stressors, resources and burden. Vitaliano considered both psychological and biological markers of distress, and expressed them in a mathematical formula in which the level of caregiver distress (burden) decreases with reduced undesirable variables or increased desirable variables:

$$\text{Distress} = \frac{\text{Exposure to stressors} + \text{Vulnerability}}{\text{Psychological resources} + \text{Social resources}}$$

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Other studies, examining racial differences in caregivers of PwDs, found stress levels to be affected by overarching factors that reflect personal context (e.g. being able to financially provide for their family and getting leisure time away)[21].

Stressors Associated with Family Caregiving

The profound cognitive and behavioural changes of ADRD include progressive loss of memory, judgment, the ability to interpret abstraction, and language and motor skills, as well as personality changes. ADRD culminate in an inability to perform instrumental activities of daily living (IADLs), such as cooking and managing money and, as the disease progresses, more basic activities like bathing and toileting. Researchers disagree on whether the level of a care recipient's functional or cognitive impairment correlates with caregiver burden[22,23]. Notably, however, a recent study found caregivers' quality of life did correlate with the severity of the care recipient's behavioural disorders and duration of the disease process[24].

ADRD has an unpredictable course and pace of decline; the only certainty is that the disease is progressive. As dementia progresses, caregivers must be increasingly vigilant, since a PwD may unexpectedly leave home or injure themselves. In the final stages, patients are often completely dependent on their caregivers, making caring for a PwD eventually an all-consuming job.

Behavioural Impairments in Care Recipients

Most commonly, the reported behavioural changes of ADRD include lethargy, withdrawal, sleep disturbance, restlessness, wandering, aggression, destroying property and verbally disruptive or sexually inappropriate behaviour[25–27]. The stress of providing 24-hour care mounts when the PwD becomes agitated, stressed or disoriented. Behavioural abnormalities appear in up to 67% of care recipients upon diagnosis[28], in 65% of institutionalized persons[26], and in 70–90% of persons with advanced dementia[29,30]. They worsen with disease progression and may be related to fatigue, change, overstimulation, excessive demands or physical stressors[31]. Moreover, the care recipient's behavioural problems are the characteristic that overwhelmingly predicts caregiver distress[22,32], making this a strong predictor of institutionalization[33].

Other Factors that Influence Caregiver Stress

Caregiving for persons with ADRD entails years of constant demands. Over the disease trajectory, the intensity and/or frequency of a caregiver's level of distress may vary widely. To understand this variability, investigators try to identify factors associated with differing outcomes. Stress may be influenced by whether the caregiver and recipient reside together, the abruptness of the disease onset, the family relationship, and the caregiver's coping strategies[34,35]; also caregiver burden was reportedly more intense for spouses than for adult children[32]. Positive outcomes, however, are associated with a strong social network and satisfactory support[36].

In sum, the relationship between the caregiver's psychological distress and physical impairment depends on many variables, for instance the care recipient's behaviours and caregiver vulnerability (e.g. age, gender, neuroticism, pre-existing hypertension, and social support). Nonetheless, the factors contributing to caregiver distress have only recently been delineated well enough to effectively direct interventions or preventative strategies[37–40].

Dementia Versus Non-dementia Caregiving

The risk for health problems increases with the physical demands of caregiving, prolonged distress and the biological vulnerability of older caregivers. Research suggests that caring for a PwD is more demanding than caring for physically impaired older adults[41]. In a review of studies of caregiving in different types of illnesses, Biegel, Sales, and Schulz[42] observed different patterns of distress. Distress peaked after the initial diagnosis, but, as time passed, the level of distress fell. This pattern, however, was not observed in family caregivers of persons with a gradual onset, where no relief of distress was observed[43].

POSITIVE AND NEGATIVE OUTCOMES OF FAMILY CAREGIVING FOR PERSONS WITH DEMENTIA

It is notable that mounting evidence suggests that some caregivers find satisfaction in the caregiving role and report life satisfaction, emotional uplifts, enhanced self-esteem and self-efficacy, optimism, and growth and meaning[44–49]. Interviews of 50 caregivers of PwDs found 58% experienced 'self-fulfilling' experiences during caregiving, with the same percentage expressing 'losses and difficulties'[50]. Positive aspects of caregiving were related to the caregiver's competence. Brown and colleagues[51] found that caregivers who provided instrumental support to friends, relatives or neighbours, or who provided emotional support to their spouses, had lower five-year mortality rates.

IMPACT OF CAREGIVING ON HEALTH OF CAREGIVERS

Despite some inconsistent findings concerning how caring for PwDs affects mental and physical health, most but not all studies find increased psychiatric and physical morbidity[52–55]. This suggests that inconsistencies are attributed to differences in caregivers' coping strategies.

Mental Health Outcomes

Caring for an older person with ADRD puts one at risk for extreme psychological distress. A number of studies link stress to factors such as the strain of providing direct care, grief from witnessing the decline of their loved ones, social isolation and role changes. These effects occur with home care, following institutionalization, and during bereavement[37,56].

Depression

Depressive symptoms are among the mental health changes most frequently reported by family caregivers of PwDs. A complex interaction of cultural factors[57,58], caregiver and receiver characteristics come into play, predicting depression[59–61]. Moreover, depression among caregivers is associated with the intensity of their reactions to the patients' memory and behaviour problems[62] and to other outcomes such as increased physical and subjective burden[63,64], and the use of psychotropic medications[22,65].

Predictors of caregiver depression include a younger age of caregiver and care receiver, Caucasian race, Hispanic ethnicity compared to black ethnicity, higher education, activities of daily living

dependence, and the recipient's behavioural abnormalities (particularly aggressive or angry behaviour). Other predictors include low income, spousal status, hours spent caregiving and functional dependence of the caregiver[61,66]. Depression is greater among females than males[6] and appears to increase over time among residential caregivers and decrease over time following institutionalization and bereavement[67]. Compared to non-caregiving men, male spouse caregivers have higher levels of depression, respiratory symptoms, and poorer health habits, although the groups did not differ on other measures of physical and mental health[68].

Anxiety

Several investigators incorporated self-reported measures of anxiety when examining depression among caregivers. Some found that caregivers who presented with symptoms of depression also often reported symptoms of anxiety[18,69]. Overall, strong evidence suggests caregivers are at risk for psychiatric symptomatology. Yet, caution must be exercised when interpreting the generalizability of these findings, since many samples may be biased towards more distressed caregivers. For example, most caregivers are recruited from chapters of the Alzheimer's Association, support groups, or through referrals by health professionals; either individuals who have little difficulty with the caregiving role or are so distressed or constrained that they cannot participate in supportive programmes or visit health care professionals, may be under-represented. Additionally, transient psychiatric symptoms may be more common than diagnosable depression. Moreover, caregiver burden does not always predict depressive symptoms, suggesting that the relationship between caregiver burden and caregiver depression is complex[66].

Physical Health Outcomes

Most studies examining the physical effects of caregiving used one or more indicators of caregiver health: (i) self-reported health status; (ii) self-reported incidence of illness-related symptoms; (iii) self-reported utilization of health care services; (iv) self-reported medication use; and (v) disease susceptibility. Predictors of poor physical health outcomes for caregivers include being older, a spouse and female[22,70]. Interestingly, however, in some cases caregiving was also reported to improve physical health. Family caregivers with coronary heart disease (CHD), who experienced emotional uplifts, also showed less severe metabolic signs that predict CHD[20,71].

The psychoneurological and immunological effects of caregiving are receiving increased attention. One study indicated that long-term residential caregiving for PwDs decreased measures of cellular immunity and increased the duration of infection; most affected were caregivers who reported less social support and more stress[72]. Stress-induced changes in physiological function increase the probability of illness[73]. Caregiver wear and tear, from repeated arousal and inefficient control of the physiological responses of stress, can also lead to pathophysiology[74,75]. Stressors can cause impaired health habits, physiological responses, physical illness and even death[11,20,76,77].

Similarly, psychological stress can increase caregiver vulnerability to disease by compromising immune system integrity[20,78]. A well-controlled study examined caregiver depression and distress as immunological modifiers and linked the poorer immune response to lower levels of helper T-lymphocytes and natural killer (NK) cells[78]. Here, caregivers also reported nearly three-fold more stress-related symptoms and higher rates of psychotropic drug use, especially if they lived with the PwD. While some studies reported that caregivers use more psychotropic medications[22,72], most reports suggest use of somatic medication does not significantly increase[20,79].

In summary, the findings for the effects of caregiving on physical health are more equivocal than those for mental health; however, the evidence is still generally weak. This may be due to different definitions of health, health outcome measures, caregiving and control samples (varying levels of vulnerability and resources), care recipient samples (functional versus behavioural impairments), and that some self-report measures of physical health may primarily reflect life satisfaction. Moreover, caregivers who provide assistance with activities of daily living (ADLs) exhibit poor nutrition and poor decision-making regarding their own health care appointments[80].

Evaluating links between caregiver distress and health will ultimately require testing complex, multivariate models. Despite methodological challenges inherent in evaluating caregiving outcomes, data suggest chronic stressors do contribute to affective disorders and may alter caregivers' sympathetic, neuroendocrine and immunological function.

FAMILY CAREGIVING: RELOCATING THE CARE RECIPIENT

Placing a relative in a nursing home is stressful for both caregiver and patient. Yet PwDs are usually placed in nursing homes only when all other avenues and resources are exhausted[81,82]. Generally, the decision is postponed long past the time when more objective persons see it as appropriate[83]. One reason for this delay is that some caregivers, especially spouses, believe their role obliges them to sole caregiving responsibility and to reject institutionalization[84]. Although children are comparatively more likely to rely on formal services and place the PwD in institutional care, they nevertheless often delay placement decisions because of reluctance to reverse roles and take charge of a parent's life[85].

Overall, the literature indicates a care recipient's extent of cognitive impairment, loss of self-care abilities, and disruptive behaviours are predictive of institutionalization. Cohen *et al*.[81] described seven variables that affect a caregiver's decision to institutionalize a dependent elder with dementia: use of services, enjoyment of caregiving, caregiver burden and health, caregiver rating and reaction to care receiver behaviour and memory problems, and presence of troublesome behaviours. Six variables predicted actual institutionalization: caregiver health and burden, use of services, care receiver cognitive function and troublesome behaviours, and caregiver reaction to behaviours. Montgomery and Kosloski[85] compared predictors of placement for adult child caregivers and spouse caregivers. Higher income, eligibility for Medicaid, lower morale and age of the elder were associated with placement for both groups, but other predictors were different. Notably, the level of affection predicted placement for children, but not spouses, while sense of obligation was predictive for spouses, but not children, who were always more likely to institutionalize the PwD. The probability of placement declined with time for a while, levelled off, and then rose as caregiving exceeded 30 months, with the probability increasing more sharply for adult child caregivers than for spouses.

Increasingly, services are supporting family caregiving in the home, but the extent to which they are meeting needs is questionable[86,87]. Neither should it be assumed that family members know how to provide all of the needed care or have access to the resources to assist them with providing care in the home[87]. One

study found that 40% of family caregivers who had placed their loved one in a nursing home reported that at least one additional community service would have delayed institutionalization[88].

Relocation raises the prospect of sharp role transition. For most spouses, relocation changes a long-standing pattern of living together and providing for the other. For children, it can restore a pattern in which the child is not living with and/or is not directly responsible for the care of the parent. PwDs placed in nursing homes may be highly resistant and fearful of the change. Given their diminished capacity for reasoning, it can be challenging to convince them they require institutionalization. This presents a stressful dilemma, and one that may be more difficult for child caregivers, because of the need to reverse roles. Constant requests to be taken home are especially stressful to families. Spouses may find it more difficult if their relationship has been loving. Family Involvement in Care (FIC) interviews[89] revealed the regret felt when placing the relative in a nursing home, but also often reflected ambivalence because a burden was lifted.

When caregivers cannot manage the care recipient's difficult behaviours, such behaviours often escalate[31,90]; this is often the primary reason for institutionalizing a family member with dementia[91,92]. Considering the psychological and financial expense associated with institutionalizing a PwD, interventions that help caregivers prevent or manage behaviours are significant. Appropriately, national recommendations emphasize research that focuses on reducing the burdens of care for family members of PwDs[1]. Indeed, the American Association of Geriatric Psychiatry, the Alzheimer's Association and the American Geriatrics Society agree, 'Interventions that reduce the risk of caregiver depression and improve tolerance and the capacity to care for patients in the home, including educational materials, counseling support groups, day care and respite care' are among the most urgent areas for research[93].

Dang *et al*.[94] recommend that clinicians use the American Medical Association's 'Caregiver Self-Assessment Questionnaire', which can be placed in waiting rooms, handed to caregivers of patients with dementia, or mailed to them prior to the scheduled appointment. The questionnaire could alert providers to problems (e.g. signs of potential abuse or caregiver 'burn out'), prompting them to suggest education or counselling interventions. Although providing educational materials alone does little to relieve caregiver burden, a meta-analysis of 34 studies concluded that it significantly benefits caregiver psychological distress, caregiver knowledge and patient mood[94]. Another study showed that counselling caregivers delayed nursing home placement for an average of six months, and was particularly effective for adult-daughter caregivers[69].

CONCLUSION

Caring for a PwD is a responsibility usually shouldered by family members, and can be chronically demanding and often overwhelming[1]. Informal caregiving of elders with chronic illnesses and disabilities has become commonplace, in part from demographic shifts. Although medical advances are increasing life expectancy, escalating health care costs shortens hospital stays and limits reimbursement for at-home professional care. Adverse outcomes depend upon the unique characteristics of both the caregiver and the care receiver. Accordingly, research suggests that combined interventions, tailored for both caregivers and care receivers, can significantly improve caregiver well-being and health and, in some instances, problematic care receiver behaviours[95].

Elder Abuse – Epidemiology, Recognition and Management

Alexander M. Thomson[1] and Martin J. Vernon[2]

[1]*Department of Elderly Care, Salford Royal Hospitals NHS Foundation Trust, UK*
[2]*Department of Elderly Medicine, University Hospitals of South Manchester NHS Foundation Trust, UK*

INTRODUCTION

During the 1980s elder abuse emerged as a health and social issue of international importance[1]. It is defined as 'a single or repeated act or lack of appropriate action occurring within any relationship where there is an expectation of trust which causes harm or distress to an older person'[2]. While most authorities include self-neglect within the broad definition, acts which threaten an elder's well-being as a consequence of their competently made decisions are specifically excluded.

Abuse may occur in one of two settings. Domestic abuse is perpetrated within the home of the victim or a caregiver by either a relative or other care provider. Institutional abuse occurs within a designated care facility (residential or nursing home or hospital) perpetrated by one or more individuals having an obligation to care for and protect the victim.

Five major categories of abuse have been identified[3,4]:

1. Physical: any activity involving force to generate bodily injury or pain, including striking or burning. This includes the use of physical or pharmacological restraint (e.g. by means of over-sedation or withholding medication to assist movement such as analgesics or medications for Parkinson's disease).
2. Sexual: any form of non-consensual sexual contact, including unwanted touching, rape, sodomy and coerced nudity.
3. Psychological: the infliction of emotional distress through verbal or non-verbal acts, including insults, threats, humiliation, infantilization and harassment.
4. Financial: the improper use of an elder's property or assets, including theft, deception, coercion and misuse of authority to act, such as power of attorney.
5. Neglect: the refusal or failure to fulfil basic care obligations including the provision of food, water, clothing, medication, comfort and protection.

PREVALENCE AND INCIDENCE

Variability in case definition obscures direct comparison, although the prevalence of elder abuse is broadly similar throughout Europe and North America. To date there are few data from developing countries. With the exception of the United States, a paucity of robust national incidence data reflects widespread absence of formal mechanisms for case reporting and validation.

Differing study populations and sampling techniques have also contributed to a range of prevalence and incidence estimates[5]. The work by Thomas[6] described a range of estimates across studies of between 2% and 10%. This suggests elder abuse is sufficiently prevalent to be regularly encountered by all health care workers looking after older adults. Lachs and Pillemer[5] estimate that for every 20–40 older adults seen, there is one victim of abuse.

VICTIM CHARACTERISTICS

Likelihood of abuse increases with age[7]. Older women are more likely than men to be victims[8] but this observation may be confounded by greater likelihood of longer life expectancy[3]. Poverty elevates the risk of abuse[7].

Shared living is considered a major risk factor, due to increased opportunities for contact. Living alone is associated with lower risk, except for financial abuse[9,10]. Social isolation from other family members and friends (apart from the perpetrator(s)) is an additional risk factor[11].

Dementia is associated with higher rates of abuse than in cognitively intact older adults[11,12]. Cooper *et al*.[13] described an abuse prevalence of 52% from carers among a population with dementia. They discussed the 'spectrum of behaviour' in patterns of abuse, with 34% reporting seemingly important levels of abuse and lower rates of more serious abuse or physical harm. Behaviour disturbance, agitation or aggression is likely to fuel caregiver abuse. Carers are themselves also at risk of physical abuse from those with challenging behaviours. In one series, a third of carers reported physical abuse by the patient, which in turn was associated with abuse of the patient by the carer[14].

Interestingly, neither the level of dependency of an older adult on a caregiver nor the severity of caregiver stress have been identified as risk factors in a variety of research studies[5]. Similarly there is no proven relationship between degree of physical impairment and abuse.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Abuse in institutional care settings has been associated with a number of factors: inadequate staffing levels, frequent use of non-permanent staff, poor staff training, development and supervision, and inadequate incident reporting systems.

Vulnerability to abuse has been associated with certain personality traits[15]. Victims of psychological abuse have less ability to control problem situations and tend to react aggressively when feeling anger or frustration. In contrast, physical abuse victims pursue passive or avoidant behaviour, while financial abuse victims possess negative beliefs of self-efficacy and turn aggression or frustration on themselves.

ABUSER CHARACTERISTICS

Greater understanding of abusive situations has focused attention on those perpetrating abuse. Nearly half of all abusers are related to the victim, but only a small minority are the primary carer[3]. Carers who do abuse suffer social isolation, feel unsupported and may be financially dependent on the person they are abusing.

The strongest associations with perpetrators of abuse are with mental health disorders and drug and alcohol misuse. In particular depression and anxiety among carers are associated with abusive behaviour[16,17].

Abusers identified as misusing substances are likely to be male children of the victim, less likely to provide care and more likely to cause physical or psychological abuse than financial abuse[18]. Alcohol misuse and dependency have been demonstrated to have a strong association with the abuser across a number of studies[19,20].

NATURAL HISTORY OF ABUSE

The inconsistencies in definitions, poor recognition and under-reporting of cases create difficulties in examining outcomes. Corroborated abuse is associated with greater risk of death for elderly victims (odds ratio 3.1; 95% confidence interval 1.4–6.7) after adjusting for co-morbid and demographic factors[21]. However abuse rarely leads to homicide: in one American study only 2% of elderly homicides could be attributed to abuse[22].

Association has also been established between abuse and adverse outcomes including depressive illness and entry to 24-hour care[23]. Victims are also more likely to use behavioural health services[24].

RECOGNITION

Diagnosis of elder abuse requires a high index of suspicion. Professionals should be alert to the presence of one or more risk factors for abuse (Table 134.1) and sensitive to principal abuse signals. Although advocated by some authorities, no good evidence exists to support the routine use of screening tools to detect abuse[5]. Some assessment instruments have had limited value, but are poorly validated and lack outcome improvements to support their regular employment. There is no replacement for the general vigilance of health care workers supported by high-quality training in recognition, assessment and management.

In cases of suspected abuse, a coordinated multi-agency approach must identify all care needs and deficiencies. Corroborated history must be obtained from all participants including victim, alleged abuser and designated carers with careful verification of information obtained from cognitively impaired individuals.

Table 134.1 Risk factors for abuse

Victim	Age >75
	Living alone (financial abuse)
	Living with spouse or child (physical, sexual or psychological abuse)
	Low income
	Cognitive impairment
	Poor premorbid relationship with carer
	Abusive, passive or avoidant behaviour
Abuser	Male (physical abuse)
	Female (psychological abuse)
	Social isolation
	Financial dependency
	Impaired physical or mental health
	Substance abuse
	History of receiving or perpetrating abuse

Symptoms and signs of abuse must be elicited during a comprehensive clinical assessment to which the victim consents (Table 134.2). Accurate documentation including note keeping, radiology and photography will facilitate planning and may be vital for future prosecutions.

MANAGEMENT

Central to effective management is the establishment of a single co-ordinating agency providing education, advice and access to resources. Intervention models should be low cost, multidisciplinary, collaborative and capable of evaluating outcomes[25]. Denial, resistance to intervention, ignorance of intervention protocols, confidentiality and fear of reprisal have all been cited as professional barriers to the management of elder abuse[26].

Identification of incipient abuse should generate a brisk response to avoid escalation. Integral to management of cases is the aim to preserve autonomous choice for the victim and avoid paternalistic action which seeks to provide a speedy resolution, perhaps through institutionalization. Assessment of mental capacity is essential to determine the extent to which they can contribute to the assessment and management process. Accurate identification of unmet care needs should generate planned and effective care strategies which engender safety without intrusion. Given that abuse may be multidirectional, attention may need to be focused on both victim and abuser.

Overtly criminal activity such as theft or assault should be dealt with by prevailing criminal law. Most countries have eschewed a legislative approach to elder abuse, relying instead upon health and social service agencies to develop locally applicable policies and procedures. In the United States mandatory reporting laws have achieved only limited success and professionals remain unfamiliar with reporting procedures[27]. Of greater potential benefit for the future is the emergence of national organizations aiming to prevent the abuse of older people by disseminating research, informing public policy and providing specialist advice and training to both professionals and the general public[28].

Table 134.2 Symptoms and signs of abuse (National Center on Elder Abuse, 2000)

Physical abuse	Carer refusal to permit examination
	Reports of being hit, kicked or mistreated
	Unexplained behavioural disturbance
	Presence of unexplained bruises, lacerations, ligature marks, fractures
	Untreated injuries in various stages of healing
	Inappropriate use of prescribed medication
Sexual abuse	Reports of sexual assault or rape
	Bruising of breasts or genital area
	Torn, stained or bloody underclothing
	Unexplained genital infection or bleeding
Psychological abuse	Reports of verbal or emotional mistreatment
	Withdrawal, non-communication or non responsiveness
	Unexplained or unusual agitation or behavioural disturbance
Financial abuse	Reports of financial exploitation
	Unauthorized or unexplained changes in banking practice
	Abrupt, unauthorised or unexplained changes to financial documentation
	Unexplained disappearance of assets
	Unmet care needs in the presence of adequate financial resources
	Sudden appearance of individuals asserting their rights to an elder's assets
Neglect	Reports of mistreatment
	Failure to provide food and hydration
	Failure to meet clearly identified care needs
	Hazardous or unsanitary living conditions

Care of the Dying

Oxleas NHS Foundation Trust, Memorial Hospital, London, UK

MENTAL ILLNESS AND DYING

It is well recognized that serious mental illnesses of all kinds are associated with higher morbidity and mortality[1,2].

In dementia, the average life expectancy after diagnosis is only 4.7 years[3]. A variety of reasons contribute to mortality from almost all medical conditions occurring during a dementia illness. Dementia itself makes patients prone to acquire pneumonia (due to swallowing difficulties), urine infections (due to poor fluid intake, incontinence) and fractures (due to mobility problems). Dementia will also lead to late diagnosis with consequent higher mortality from many conditions. It limits the treatment options for conditions such as cancer, where the dementia may make intensive and painful treatments too burdensome to consider. Poor compliance with treatment also causes mortality. When dementia occurs in people with Parkinson's disease or Huntington's disease, these increase mortality as well[4]. However, in practice, most death certificates for people who die with dementia make no mention of any contribution made to the death by the dementia[5].

Delirium, which has a high incidence in the elderly and especially in those with multiple physical pathologies, is also associated with a high mortality[6]. While the mortality of delirium is most often thought to be due to its medical causes, death is also undoubtedly more likely due to the poor compliance and reduced motivation to rehabilitate that will be seen in delirium. People with a hyperactive delirium may pull out their drips and resist treatment just when they really need it.

In delirium, the therapeutic aim would be, of course, to make people better and avoid the excess mortality. Much too can be done in schizophrenia to reduce mortality through optimizing treatment, risk management, advice on smoking, diet, exercise and treatment for the antipsychotic-associated diabetes, hyperlipidaemias etc. However, in conditions such as dementia and Parkinson's disease it becomes clear at a certain time that life is indeed drawing towards an end. At such time, care rightly becomes more palliative (with the aim of maximizing comfort and quality of life), ahead of curative treatment.

Palliative care is the active holistic care of patients with advanced progressive illness. Management of pain and other symptoms and provision of psychological, social and spiritual support is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families. Many aspects of palliative care are also applicable earlier in the course of the illness in conjunction with other treatments. Palliative care should help people to live as well as possible until they die. It accepts natural death but seeks neither to prolong nor shorten life.

Clinicians, patients' families and nursing home staff need to recognize and treat advanced dementia as a terminal illness requiring palliative care[7,8].

INTERNATIONAL PERSPECTIVE

Internationally, practice is not uniform but there is a widespread interest and increasing understanding of the need to develop a good evidence base and improved palliative care for people with advanced dementia[7,9,10]. Although in the USA, people with advanced dementia do not need to have another serious illness to qualify for hospice care[7], access of people with advanced dementia to palliative care services is limited both in Europe and in the USA[11]. In the UK, despite the willingness to see non-cancer patients, people with dementia in acute hospitals are only a third as likely to be referred to palliative care as other patients[12], and few are admitted to inpatient hospices[13]. A recent US study has highlighted the low referral rate to palliative care services (22%) and high occurrence of burdensome interventions in people with advanced dementia (40.7% in their last three months of life)[8].

In Germany there is concern about the lack of clear clinical and ethical guidance for decision making in advanced dementia, including the appropriateness of using tube feeding[14]. In France there is increasing interest in developing adequate specific services which follow a palliative care model and a few studies are underway[9]. In some countries (e.g. USA, Germany) it is much commoner to use artificial nutrition and hydration in those dying with dementia[15]. The insertion of PEG tubes (as well as the use of mittens and restraints which are sometimes needed to enable this practice) may be seen as preserving life or, by some, as a burdensome medical intervention which may not be appropriate. UK practice is quite firmly against such methods[16]. But conversely, there is substantial concern in the UK about the underuse of hydration in those who are dying and there are clear reports of a harrowing death occurring without the use of any fluids[17]. We suspect that there is a need for balance here. European continental practice does include more use of parenteral fluids when these are well tolerated by the patient[9].

In other jurisdictions, where euthanasia is legal (e.g. Holland, Belgium, Switzerland, Oregon), euthanasia can also be applied without consent to people with dementia who lack capacity to decide

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

for themselves. But many worry that the availability of euthanasia may make good palliative care less important, and training of lower quality[18]. Deep sedation has been seen as an alternative to euthanasia in Holland[19]. Concern has also been expressed in the UK about the use of some care pathways for those who are dying[20]. Perhaps the biggest worry is that if a diagnosis of dying is made in someone who is not actually imminently dying, the care consequent upon that diagnosis (such as administration of inappropriate sedatives and withdrawal of fluids) may sometimes assure a death that was not imminent. But in the end whichever the jurisdiction there is a very clear need for good and appropriate care for those who are dying. It is entirely unacceptable that those who are dying might not have access to good palliative care in whichever jurisdiction they live. After all, palliative care exists to help people live as well as they can until they die and that must, surely, be available to all.

WHAT ARE THE KEY AIMS OF GOOD PALLIATIVE CARE OF DEMENTIA?

1. Perhaps the greatest aim of good care of the dying is to enable people to live as well as possible until they die. Frail and demented elderly often contribute in many ways to their family and others during their last illness and many people with dementia live well.
2. When patients with dementia or other terminal illnesses are distressed, then that distress ought to be alleviated.
3. Discussion about dying, with a willingness to inform both patients and carers, is important. Discussions enable advance illness planning which can be of great help later on in enabling those with dementia to live as well as possible and also to die well. Last-minute trips to hospital via A&E are to be avoided, and this will most likely be through good discussion and planning.
4. Care of the dying should seek to ensure that treatments given are effective, appropriate and not burdensome, primarily focused on enabling the patient to live well until they die and to reduce suffering.

PRINCIPLES OF PALLIATIVE CARE AS THEY APPLY TO DEMENTIA

Upon its founding, the hospice movement saw symptom control and the alleviation of distress as priorities. Hospices moored this alongside high-quality care and good environments providing oases of quality that were originally mainly afforded to those dying with cancer.

Dame Cicely Saunders, who founded the hospice movement, identified the reality of 'total pain':

- Pain is not just physical, but mental and existential too. All forms of pain/distress must be addressed and treated. It should be said here that the notion that pain (distress) can be both mental and physical is hardly alien to dementia care. Such an understanding has always been a central part of old-age psychiatric care.
- She saw that the patient is a whole person, an interplay of physical, psychological, social and spiritual dimensions. These all have an effect in a single individual and interplay together. So doctors must recognize and respond to psychosocial and spiritual distress, and not just deal with physical disease.
- She saw that the family was the unit of care and that care had to become centred around the person by recognizing the broader family and community.
- She established that symptoms could be analysed scientifically in the same way as any other illness so as to enable best care[21].

The models of palliative care bring with them some useful ethical views. It has long been accepted that sometimes the importance of distress reduction may mean that side effects of treatment might shorten life (double effect). A comfortable death can often be achieved by the appropriate use of medicines, and this may be one reason (see below) why antipsychotics may be justified. The oft-quoted ethics of 'first do no harm' may work a little less well. If the only aim is to avoid harmful treatments, it may not be possible to adequately alleviate distress. The Hippocratic position of 'I will never intend harm' would apply better as all treatment may bring a risk of harm but the intention must always be to improve the patient's condition. So, in the end, the purpose of care is central. If in the care of the dying the primary purpose of care may well be to reduce suffering, while accepting some risk of harm, that is fine. But if the primary purpose is to shorten life, then of course that is not.

The other key concept here is burden of care. When we are mentally well we will accept burdensome treatments so as to become well again, but as frailty increases and death nears, it becomes increasingly wrong to apply burdensome treatments. This helps to define appropriate and inappropriate care.

WHEN IS A MOVE TOWARDS PALLIATIVE CARE INDICATED IN DEMENTIA AND SIMILAR ILLNESSES?

Palliative care may be provided from the onset of an illness if symptoms are distressing. But generally, early on in illness, attempts at a cure and active treatment have more prominence. In progressive, fatal conditions there will, however, be a switch towards a more palliative approach. Factors that indicate that a switch is appropriate are set out in Box 135.1[22].

Box 135.1

Indicators for a transition towards more palliative care

Severe distress (mental or physical) which is not easily amenable to treatment

Or

Severe physical frailty which is not easily amenable to treatment

Or

Another condition (e.g. co-morbid cancer) which merits palliative care in its own right

Occurring in someone with a diagnosis of moderate or severe dementia or other progressive and fatal mental illness.

Therefore, in a frail and weak person with dementia, who can barely walk and is unlikely to survive acute medical care, a gentler and more palliative approach is needed. Similarly, in someone who is suffering due to ongoing mental distress or physical pain a palliative approach is needed. Finally, if someone has cancer and the demands of chemotherapy would be too great (due to the dementia), the focus of treatment must be palliative.

The *Gold Standard Framework* also sets out two ways of identifying when end-of-life care is appropriate[23]. Firstly it asks whether

or not the clinician would be surprised if the patient died in the next year. This is a simple question but it is clear that accurate prognosis is very hard in dementia. So, the question will often not be answered positively even in advanced dementia. Many who die would not have been identified by clinicians using the Surprise Question[24]. Moreover, those living happily with dementia may not need specific end-of-life care.

The Gold Standard Framework also suggests that the following indicate the need for end-of-life care:

- unable to walk without assistance; and
- urinary and faecal incontinence; and
- no consistently meaningful verbal communication; and
- unable to dress without assistance;
- Barthel score < 3;
- reduced ability to perform activities of daily living (ADL).

Plus any one of the following: 10% weight loss in previous six months without other causes; pyelonephritis or UTI; serum albumin <25 g/l; severe pressure scores, e.g. stage III/IV; recurrent fevers, reduced oral intake/weight loss; aspiration pneumonia.

However, these indicators are very physical in nature and there is a lack of consistency in the indicators of severity. Inability to communicate meaningfully sits awkwardly alongside reduced ADL skills as an indicator of severity. More importantly, these indicators do not recognize the importance of distress reduction in those with a difficult dementia complicated by behavioural challenge and psychological distress.

WHAT ARE THE FEATURES OF DISTRESS IN PEOPLE WITH ADVANCED DEMENTIA AND OTHER CONDITIONS WHERE IT IS HARD FOR THEM TO EXPRESS THEMSELVES?

Distress might be demonstrated by some or all of the following:

- anger/frustration
- aggression/agitation
- fear/anxiety
- tearfulness/misery
- pain when still
- discomfort on moving
- restlessness
- insomnia
- calling out/vocalization
- wandering and persistent challenging behaviours when these appear to be driven by distress or fear
- autonomic arousal, sweating, tachycardia, hypertension.

WHAT ARE THE CAUSES OF DISTRESS?

Distress may be caused by mental illness, other mental and psychological difficulties and physical difficulties/pain. Distress is in essence pain that is either mental or physical and no sort of distress is less worthy of palliation than any other. So the following causes of distress must be explored:

- depression
- psychosis
- pain
- poor understanding
- fear and anxiety
- insomnia
- hunger and diet
- boredom, isolation and lack of spiritual care
- poor environment including poor staff practices, etc.

In a chapter of this length we can but mention the causes and make a few comments. Physical pain is frequently missed and undertreated in dementia. Its treatment provides a real modality to reduce distress in patients dying with dementia and other mental illnesses. The prevalence of pain in US nursing homes has been estimated between 26% and 83%[25]. Pain is not reported by the elderly who are cognitively intact as it is often attributed to 'natural ageing' and those with dementia are often unable to express their pain[26]. However, studies have demonstrated that patients with a diagnosis of dementia are less likely to receive analgesia compared to those without this diagnosis[27].

Those who appear depressed may well respond to an antidepressant and those who show evidence of psychosis may respond to antipsychotics. Of course, given the harm that we know they do[28], a discussion about risk of harm must always be had whatever the indication or the use of antipsychotics. But if, in the end, antipsychotics represent the best way to reduce severe distress in someone with dementia, then their use may be justified[29].

ADVANCE CARE PLANNING

Receiving a diagnosis such as dementia will rightly lead to a desire to think about and make plans for the future. But the fear that dementia brings may be huge and it is important to give an opportunity to discuss and allay fears where possible. In truth, dementia is a distressing condition, but patients need reassurance that distress is usually managed with the right care, support and medications. Discussion of living well with dementia may be very reassuring. Understanding the palliative model of care may help considerably. A discussion on prognosis and advance care planning can start at diagnosis, and be developed further during the transition from restorative care towards more palliative care.

Of course, early on it is right to treat the memory impairment and to work out ways to delay or reduce disease progression. But, as the illness progresses, treatment is more focused on symptom control and reduction of distress. Various methods allow the planning of care as dementia advances:

Advance Patient Statements

These are broad statements of preference about future care and can be very useful. Patients may ask for specific care at specific times, or ask for assurance that fluids will be given[30]. Most often a simple statement such as "If I have an untreatable or terminal illness I ask for sensible treatments that have a reasonable chance of benefit and that avoid excessive burden" may be helpful. Such statements can enable the patient to guide others towards more appropriate care once capacity has been lost.

Preferred Priorities of Care

The preferred priorities of care protocols[31] enable people with any diagnosis to set out what their priorities are and where they would like to be cared for during their last illness. Of course most choose home,

but other preferences too may be helpful. Some will wish a certain style of care, others to see the right people, some to have the right spiritual care etc. Of course such statements should preferably be advisory and not binding as it is hard to predict precisely what needs there will be. In dementia care it is not infrequent to find patients have an expressed desire not to go into nursing care, but that at the time, it turns out that this may be the best care and that they are demonstrably happier (see problems with advance refusals below).

Illness Contingency Planning

As illness progresses it is sensible to consider the scenarios that may lead to change of care. In the UK there is anxiety that death at home is uncommon and also that transfer to acute hospitals from nursing care at a time when patients are, in fact simply dying, occurs too often[32]. It is perfectly sensible to hope to avoid the chaos of acute hospital care at a time when death is inevitable, but with dementia there are special difficulties in achieving this and support for dementia at home until death (though highly effective and well regarded by carers[33]) is rarely available and there are very few specialist services that aim to support such care. This is in complete (and unjustifiable) contrast to the situation for cancer care and other illnesses.

Inevitably though, infections and pneumonias may, unless already thought through, trigger a referral to an emergency department. Several questions can be usefully asked and discussed with carers and advocates and may take into account the declining physical functions and increased risk of other illnesses, infections, falls and fractures associated with dementia, see Box 135.2. It is probably true that the most effective part of this is the discussion itself. A discussion with carers will often have a good effect and enable confidence around ongoing care and dying.

Box 135.2

Advance illness planning questions

Is cardiopulmonary resuscitation, ventilation or intensive care medicine appropriate?

Would treatments with severe side effects be appropriate?

Would complex surgical procedures (such as a major abdominal operation) be appropriate?

Would hospital admission be appropriate for injuries such as fractures?

Would hospital admission be appropriate for illness such as chest infections?

If dehydration occurs and is causing the patient to suffer then would hospital admission be appropriate to treat?

When dying is imminent and the patient is distressed *we would expect* that medication will be given to alleviate the distress that may occur during death.

For some problems the solution will still be hospital. The best treatment of a broken hip is to mend it. The best treatment of a urine infection is antibiotics. But with a pneumonia, oral antibiotics with care at home by usual carers may well be associated with a better outcome than a transfer to hospital. So any plan must always remain flexible to a degree so that contingency can be dealt with.

Advance Decisions to Refuse Treatment

Advance decisions to refuse treatment (ADRTs) may be more challenging in dementia care. In England, Wales[34] and Scotland they are binding but are, fortunately, subject to stringent tests of validity and applicability. As with advance statements, they may well be helpful and give good advice but must be specific and valid. They do enable those who lose capacity to continue to guide their care, but they also carry some risks, and a binding decision might cause unanticipated effects[35].

Case Example

A person with dementia has stated that he only wants symptomatic treatment once his dementia is moderate or severe. Restorative treatment is refused, in the hope that this will enable comfort and that he will not suffer unduly. He then develops a urine infection.

- Does the ADRT prohibit treatment of the infection or can the antibiotic be construed as symptomatic treatment? If it cannot, must the enhanced suffering of living without antibiotics be accepted even though the intention was to reduce distress?
- What if he develops a fractured hip? Is surgery the best analgesic and is it prohibited by the ADRT?
- What if, at the stage of dementia he has, he is happy, enjoying living with his family and all seems well?

The Mental Capacity Act gives some helpful clues here. The ADRT would be invalid if:

- the person withdrew the decision while they still had capacity to do so
- after making the ADRT the person made a lasting power of attorney (LPA) giving an attorney authority to make treatment decisions that are the same as those covered by the ADRT
- the person has done something, which is not in accordance with the ADRT remaining their fixed decision (i.e. they have changed their mind).

The ADRT would be inapplicable if:

- the proposed treatment is not the treatment specified in the ADRT
- the circumstances are different from any specified in the ADRT
- there are reasonable grounds for believing that circumstances have now arisen, which were not anticipated by the person when making the ADRT and which would have affected the ADRT had he anticipated them at the time.

In the case set out, there is a lack of specificity about treatment of a UTI or broken hip making the ADRT not applicable. There would also be reasonable grounds to think that the current circumstance was not anticipated. And, of course, questions about the level of understanding at the time of making the ADRT must be raised. Finally, note that ADRT's are not valid if they apply to life sustaining treatment and are not in witnessed and writing.

Given the complexity, possible benefits and also the possible harms of ADRTs, it is clearly appropriate that dementia specialists ought to advise those thinking of making an ADRT of the risks of making them as well as some of the possible benefits[35].

Lasting Power of Attorney (LPA)

The Mental Capacity Act in England and Wales and Adults with Incapacity Act in Scotland also allow people to appoint decision makers (such as a relative, friend or solicitor) to make decisions for them at a time when they lose capacity. Generally an LPA will trump an advance statement. Authority passes from the ADRT to the LPA if an LPA is appointed. The LPA, of course, must include a respect for the previous wishes and views of the patient in their decision-making process.

PARTNERSHIP WITH PALLIATIVE CARE

Specialist palliative care services do not have the capacity to provide the palliative care needs for those with dementia. Moreover, old-age psychiatry settings, including continuing care units can be seen as providing palliative care by virtue of the work they do in reducing the distress of severe and complex dementia. It is true that old-age psychiatry often underestimates physical pain in dementia, but, on the other hand, specialist palliative care services may struggle with patients who wander and present challenging behaviour. In each district therefore both old-age psychiatry and specialist palliative care can form useful partnerships and undertake mutual learning from each other. This is described in much fuller detail elsewhere[22].

CONCLUSION

The care of the dying is an integral part of good care of the elderly. Mental health services will do well to acknowledge this and develop their understanding of what they already do in terms of palliative care and to then learn more about what they do not do well.

INTRODUCTION

Prevention in the mental health field has been seen, traditionally, as an area that has been implicitly restricted to issues in childhood and adolescence. If anything, prevention in geriatrics was seen as an oxymoron. Theory and research in prevention were, for a long time, restricted to issues of child development and intervention early in the life course. In an influential report, the Institute of Medicine (IoM) of the US National Academy of Sciences assessed the state of knowledge in prevention research in the 1990s, but could find hardly any studies aimed at prevention of mental disorders in older adults[1]. A more recent follow-up report on prevention of mental disorders by that same institute is aimed completely at children, youth and young adults, while prevention in older adults is not mentioned at all[2].

At the same time, however, prevention of mental disorders in older adults has been the focus of a new line of research. This research has resulted in a growing body of knowledge on how to identify those with the highest risk of developing a mental disorder, several preventive interventions, and some randomized controlled trials showing that prevention may be possible and effective in older adults. Furthermore, considerable progress has been achieved in the field of prevention of mental disorders for younger adults in recent years. The growing number of randomized controlled trials has shown that prevention of depressive and anxiety disorders in adults in general is probably effective, and there is no reason to assume that interventions which are effective in younger adults would not be effective in older adults.

Why be concerned with prevention in late life? As is well covered in other sections of this text, there is the demographic imperative brought about by the overall ageing of the world population and in particular by the ageing of the older population. As pointed out in the classic paper by Kramer (1980)[3], the same dynamics: public health measures, technological development and lifestyle changes, that created this growth in the overall population were also relevant to growth of the population of those with chronic illnesses and disabilities. They conclude that, in the absence of cures or effective preventive strategies, we will see an explosion in the number of older persons with serious and persistent disabling illnesses, particularly mental disorders. The availability of more efficacious treatments and the accessibility of appropriate services in the community combined to produce huge gains in the life expectancy of those with mental disorders, who in earlier times would have died long before reaching old age. This demographic imperative leads to the conclusion that prevention must be an important part of the agenda of geriatric psychiatry.

For example, major depression currently affects about 3.6–4.8% of persons of 60 years or older, and many more report clinically relevant depressive symptoms[4,5]. At this moment, major depression in all age groups is the fourth disorder worldwide in terms of disease burden, and it is expected to be the disorder with the highest disease burden in high-income countries by the year 2030[6]. Furthermore, the prevalence of depressive disorders in older adults is projected to double from its present level by 2050[7]. Depression is not only a highly prevalent disorder, but it is also associated with a huge loss of quality of life in patients and their relatives[8,9], with increased mortality rates[10], with high levels of service use and with enormous economic costs. The economic costs of depression in the United States were estimated to be $83 billion in 2000[11].

Another reason why prevention is important is that current treatments can reduce the disease burden of depression only to a limited extent. A recent study in Australia estimated that about 16% of the disease burden of major depression is averted in the current health system[12]. Because many patients do not receive an evidence-based treatment, this percentage could rise to 23% if all patients received such an evidence-based treatment. Furthermore, about 40% of all people with a depressive disorder do not receive any treatment. If it would be possible to deliver treatment to all patients with a depressive disorder, 34% of the disease burden of depression could be averted. So, although current treatments are usually considered to be effective in treating depressive disorders, it is estimated that these treatments can reduce the disease burden of

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

depression by a maximum of 34%[12]. Prevention of the incidence of new cases of major depression has been suggested as an alternative for treatment which may reduce a part of the 66% of the disease burden which is not averted by current treatments[13,14].

In the current chapter we will give an overview of the field of prevention of mental disorders in older adults. First, we will give a definition of prevention in the mental health field. Then we will focus on recently developed methods of identifying the optimal high-risk groups for preventive interventions. Finally, we will describe the interventions that have been developed and the results of research examining the effects of these interventions.

WHAT IS PREVENTION?

The traditional public health view derives from infectious disease and is divided into primary, secondary and tertiary prevention. Primary prevention is directed towards maintaining health by isolating the causes of disease and eliminating or counteracting them. Secondary prevention is directed towards enhancing recovery by case identification and prompt intervention early in the course of illness. Tertiary prevention is directed towards those already ill and emphasizes treatment and rehabilitation.

There is a growing consensus that the traditional public health view is not optimal in mental health. The components of this approach including, for example, concepts such as pathogens, risk factors, disease vectors and definitions of caseness do not translate easily into psychopathology or chronic disease. In the definition of depression which is currently used by most researchers and practitioners in the mental health field, prevention comprises all interventions which are conducted before subjects meet the formal criteria of a mental disorder (according to the DSM-IV[1]). Curative interventions are given to persons who suffer from acute disorders, and maintenance treatments are given to patients with chronic disorders. In this spectrum of interventions, three types of prevention can be distinguished:

Universal prevention is aimed at the general population or parts of the general population, regardless of whether they have a higher than average risk of developing a disorder. The best-known examples of universal prevention include school programmes aimed at all students, whether they have an increased likelihood of developing a mental disorder or not; and mass media campaigns, aimed at the general population.

Selective prevention is aimed at high-risk groups, who have not yet developed a mental disorder. High-risk groups include people who have recently experienced a stressful life event or who experience a chronic stressor, such as divorce, losing a family member through death, caring for an ill family member, and unemployment.

Indicated prevention is aimed at individuals who have some symptoms of a mental disorder but do not meet diagnostic criteria.

In this chapter, we will give an overview of selective and indicated preventive interventions for older adults. Because universal interventions have not been developed systematically or examined in well-designed trials, we will not discuss these possibilities here. Then we will look at the research examining whether preventive interventions are actually capable of preventing the incidence of new cases of mental disorders, and we will describe new methods of identifying optimal target groups for prevention of mental disorders in older adults.

SELECTIVE PREVENTION

In the past decades, several indicated preventive interventions for older adults have been developed, including interventions aimed at widows and widowers, caregivers of frail older adults, older adults with a chronic general medical illness, and inhabitants of homes for the elderly and nursing homes. Several of these interventions are not specifically aimed at older adults, because there are also younger adults who lose their spouse or get a chronic general medical disorder, but the chance of belonging to such a high-risk group is much greater among older adults. Therefore, it seems reasonable to consider such interventions as prevention for older adults.

One important group of selective preventive interventions is aimed at widows and widowers. They are an important high-risk group for mental disorders[15], and several preventive interventions have been developed, including social support groups and widow-to-widow programmes. In social support groups, widows and widowers come together in small groups to exchange experiences and emotions, with a clear preventive focus. However, research examining the effects of these groups has not resulted in strong evidence for their effectiveness[16]. Another preventive intervention developed for widows and widowers are the so-called 'Widow-to-widow' programmes[17,18]. In these programmes, widows who have recently lost their spouse are visited by another widow who lost their spouse some time earlier. Early research showed promising effects of these programmes, but a larger recent trial did not find any beneficial health effects of such a programme[19].

Another group of selective preventive interventions is aimed at caregivers of frail older adults. Because of the stressful situation they live in and the burden of care, this is an important high-risk group for the development of mental disorders[20]. Several types of interventions have been developed for caregivers, many of which have a clear preventive goal in terms of preventing mental disorders or severe stress-related problems. Interventions for these caregivers include support groups and psycho-educational interventions[21], respite care[22], home visits[23], and multi-component interventions in which different interventions are combined and adapted to the need of the caregiver[24]. Research examining these interventions has typically resulted in small to moderate effect sizes on mental health outcomes in caregivers, with limited clinical impact[25,26], although multi-component interventions seem to be more effective[27].

Several multifaceted interventions have been developed for the prevention of late-life depression in residential care[28,29], where the prevalence of depressive disorders is very high[30]. Such interventions focus on the training of nurses and doctors, on consultation and on supportive interventions for the residents. A few trials have found encouraging effects of these interventions[28,29]. Another study found significant effects for screening and early intervention in residential homes for the elderly[31], although this should be considered as indicated prevention or even treatment.

Older adults with chronic general medical illnesses are another important target group for selective prevention. In this area, several well-designed studies have been conducted, and these studies have actually examined whether preventive interventions are capable of preventing the onset of new cases of mental disorders. Rovner and colleagues (2007)[32] screened older patients with neovascular macular degeneration, and found that problem-solving treatment resulted in a significantly lower incidence rate of new cases of depressive disorders at two and six months follow-up. Robinson and colleagues

(2008)[33] found that both problem-solving treatment and antidepressive medication resulted in a significantly lower incidence rate of major depressive disorders in stroke patients.

This overview of selective preventive interventions is not comprehensive, but it gives a good idea of the possibilities that are available for developing preventive interventions for older adults at risk of getting a mental disorder.

INDICATED PREVENTION

In the past decades, several indicated preventive interventions, aimed at older adults with sub-threshold symptoms but no mental disorder, have been developed. Until now, these interventions have focused mainly on depression. The first type of indicated prevention we want to present is the psycho-educational 'Coping with Depression' course (CWD). This intervention was originally developed as a group treatment for depression. However, because of its psycho-educational nature, it can also be applied relatively easy as a preventive intervention. As we will see later on, the CWD (for all age groups) has been used in 6 of the 19 randomized controlled trials which have examined the effects of prevention on the incidence of major depression in those who did not have a depressive disorder at baseline.

The CWD is a cognitive behavioural intervention which is usually conducted in group format with 8 to 12 participants. Because of the psycho-educational format, there is no therapist or patient, but only teachers and students. Therefore, older adults with depressive symptoms do not have to go into treatment, but only go to a course where they learn how to improve their mood. Apart from behavioural activation, the students also learn cognitive restructuring skills, and social skills. The CWD is not only used in older adults, but also in many other target groups, including adolescents, minority groups, primary care patients, and general medical patients. There is much research examining the effects of the CWD as treatment of existing depressive disorders and as prevention of new cases[34,35]. These studies show that the CWD is an effective treatment for depression, but is also effective in preventing new cases of depressive disorders. A recent randomized controlled trial in the Netherlands, where the CWD is offered as a preventive intervention to older adults in about 80% of the regions, showed that the CWD effectively reduces the level of depressive symptoms in participants in these courses[36]. However, this study also showed that about 40% of the participants in these courses in routine care did have an established major depressive disorder, and so it cannot be seen as a purely preventive intervention. However, because of the low threshold for participation, and the reluctance of many older adults to seek treatment for existing depressive disorders[37], this does not seem to be a problem from a public health point of view.

Another preventive intervention for depression in older adults is life review and reminiscence. In life review interventions, older adults discuss their life and the evaluation of each important period in their life with a trained professional. Several randomized controlled studies and meta-analyses have shown that these interventions are effective in reducing existing depressive symptoms[38], as well as increasing life-satisfaction and emotional well-being[39]. Although the effects have not yet been examined in target groups in which sub-threshold depression was established with a diagnostic interview, life review seems to be an excellent intervention for indicated prevention, because of its low threshold for participation, because the stigmatizing word 'depression' is not needed, and because no understanding of negative thoughts or other complex psychological issues is necessary for participating successfully in this intervention.

More recently, the internet has been found to offer promising new opportunities for the prevention of mental disorders in all age groups, including older adults. A considerable number of studies have found that internet-based cognitive behaviour therapy (CBT) is effective in the treatment of depression and anxiety disorders[40]. In one study, internet-based CBT has been found to be effective in the treatment of sub-threshold depression in older adults[41], which can be seen as indicated prevention. This study showed that internet-based CBT had large effects on depressive symptomatology in older adults, and was as effective as a preventive group intervention.

Another recent development is the use of stepped-care models for the prevention of depressive disorders in older adults with sub-threshold depression or anxiety[42,43]. In a large, randomized, controlled trial, older adults with sub-threshold depression or anxiety were recruited from primary care and assigned to a preventive stepped-care programme or usual care. Stepped-care participants sequentially received watchful waiting, CBT-based bibliotherapy, CBT-based Problem Solving Treatment, and finally referral to primary care for medication, if required. It was found that cumulative incidence of DSM-IV major depressive disorder or anxiety disorder after 12 months was reduced from 24% (20/84) in the usual care group to 12% (10/86) in the stepped-care group, which indicates a relative risk of 0.49 (95% confidence interval: 0.24–0.98). These results are better than those found in the meta-analysis of preventive interventions for depression[44], and may indicate that stepped care is an excellent method for the prevention of mental disorders in older adults.

IS IT POSSIBLE TO PREVENT THE INCIDENCE OF MAJOR DEPRESSION?

In the past decades, hundreds of controlled studies have examined the effects of mental health programmes aimed at preventing mental health problems in children, adolescents, adults and older adults[14,20]. This considerable body of research has shown that some prevention programmes in mental health are capable of strengthening protective factors, such as social skills, problem-solving skills, stress-management skills, pro-social behaviour and social support; that these programmes can reduce the consequences of risk factors, psychiatric symptoms and substance use; and that they may have positive economic effects. Despite this large body of research, however, relatively few studies have examined whether these prevention programmes are actually capable of reducing the incidence of new cases of mental disorders defined according to diagnostic criteria, although this research question can easily be regarded as one of the most important ones, both from a public health perspective and from a scientific point of view.

In the past 15 years, a growing number of studies has examined whether it is possible to prevent the incidence of mental disorders in persons who do not have an established disorder at the start of the preventive intervention. Most of these studies are aimed at the prevention of depression[44], and some are aimed at the prevention of anxiety disorders[45–48]. A recent meta-analysis of studies examining the effects of preventive interventions on the incidence of depressive disorders found that the incidence rate ratio of developing a depressive disorder was 0.78 (95% confidence interval: 0.65–0.93) for participants in the prevention conditions compared to control subjects, which indicates that participants in the preventive interventions have 22% less chance of developing a depressive disorder in the next year[44].

Only a few of the studies in this area have been conducted with older adults[32,33,43], but those that have been conducted find results which are comparable to the studies that have been conducted with younger adults. More research is clearly needed to establish the possibility of preventing the incidence of mental disorders in older adults, but research in younger adults suggests that this is a promising field of investigation.

IDENTIFYING TARGET GROUPS FOR PREVENTIVE INTERVENTIONS

As we have seen earlier in this chapter, several interventions have been developed for older adults who are at risk for developing a mental disorder, such as caregivers of frail elderly, those who have lost their spouse, people who have chronic general medical disorders, and people with sub-threshold depression. Although many of such risk indicators for mental disorders are known, their specificity is low. This means that most people in these high-risk groups will never develop a mental disorder[14,49]. Although much epidemiological research is available showing that such indicators are associated with an increased risk of developing a mental disorder, this research is not very useful in identifying the optimal high-risk groups for preventive interventions. The traditional indicators of the strength of a predictor for the incidence of such disorders, such as a relative risk or odds ratio, are not sufficient for identifying the best target populations for preventive interventions. Suppose, for example, that the risk of developing a major depressive disorder in the general population is 2.5% in one year[50,51]. If a high-risk group has a relative risk of developing a depressive disorder of 4.00, this will be highly significant (if the research population is large enough). But, this means that still only about 10% of the high-risk group will actually develop a depressive disorder, and 90% will not. A high-risk group will probably be difficult to motivate for participation in a preventive programme if only 10% eventually will develop the disorder, apart from the question of whether it is ethically acceptable to intervene in such a population. Furthermore, such an intervention is probably not very efficient and cost effective, because by far the majority will never develop a disorder and the intervention has no preventive effect in this majority.

Recently, more advanced methods have been developed to identify the optimal target groups for preventive interventions in at-risk older adults. After the identification of significant risk indicators, this method starts with calculating three other statistics that can help us in identifying the optimal target populations. First, the exposure rate (ER), which gives the percentage of the population exposed to the risk indicator. The second statistic is the population attributable fraction (AF), which indicates by how many percentage points the current incidence rate of depression in the population would be reduced if the adverse effect of the risk indicator is completely blocked[13,52]. This equals the maximum possible impact of a completely successful preventive intervention. Third, the number-needed-to-be-treated (NNT) can be interpreted as the number of people that should be targeted by a preventive intervention to avoid the onset of the disorder in one person (assuming that the preventive intervention is completely successful in containing the adverse effect of the risk factor).

When target populations for preventive interventions are selected, the ER and the NNT should be as small as possible, while the AF of the target population should be as high as possible. This allows us to identify small target populations with the largest possible proportion of new incident cases, while the number of subjects that have to be treated with the preventive intervention is as small as possible. There are several ways of finding the most optimal combinations of risk indicators (small ER and NNT, large AF), including a straightforward exploration of all possible combinations of significant risk indicators[13], but also more sophisticated methods such as CART analyses (classification and regression tree analysis), and bootstrap aggregation (bagging).

In one study, it was found that older adults with (subclinical) depressive symptoms, functional limitations, a small social network, and female gender comprised only 8% of the total older population (ER), while 24.2% of the new incident cases could be attributed to this group (AF)[53]. The number of subjects from this population that would have to receive a preventive intervention in order to prevent one incident case (NNT) was 4 (assuming that the intervention was 100% successful). In another prospective study among older adults, CART analyses were used to identify the optimal groups for indicated prevention (high-risk groups) and universal prevention (sub-threshold depression present)[54]. In the selective prevention model, spousal death showed the highest risk, becoming even higher if the subjects also had a chronic illness. In the indicated prevention model, sub-syndromal symptoms of depression were associated with a risk of almost 40% of developing depression and an NNT of 5.8, accounting for 24.6% of new cases. Adding more risk factors raised the absolute risk to 49.3%, with a lower NNT, but also lower AF values. Overall, the attributable fraction values in the indicated model were found to be higher, identifying more people at risk. A third prospective study was aimed at the identification of the optimal target groups for prevention of anxiety disorders among older adults[55]. In this study it was found that several factors were significantly associated with increased risk of developing anxiety, including sub-threshold anxiety, depression, two or more chronic illnesses, poor sense of mastery, poor self-rated health and low educational level.

Although this methodology of identifying the optimal target groups for preventive interventions in epidemiological research has been developed well, it has not yet been used in actual intervention studies. Designing such studies is certainly one of the most important challenges for interventions researchers in the years to come.

CONCLUSIONS

In this chapter, we have tried to illustrate why prevention of depression in older adults is important. Reasons for its importance include its very high prevalence, incidence, disease burden and the huge economic costs of depression. It is also important because current treatments can reduce the disease burden by about one-third, while two-thirds cannot be avoided, even when only evidence-based treatments are given and all depressed patients receive such an intervention.

We also showed that traditional epidemiological research cannot identify the best target populations for prevention. Relatively simple statistics, such as the exposure rate, the population attributable fraction, and the numbers-needed-to-be-treated can be used to select those high-risk groups which are as small as possible, but explain as many of the new incident cases as possible.

Research in the past decade has also shown that preventive interventions in all age groups are probably effective and can reduce the incidence by about one-quarter, and the few studies that have been conducted with older adults find comparable results. Psychoeducational cognitive behaviour therapy is the most used preventive intervention for depression and is already implemented in some countries. In the next few years, the internet will probably give new

opportunities for the broad implementation of preventive interventions, because access is easy, scalable, economically affordable and effective. Another important development is stepped-care interventions with more intensive treatments when no reduction of depressive symptoms has been realized. It is expected that this type of intervention will be able to reduce the incidence of depression in older adults further.

There is a significant epidemiological transition towards older age and greater morbidity. This process is equally manifest in the workforce for health. After all, the average age of the health care professionals is increasing rapidly. To illustrate, over 50% of the nurses in the European Union are older than 45 years, and their mean age is still on the increase. Increasing demands for health care and restricted supply is one of the key problems in the near future. Therefore a health care system needs to be able to produce significant health gains in an acceptable, effective, scalable and economically affordable way. Empowering people to become the managers of their own good health via preventive self-help interventions offered over the internet is probably one of the most important steps that we need to take now for a better future.

INTRODUCTION

On 12 November 1962, in *The New York Times*, Earl Warren, the Chief Justice of the United States, wrote:

> In civilized life law floats in a sea of ethics. Without law, the least scrupulous might prevail, but without ethics, law itself could not exist . . . without ethical understanding, the law, as a ship of state, would be stranded on dry land.

Mental health is the branch of clinical practice where clinicians can deprive people of their liberty and enforce treatments on them against their wishes. Our clinical decisions are, at one and the same time, ethical; but our ethical decisions must also be, at one and the same time, legal. Our concepts – 'mental disorder', 'incapacity' – carry clinical, ethical and legal weight and show the links between law, ethics and practice.

In this chapter, I shall sketch the mental health legislation that governs England and Wales. For the sake of brevity and prudence, I shall mention other UK jurisdictions only in passing. (Fuller accounts of the laws governing England and Wales can be found in standard texts[1,2].) I shall attempt to raise some broader issues of principle. In this I want to take my lead from Earl Warren, because I want to point to the ways in which there is a necessary interaction between ethics, which in this context I take to imply practice, and law.

In the spirit of questioning, I shall first set the historical scene and gesture at areas of debate. I shall then briefly sketch the main provisions of the two laws now governing practice in England and Wales: the *Mental Capacity Act 2005* (MCA) and the *Mental Health Act* (MHA) *2007*.

SLOW BIRTHS AND CONTROVERSIES

Law is not static, but evolving. The MHA 1983, which was amended by the MHA 2007, had its roots in the 1959 Act, which incorporated the recommendations of the Percy Commission of 1957. That Commission had concluded:

> . . . that the law should be altered so that whenever possible suitable care may be provided for mentally disordered patients with no more restriction of liberty or legal formality than is applied to people who need care because of other types of illness, disability or social difficulty[3].

The Percy Commission recommended that compulsory detention should only be employed where necessary. They made it clear that they wished to see 'the need for care' and 'the justification for compulsion' as two quite separate questions[3]. The assumption, they suggested, that compulsory powers must be used unless the patient can express a positive desire for treatment should be abandoned and replaced by 'the offer of care without deprivation of liberty, to all who need it and are not unwilling to receive it'[3]. This seems very humane and it got rid of the previous situation in which incapacitated compliant patients had to be detained, because they could not agree to treatment. However, although the subsequent 1959 Act was,

> heralded as a great piece of liberalising legislation, . . . its reputation became tarnished by concern about failures of services and abuses of professional power. The Act was seen as being deficient in safeguarding the rights of detained patients[4].

So the pendulum swung in favour of greater safeguards for patients. Now we are concerned that the pendulum has gone too far: beyond safeguarding patients to protecting the public from the risks of the potentially dangerous mentally ill[4]. The insistence on reform of the 1983 Act on the part of the government came about when Michael Stone, who had an antisocial personality disorder and had been under psychiatric care, killed a mother and daughter. This led to the home secretary, Jack Straw, offering the following condemnation of psychiatrists:

> Quite extraordinarily for a medical profession, they have said they will only take on those patients they regard as treatable. If that philosophy applied anywhere else in medicine there would be no progress whatsoever. It's time, frankly, that the psychiatric profession seriously examined their own practices and tried to modernize them in a way that they have so far failed to do[5].

The strength of feelings was shown by the response of Robert Kendell, then the President of the Royal College of Psychiatrists, in a radio interview:

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

> There may be a place for some form of preventative detention for men like this. That is an issue for parliament. The home secretary cannot expect psychiatrists to do his dirty work for him when it is at present excluded by law[6].

On the grounds that the 1983 Act was intended for a time when community treatment was in its infancy, when detention in hospital was the main issue, the government set about modernizing mental health law in England and Wales[4]. The subsequent history is well documented: following an expert scoping report, a green paper, a white paper, two draft bills and eight years, in the face of 'vehement, sustained, and almost unanimous opposition from those with an interest in mental health care'[7], the government announced that it would simply amend the 1983 legislation rather than try to bring in a new Act. Nonetheless, as many feared[7], it is arguable that the government's agenda of public safety won the day.

There are certainly contradictory views of the MHA 2007. Writing just before it was passed, Lepping highlighted 'a clear shift away from liberal individualism towards utilitarian thinking'[8]. His complaint was that the government was focusing largely on risk. He felt that innovations such as community treatment orders and the broadening of the definition of mental disorder favoured 'public safety considerations over individual rights'[8]. Responding to this paper, just after the Bill became law, Maden retorted that, 'The best that professionals can do under the 1983 law is sometimes not enough to prevent foreseeable disaster'[9]. He was somewhat dismissive of medical ethics ('. . . much of medical ethics consists of coming to terms with scientific discoveries') and upbeat about the possibility of predicting violence. In his view, the new Act was a continuation of a process that started with the murder of Jonathan Zito by a psychotic patient in 1992. Since then, he argued, there had been,

> a general increase in aversion to risk which is not confined to mental health or, indeed, to any one country. There is no ethical basis for arguing that mental health should remain exempt from this trend, which has swept through most democracies[9].

Maden then referred to changes to criminal justice legislation in England and Wales that 'resulted in judges imposing about 150 indeterminate sentences each month on the grounds of public protection'[9]. This reference was to the *Criminal Justice Act 2003*, which allows dangerous offenders to be given indeterminate sentences, even if their offences do not otherwise justify such detention. Maden presents this almost as a justification for the changes to mental health legislation, as if to say that psychiatrists should stop moaning about rights and get on with accepting their duty to protect the public. Other psychiatrists, however, have not been so happy with the *Criminal Justice Act 2003*, and specifically not with its ethical implications. For,

> . . . under the 2003 Act, psychiatrists are required to give evidence about risk to the sentencing court in relation to a person's mental disorder, irrespective of the treatability of that disorder. This poses similar ethical dilemmas concerning the use of psychiatry solely for public protection, as well as for punishment of offenders, rather than for treatment[7].

Furthermore, the emphasis on public protection flies in the face of recommendations made by the government's own scoping committee – the Richardson Committee:

> We are convinced that whatever the precise scope of a mental health act it must primarily be seen as a health measure and must be consistent with the professional ethics of the health services. This is not to deny the importance of public protection but to place it within the appropriate context within which it can best be promoted. The importance of respecting and enhancing patient autonomy is now gaining increased recognition within the health services generally . . . and we are satisfied that it must acquire similar recognition within mental health services specifically[10].

If the MHA 2007 took almost 10 years to be born, the MCA took even longer. It emerged in response to high-profile cases in the late 1980s of people with learning disabilities and enforced sterilization[11]. Whereas reform of the MHA has been surrounded by controversy, the MCA developed from an exceptionally well-argued Law Commission Report[12], which led to a very cogent document from the government[13] and a good deal of agreement as subsequent documents emerged prior to its delivery. One largely groundless concern has been that the MCA might bring in euthanasia by the back door. The Act, however, contains a number of defences against this possibility. More alarming to the clinician, perhaps, is the amendment to the MCA – the Deprivation of Liberty Safeguards (DOLS) – brought in by the MHA 2007, to which we shall return.

Nevertheless, there was debate concerning whether, in fact, there should be two Acts (for capacity and for mental health) or just one. It has recently been announced that Northern Ireland will have a single Act, which many elsewhere in the UK will regard with envy. Meanwhile, in Scotland, capacity legislation was amongst the first Acts to be passed by the Scottish Parliament in the form of the *Adults with Incapacity (Scotland) Act 2000*. There is separate mental health legislation, but in the *Mental Health (Care and Treatment) (Scotland) Act 2003*, decision-making ability is a criterion for both emergency detention (36(4)(b)) and for short-term detention (44(4)(b)), where 'because of the mental disorder, the patient's ability to make decisions about the provision of medical treatment is significantly impaired'.

The argument about whether incapacity should be the criterion for compulsory detention and treatment harks back (in a sense) to the aspiration of the Percy Commission[3] that mental illness should be treated no differently from other illnesses. The suggestion is that the rationale for imposing treatment on someone should only be that the person lacks the capacity to make a decision him- or herself. Because this could be applied equally to people with mental illness and to those with other illnesses, it has been argued that this is a way to decrease discrimination and stigma.

> The message is as follows, though ill, those with a mental disorder are somehow different. That is why they require separate legislation. They may be treated against their will irrespective of whether they have the capacity to consent to treatment. This suggests a pervasive and disturbing notion that 'mental' patients somehow are incapable of possessing a full degree of autonomy; mental disorder automatically diminishes the sufferer; he or she is not a complete 'person'[14].

Pursuing this point is beyond my present remit and, in the context of England and Wales, is purely academic. I shall turn to consider some of the details of the Acts, with the caveat that what follows is merely a sketch (see[1,2]).

MENTAL HEALTH ACT 2007

The MHA and the MCA both have accompanying Codes of Practice. Whilst the Codes merely provide guidance, it is clear that they cannot be ignored or deviated from without good reason. Box 137.1 contains the five guiding principles of the MHA Code of Practice.

Box 137.1

Summary of Guiding Principles in the MHA Code of Practice

Purpose Principle: Decisions under the Act must be taken with a view to minimizing the harm done by mental disorder, maximizing the safety and well-being of patients and protecting the public from harm.

Least Restriction Principle: People taking action without a patient's consent must attempt to keep to a minimum the restrictions they impose on the patient's liberty, having regard to the purpose for which the restrictions are imposed.

Respect Principle: Diverse needs, values and circumstances, including race, religion, culture, gender, age and sexual orientation must be respected.

Participation Principle: Patients must be involved as far as is possible in planning care. The involvement of carers and others with an interest in patients' welfare should be encouraged unless there are particular reasons to the contrary.

Effectiveness, Efficiency and Equity Principle: Resources are to be used in the most effective, efficient and equitable way.

Some of the changes to the MHA are less likely to affect the older patient. For instance, the MHA 2007 now defines mental disorder simply as 'any disorder or disability of the mind' (Section 1(2)). As in the past, dependence on alcohol or drugs is excluded from the definition of a disorder or disability of the mind, but promiscuity, other immoral conduct and sexual deviancy have been removed from the exclusions. The presumed reasoning behind this change and others is that they allow the detention of a broader range of people who can be subjected to a broader array of treatments. It is coupled with a change that broadens the professional groups that undertake particular roles, so that, instead of 'responsible medical officers', the MHA 2007 talks about 'responsible clinicians', who no longer need to be medical doctors. In addition, the treatability test has been replaced by an 'appropriate treatment test' (Section 4), where this means that the medical treatment is appropriate to the person's case and broadly conceived to alleviate or prevent a worsening of the person's disorder, or one or more of its symptoms or manifestations.

Of more relevance to older patients is the new right to apply to a county court to change the nearest relative (Section 23). This can be seen as a way for patients to maintain their autonomy. Similarly, the amendments in the MHA 2007 include the provision that patients have a right to an advocacy service when under compulsion (Section 30). Patients who are detained should be offered an Independent Mental Health Advocate (IMHA). Again, this could be potentially very helpful to older patients, although how this will work in practice is as yet unsure.

Perhaps the most significant change that could potentially affect older patients is the new provision of Supervised Community Treatment (SCT) (Sections 32–36). SCT provides a framework for the management of patient care in the community, following detention under e.g. Section 3, and gives the responsible clinician the power to recall the patient to hospital for treatment if necessary. SCT is an alternative to Guardianship, concerning which the law has also been changed. It is now possible to convey the person to the place where he or she is required to reside, which is one of the powers given to the Guardian. The other two powers are: to require the patient to attend for treatment and to allow relevant professionals to have access to the place where the patient lives. In deciding between guardianship and SCT, the Code of Practice suggests that under SCT the focus is on ensuring that the patient continues to receive necessary medical treatment for mental disorder without having to be detained again and it allows compulsory recall, especially where speed is likely to be important (Chapter 28 MHA Code of Practice). On the other hand, the focus of Guardianship is on the patient's general welfare rather than being specifically on medical treatment. Guardianship should be considered where there is little risk of the patient needing to be admitted compulsorily and quickly to hospital. But Guardianship is required where there is a need for enforceable powers to require the patient to reside at a particular place. However, this does not allow the person to be deprived of their liberty and, if this is likely to be the case, then this must be authorized separately under the MCA. The Code also says that it will not always be best to use guardianship as the way to decide where patients who lack capacity must live, since it would be possible to, more simply, use Section 5 of the MCA, which allows that the person's liberty can be restricted. However, some legal experts suggest that Guardianship provides a greater degree of protection to all concerned.

MENTAL CAPACITY ACT 2005

The MCA is much more routinely applicable to older patients, being relevant whenever a person cannot make decisions for him- or herself. It has a dual function: it enables people to retain some control or influence over the decisions that are made on their behalf and it protects those who must provide care to people who cannot decide for themselves. Box 137.2 shows the principles that summarize the intent of the MCA.

Box 137.2

Principles of the MCA (Section 1)

- A person is assumed to have capacity.
- All practicable steps must be taken to help the person to make a decision.
- People are entitled to make unwise decisions.
- Any actions taken on behalf of a person who lacks capacity must be in the person's best interests.
- Before any action is taken it should be the least restrictive of the person's rights and freedom of action.

Section 2 of the MCA defines incapacity as follows:

> . . . a person lacks capacity in relation to a matter if at the material time he is unable to make a decision for himself in relation to the matter because of an impairment of, or a disturbance in the functioning of, the mind or brain.

This leads to a two-stage test of incapacity: first, does the person have an impairment of, or a disturbance in the functioning of, their mind or brain? Secondly, does the impairment or disturbance mean the person is unable to make a specific decision when they need to? This is judged by asking whether the person is able to retain (at least for a short while), understand and weigh up the relevant information and communicate his or her decision.

If the person lacks capacity, the central plank of the MCA is that decisions must be made in the person's best interests (Section 4). The MCA Code of Practice explains that 'best interests' cannot be defined because it will be so particular in different circumstances for different people. But it sets out (in Chapter 4) a checklist to help judgements to be made. At the heart of the checklist is the idea that the person's past and present wishes and feelings, values and beliefs, should inform the decisions that are made on his or her behalf. In addition, the views of anyone else engaged in caring for the person or anyone who might have an interest in the person's welfare must be consulted if at all possible. Whilst the details of the MCA should be consulted, this brings into view two other important aspects of the Act. First, it confirms the legal standing of valid and applicable advance refusals of treatment (but they must be both valid and applicable). Secondly, it establishes the concept of a Lasting Power of Attorney (LPA), to make decisions about matters of welfare, which include decisions about healthcare and changes to the place of residence. A LPA, like the previous Enduring Power of Attorney, can also be made to cover property and finance. But a welfare LPA means that a doctor might be faced by a relative with the power to give or withhold consent to the patient's treatment. However, as with all decisions for people who lack capacity, the decisions made by the donee of the LPA must be in the person's best interests and they can be challenged in the Court of Protection if they are not.

Unlike the MHA, the MCA does not allow everyone to have an advocate, but where serious medical treatment decisions or changes to the place of residence are being contemplated, *if the person is not supported* other than by professionals, an Independent Mental Capacity Advocate (IMCA) must be appointed. This is yet another way in which the MCA seeks to protect and enhance the rights of people who lack capacity. This brings to mind Sabat writing:

> The means by which we evaluate, and arrive at our conclusions about, the afflicted person's competency may well ultimately be a test of our own competency as thoughtful, judicious, humane human beings[15].

Sections 5 and 6 of the MCA allow that a person may be restrained as long as this is proportionate. However, by an amendment to the MCA brought in by the MHA 2007, it is made clear that, even if restrictions of liberty can be sanctioned under certain circumstances, a deprivation of liberty requires greater safeguards and must be avoided if at all possible. If, where the person lacks capacity and in his or her best interests, a deprivation of liberty is required, then appropriate authorization must be sought. These are the Deprivation of Liberty Safeguards (DOLS). The technicalities of DOLS are beyond the scope of this chapter (see[16]). The distinction between a *restriction* of liberty and a *deprivation* of liberty seems crucial in this connection, but it, too, like 'best interests', cannot be pinned down. This makes life difficult and uncertain at the coalface, but is of considerable conceptual interest. The issue is nonetheless clear: as a matter of human rights, vulnerable people must be protected by the law.

CONCLUSION

This brief foray into the law brings us back to Earl Warren: 'Without law, the least scrupulous might prevail, but without ethics, law itself could not exist'. We can see how the laws establish principles as guides to practice, but in the end it is practitioners who must put the law into effect. It is our patterns of practice – be they ethical or unethical – that shape our lives and thereby, collectively, the moral standing of our societies.

Training Requirements for Old Age Psychiatrists in the UK

Susan Mary Benbow[1] and Aparna Prasanna[2]

[1]*Centre for Ageing and Mental Health, Staffordshire University, Stafford, UK*
[2]*Wolverhampton Primary Care Trust, Penn Hospital, Wolverhampton, UK*

In the UK over the past 30 plus years increasing numbers of psychiatrists have specialized in working with older adults. Various terms are used to describe this area of work: psychogeriatrics, geriatric psychiatry, old age psychiatry and older people's mental health are probably the most common. In 1978 the Royal College of Psychiatrists formed a Section (which later became a Faculty) of Old Age Psychiatry and in 1989 the Department of Health recognized old age psychiatry as a specialty: this was regarded as a milestone in the specialty's development at the time. The Royal Colleges of Physicians and Psychiatrists produced a Joint Report in 1989, which devoted a chapter to education and training in the psychiatry of old age[1]. Prior to this there was no designated training programme for psychiatrists aiming to work with older people.

BACKGROUND: GROWTH OF THE SPECIALTY

In the early 1980s two surveys of old age psychiatry services reported considerable growth in the developing specialty[2,3], and over 200 consultants were identified by late 1983. The authors predicted continuing growth in the specialty and a need to expand training placements. At that time the Joint Committee on Higher Psychiatric Training at the Royal College of Psychiatrists required higher trainees to spend 12 to 18 months in posts where the majority of the work was in old age psychiatry, and 28 senior registrar placements were identified.

In 1990 there were 360 consultants working mainly in old age psychiatry and by 1993 the total had increased to 405[4]. Figures collected by the Faculty of Old Age Psychiatry showed a continuing gradual increase in consultant numbers, but with a high vacancy rate.

The first Joint Report[1] had recommended that each medical school should have a senior academic in old age psychiatry and that all medical undergraduates should receive training in the subject. Faire and Katona[5] surveyed undergraduate teaching in the UK and reported a considerable expansion in academic old age psychiatry posts. However, they also found a great variation in the amount of clinical experience on offer and the authors felt there was a strong case for all medical students having clinical experience in the specialty as recommended by the Joint Report. Gregson and Dening[6] surveyed teaching hospital psychiatrists and found that many teachers set no learning objectives in old age psychiatry. Most respondents wanted their teaching to impart enthusiasm for the subject, a sense of hope in working with mentally ill older adults, and an awareness of issues specific to ageing and ageism.

The second Joint Report[7], published in 1998, recommended that the characteristics of mental disorders in older people and the principles of good quality care should be included in the core curricula of all schools of medicine and nursing, and by the time the second edition of this book was published, there were chairs or readerships at a number of medical schools in the UK, although some gaps remained. The twenty-first century brought with it the National Service Framework for Older People[8], which estimated that by 2009, extrapolating from the numbers of existing trainees, there would be 670 old age psychiatrists. It argued the case for increased staff numbers to improve the mental health of older people, and also noted that its recommendations had implications for education and training in undergraduate and postgraduate medicine.

Despite growth in the specialty of old age psychiatry, the long-term prospects continue to cause concern. The Dean of the Royal College of Psychiatrists wrote in his May 2009 newsletter[9] that recruitment into psychiatry as a medical specialty is 'in crisis' with only 6% of candidates for paper 2 of the Membership examination in summer 2008 having gained their primary medical qualification in the United Kingdom. One response to this has been initiatives to try to attract more UK medical students into the specialty, e.g. an official Royal College of Psychiatrists group has been set up on a popular social networking website.

Alongside these developments, postgraduate education has undergone considerable reorganization over recent years. *Modernising Medical Careers*[10] was published in 2004. It aimed to streamline training based on competency-based curricula, and also brought in the foundation programme for newly graduated doctors. In 2005 the Postgraduate Medical Education and Training Board (PMETB)[11] took over responsibility for standards and quality assurance of postgraduate education, training and assessment in medicine and dentistry. The foundation programme has introduced foundation posts in psychiatry to many areas, and with it an opportunity to attract new medical graduates into the psychiatric specialties.

SPECIALIST TRAINING IN OLD AGE PSYCHIATRY

The total minimum duration of specialist training in old age psychiatry is currently six years, of which three years is in core or generic training (core trainee CT1–3) and three years in advanced training (specialty registrar ST4–6). A new curriculum for specialty training in psychiatry and its specialties was approved by PMETB in April 2009 and was introduced in August 2009[12]. Figure 138.1 illustrates the structure of training.

Core Training

A newly qualified doctor intending to specialize in psychiatry will first spend two years on a foundation programme. Following this, competitive recruitment into psychiatry in England is by a standardized national recruitment programme through the Royal College of Psychiatrists. The trainee will undertake core training, which lasts three years and concentrates on providing a range of experience in the specialties and subspecialties of psychiatry. This part of training is common to the various psychiatric specialties. Core training aims to develop history taking, formulation and case presentation skills, therapeutic skills and clinical judgement, relationship with patients/carers and colleagues, and appropriate use of mental health legislation. Experience in old age psychiatry is regarded as an important part of core training because of the increasing elderly population and the high rates of mental illness in older people.

During this time the trainee is preparing to take his/her examination for membership of the Royal College of Psychiatrists. The minimum requirement to sit the Parts 1, 2 and 3 written papers for the Membership examination is 12 months' experience in psychiatry. This may include four or six months of experience of old age psychiatry. The Clinical Assessment of Skills and Competencies (CASC) exam can only be taken after 30 months of experience in psychiatry and is a requirement for entry into advanced training in the different specialties.

In addition, throughout their core and advanced training, trainees undergo a series of workplace-based assessments (WPBA). A number of assessment tools such as assessment of clinical expertise (the trainee's ability to assess a case), case-based discussion (discussion of a clinical case in which the trainee has made a significant contribution) and direct observation of procedural skills (assessment of a practical procedure) can be used[14]. Evidence of achieved competencies is collected using a combination of electronic and paper portfolios.

By the end of three years of approved supervised placements in core training, the trainee is ready to move onto advanced training and will hold the Membership of the Royal College of Psychiatrists (MRCPsych). They will have had sufficient exposure to the psychiatric specialties to decide on their career intentions.

Advanced Training

Higher training offers an educational programme that aims to prepare a trainee for independent practice in psychiatry. Following competitive entry into a specialty training programme, a National Training Number (NTN) is awarded by a Postgraduate deanery. The PMETB sets the standards for training and approves the curriculum, which is developed by the Royal College of Psychiatrists[15]. Trainees receive educational and clinical supervision by approved trainers. On successful completion of an advanced training programme, the Certificate of Completion of Training (CCT) is awarded by the PMETB on recommendation by the Royal College[16]. This gives entry to the General Medical Council's Specialist Register[17]. Since 1997, entry into the Specialist Register has been mandatory for specialists who wish to take up a consultant post in the National Health Service.

Currently, trainees can gain a single CCT in six psychiatric specialties: General Adult, Old Age, Forensic, Child and Adolescent, Learning Disabilities, and Psychotherapy. General Adult psychiatry trainees can gain further endorsements in Liaison, Substance Misuse and Rehabilitation psychiatry. Old Age psychiatry trainees spend three years in advanced training of which one year may be spent in General Adult psychiatry or one of its subspecialties. Academic Clinical Fellows and Clinical Lecturers can (with prior approval) count the time spent in such posts towards a CCT.

During their training, specialty registrars are expected to develop their professional attributes, core knowledge and skills, carry out audit, get involved in teaching and management, and develop research and/or special interests. Eight 'core' sessions are devoted to experience in old age psychiatry (or other specialty). This involves working with a multidisciplinary team to provide a service to a defined population. Two sessions are available to develop research and audit experience or other special interests. Trainees could opt to gain formal higher qualifications relevant to old age psychiatry during this time. Many trainees choose to gain further experience in psychological therapies[18]. They are also expected to gain experience of geriatric medicine at some stage of their training, and this is usually achieved either as a short-term attachment or using special interest sessions.

CONTINUING PROFESSIONAL DEVELOPMENT AS A CONSULTANT

Loane and Barker[19] surveyed newly appointed old age psychiatrists to investigate their views of their higher training experience. Overall their respondents felt that clinical experience was satisfactory, but management experience was lacking in a number of areas, and training was identified as insufficient in relation to experience in dealing with complaints, dealing with difficult professional relationships, recruitment and disciplinary proceedings. Higher trainees are

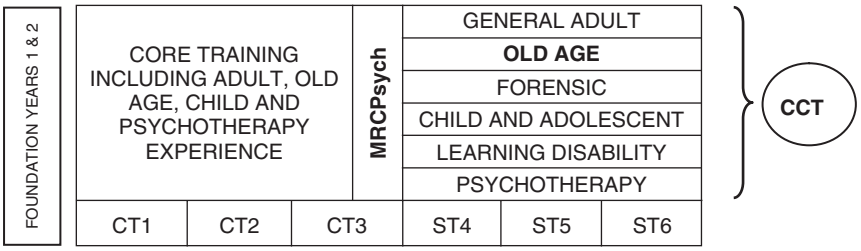

Figure 138.1 Training pathway in psychiatry (adapted from six-year psychiatry plan, Royal College of Psychiatrists[13])

expected to get training in management but it is difficult to pitch it at the right level, and constant changes in the health service are challenges to confidence and competencies.

Today lifelong learning is regarded as essential for all health care professionals[20]. Learning does not stop at the transition from trainee to consultant; indeed, some might say that this is the point at which learning really starts. In 2001 the Royal College of Psychiatrists introduced personal development plans (PDPs) as a way of planning continuing professional development prospectively and linked to clear objectives; together with this, participation in peer groups is required in order to review and assist in developing PDPs[21]. This means that consultant old age psychiatrists plan their CPD, although it needs to be flexible and to evolve with the specialty, the individual and the job, since increasingly consultants' interests, disciplines and posts evolve as their career progresses. This may be one way for people to re-energize and deal with the stresses of their multiple roles[22]. CPD is a positive opportunity for consultants to continue learning and developing throughout their working lives.

LIFELONG LEARNING

Learning starts in medical school and continues throughout the working life of the old age psychiatrist. As is true of the whole of medicine, the context within which the specialty operates is constantly evolving, and the specialty itself continues to develop and change[23]. There are always threats and opportunities on the horizon. Old age psychiatry and its practitioners cannot stand still. The enthusiasm which teaching hospital psychiatrists aim to impart to their medical undergraduates can be maintained throughout specialist training and boosted during the course of a consultant career by continuing professional development and the challenge of working in a constantly changing health and social services context.

Training Requirements in North America

Paul D. Kirwin[1] and Kirsten M. Wilkins[2]

[1]*Associate Professor of Psychiatry, Geriatric Psychiatry Fellowship Director, Yale University School of Medicine, VA CT Healthcare System*

[2]*Assistant Professor of Psychiatry, University of Oklahoma College of Medicine-Tulsa, Tulsa, OK*

The imperative for training specialists in geriatric psychiatry has never been greater. As the United States' 76 million baby boomers near retirement age, the number of Americans over age 65 will double to 70 million, one-fifth of the U.S. population. Americans older than 85 represent the fastest growing segment of this population and are projected to grow from five million today to an estimated 21 million by 2050. By the year 2010, there will be approximately 40 million people in the United States over the age of 65[1]. Almost 20 percent of those people will experience mental health problems[2].

Facing this exploding demographic imperative is a shrinking workforce of those with specialty training in the diagnosis and treatment of neuropsychiatric disorders in late life. In 2001, there were about 2,600 geriatric psychiatrists in the U.S. By 2007 there were only 1,596 geriatric psychiatrists–rather than the 5,000 needed to provide adequate care for the current population of older adults. The steep decline in the numbers of geriatric psychiatrists is accounted for by attrition and a failure of many who remain in active practice to recertify. Recruitment into the field is also waning, with less than half of geriatric psychiatry fellowship positions filled in 2006–2007. We are currently graduating approximately 80 new geriatric psychiatrists a year. By the year 2030 accounting for attrition, we are projected to have approximately 1,659 geriatric psychiatrists, or one geriatric psychiatrist per 20,195 older Americans. The field of geriatric medicine faces parallel workforce shortages with a 25% drop in geriatricians in the last five years. Over the next 20 years this disproportion is expected to worsen: from 1 geriatrician per 2,456 elderly currently to 1 per 4,254 older Americans by 2030. By 2030, it is projected that less than one third of the required geriatricians will be available for older Americans. Clearly there is a pressing need to train more experts in geriatric psychiatry and medicine, and to expand clinical training in geriatrics in both general psychiatry and medicine residency programs to adequately prepare a workforce ready to care for the expanding U.S. elder population[3].

The problem extends to other specialists in mental health and aging. In social work, only about 1,115 (3.6%) of Master's level social work students specialize in aging and only about 5% of practitioners at any level identify aging as their primary area of practice, even though the National Institute on Aging projected that by 2020, 60,000–70,000 gerontological social workers will be needed. Among psychologists, only about 3% view geriatrics as their primary area of practice and only 28% of all graduate psychologists have some graduate training in geriatrics[4].

Training in general psychiatry and then in the sub-specialty of geriatric psychiatry is extensive. The Accreditation Council for Graduate Medical Education (ACGME) in conjunction with the American Board of Psychiatry and Neurology stipulate that one must complete four years of post medical school graduate training in general psychiatry before being eligible to enter advanced training in geriatric psychiatry. One month of general psychiatry residency is dedicated to training in geriatric psychiatry. The quality of this geriatric psychiatry experience, in particular, the quality and attributes of the educators providing the training are associated with the development of interest in the field[5]. Following completion of the general psychiatry residency, the geriatric psychiatry fellowship is typically one year in length. Many programs offer additional training years for research, but these are optional and not required to sit for the advanced board exam in geriatric psychiatry.

The ACGME provides program requirements that specify the scope and content of training in general psychiatry and all psychiatry subspecialties. Programs undergo periodic "site visits" by the ACGME to ensure that the quality of the training program meets the expectations outlined in the program requirements. The twenty-plus page ACGME Geriatric Psychiatry Program Requirements necessitate that training experiences are rooted in six core competencies. The program must demonstrate that fellows have educational opportunities to gain knowledge, skills, behaviors and attitudes in these six domains: Patient Care, Medical Knowledge, Practice-Based Learning and Improvement, Interpersonal and Communication Skills, Professionalism, and Systems-Based Practice. These six core competencies have been adapted to fit the scope of training needs of a geriatric psychiatry fellow[6].

Ideally, training in geriatric psychiatry offers a rich combination of experiences designed to provide psychiatrists with expertise in the diagnosis and treatment of psychiatric and neuropsychiatric disorders in late life, to develop skills as educators, and to stimulate interest in research. A training program should provide opportunities to learn about the socio-cultural, legal, ethical and financial issues associated with the care of older adults. Supervised clinical training should occur in a broad array of settings, including outpatient and inpatient environments, nursing home and long term care

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

settings, cross disciplinary consultation opportunities, home-based services, community-based offices and clinics, and both inpatient and outpatient-based research programs.

A critical element in a successful geriatric psychiatry training program is mentorship. Unlike large residency training programs, fellows often work side-by-side with their program directors and senior attending psychiatrists. This day to day interaction is fundamental to a fellow's professional and personal development as a colleague. Imparting enthusiasm, attending to a fellow's interests, encouraging their abilities, and assisting with their limitations are essential for a fellow's growth. Successful mentorship relationships often last far beyond training and become an essential resource during the development of a career. They also serve as powerful models for developing one's own mentorship sensibilities. Mentorship is a deeply satisfying process and is vital to the overall success of the training program.

In 2008, the Institute of Medicine (IOM) released a study of the readiness of the nation's healthcare workforce to meet the needs of its aging population. *Re-tooling for an Aging America: Building the Health Care Workforce* called for immediate investments in preparing our health care system to care for older Americans and their families[7]. Yet the prescient and insightful report precluded in-depth consideration of the workforce needed for treating mental illness. The American Association for Geriatric Psychiatry (AAGP) formally requested that the study be followed by a complementary study focused on the specific challenges in the geriatric mental health field. The AAGP asserts that "virtually all healthcare providers need to be fully prepared to manage the common medical and mental health problems of old age. In addition, the number of geriatric health specialists, including mental health providers, needs to be increased both to provide care for those older adults with the most complex issues and to train the rest of the workforce in the common medical and mental health problems of old age. The small numbers of specialists in geriatric mental health, combined with increases in life expectancy and the growing population of the nation's elderly, foretell a crisis in health care that will impact older adults and their families nationwide. Unless changes are made now, older Americans will face long waits, decreased choice, and suboptimal care"[8]. Then, in December of 2009, after extensive efforts by the AAGP and other organizations, Congress passed legislation designating $900,000 for the Institute of Medicine (IOM) to conduct a study on the mental health workforce necessary for our nation's growing geriatric and ethnic populations, which promises to provide guidance on how to address geriatric mental health workforce inadequacies.

Multifaceted incentives to enter training in geriatric psychiatry are necessary. Initiatives in the public policy arena include legislation to provide loan forgiveness for health care professionals who enter geriatric specialties. The AAGP has promoted legislation to create a new program for loan repayment for specialists across disciplines that enter geriatric specialties. The AAGP also supports legislation to allow fellows in geriatric medicine and geriatric psychiatry to include fellowship training as part of their obligated service under the National Health Corps Loan Repayment Program, a program designed to encourage health professionals to provide clinical care to underserved populations. The AAGP has also requested that the ACGME review the current structure of fellowship training to allow for more flexibility and promote recruitment of psychiatrists into the field of geriatric psychiatry. Specifically, the AAGP has asked the ACGME to consider allowing residents to use their fourth year elective time in general residency training to specialize in geriatric psychiatry and then be eligible to sit for the general and subspecialty certification at the end of four years of training. The organization also supports a training model to integrate research training in geriatric mental health over a two year period, the fourth and fifth year of training, to stimulate and encourage academic research careers.

Recently, there have been promising developments which should promote easier access to skilled mental health care for the elderly. The U.S. Congress passed legislation (over President Bush's veto) on July 15th, 2008 that eliminated long standing discriminatory co-payment rates for Medicare outpatient psychiatric services. Cost sharing for outpatient mental health services will phase down from 50 percent to 20 percent by 2014. On the private insurance side, in 2008 Congress also passed legislation to ensure mental health parity which stipulates that for employers with greater than 50 employees, any limits on mental health treatments (including substance abuse) must be no greater than the limits placed on medical and surgical benefits.

The demographics of aging and mental illness clearly indicate a growing need for specialists trained in comprehensive psychiatric care of older adults. Despite the availability of geriatric psychiatry training and the growing population of older adults, current statistics suggest an alarming paucity of psychiatrists who are specialty trained in geriatrics. As such, it is essential to increase the geriatric psychiatry workforce. This includes increasing recruitment of general psychiatric trainees into the geriatric psychiatry sub-specialty, in order to both provide care for the growing population of older adults and to train general psychiatric and medical practitioners, who will likely be providing the bulk of the psychiatric care of older adults. Several strategies to increase the geriatric psychiatry workforce are currently being explored, including structural changes in sub-specialty training programs, financial incentives such as loan repayment programs, and earlier and broader experiences with geriatric psychiatrist educators during general psychiatry residency training. Equally important in ensuring that the elderly will receive optimal care are initiatives directed at improving their access to specialty mental health services.

In spite of an evolving economic landscape, a decision to enter the field of geriatric psychiatry has always been a decision of the heart, and not the pocket-book. It attracts those who love to hear stories from those who have lived the longest and acquired wisdom borne of life long experiences. For most elderly, the onset of mental illness is a new and horrifying experience. Their distress is profound, as is their gratitude for skilled intervention. One gets to make a difference in geriatric psychiatry, and this ability to intervene with patients and families in both curative and supportive ways brings the geriatric psychiatrist deep satisfaction. Working with the elderly attracts those with a sense of mission, a calling to take care of our most vulnerable citizens – those who face the double prejudice of old age and mental illness.

Education in Old Age Psychiatry: Recent and Future Developments

Hugo de Waal

East of England Postgraduate School of Psychiatry, Fulbourn, Cambridge, UK

INTRODUCTION

Over the past few decades geriatric psychiatry has developed as a psychiatric subspecialty to varying degrees in different countries[1]: while in some it is recognized as such at governmental level (e.g. the UK[i]), elsewhere it developed a defined medical identity more within the medical profession (e.g. the USA, Australia, Canada), or it functions as a less well circumscribed area of special interest of medical practitioners, whose designation often lies in other specialties, such as general psychiatry, neurology or geriatric medicine (e.g. the Netherlands).

In 1998 the World Health Organization (WHO) in collaboration with the International Psychogeriatric Association (IPA) published three consensus statements on geriatric psychiatry, the third of which focused on education. Its aim was 'to propose wide guidelines favouring an education of good quality, taking into account the complexity of the subject to teach and of the public concerned'[2] – not a straightforward ambition, given the fact that worldwide geriatric psychiatric services and education range from non-existent to highly sophisticated and mature, well-embedded in health provision and educational accreditation systems.

The following presents the impact of various circumstances and factors upon the development of education in geriatric psychiatry and highlights some trends that may prove important for the future of training and education in this subspecialty.

THE LINKS BETWEEN EDUCATION, CAREER CHOICE, SERVICE PROVISION AND SUBSPECIALTY RECOGNITION

Career Choice

Training and education in geriatric psychiatry are influenced to a considerable extent by factors related to career choices made by medical graduates in general. In the United States, Bragg and Warshaw reported that problems persist in recruitment and retention of 'high-quality USMGs' (United States Medical Graduates) in both geriatric medicine and geriatric psychiatry. They identified early exposure to geriatrics as an important factor in selecting it as a career[3], as did Lieff *et al*., who investigated more fully which particular experiences showed a positive effect: they mention specific teacher attributes, training experiences, personal experiences with seniors, and the medical, neuropsychiatric and multifactorial nature of the field[4]. Similarly, in the United Kingdom, McParland *et al*. showed how undergraduate experience is essential in choosing the specialty and the more so if that experience is positive and of a high quality[5].

There are other, related factors at play with regard to career choice: Goldacre *et al*. report that in the United Kingdom non-white consultants who qualified abroad were at 18.4% significantly over-represented in geriatric psychiatry[6]. This pattern of skewed ethnic representation can be recognized in general in British psychiatric training: in his recent newsletter the Dean of the Royal College reported that at the last sitting of the final membership examination (the so-called Clinical Assessment of Skills and Competencies) only one out of eight candidates was a UK graduate[7]. It is therefore clear that the UK remains a net importer of doctors, and this pertains to geriatric psychiatry even more than to some of the other psychiatric subspecialties. He believes that two important explanatory factors can be found in 'the current dismal experience of many medical school clinical attachments' and 'the poor penetration of psychiatry into the Foundation years' (the British version of post-qualification, pre-registration training). One could therefore conclude that even in the UK there are major difficulties in recruitment and retention in psychiatry (and therefore in geriatric psychiatry), regardless of the fact that internationally the UK could be regarded as advanced in its development of geriatric psychiatric services and related training and education.

Service Provision

Surveying the international picture of education in old age psychiatry, it soon becomes clear that it appears mature and sophisticated in those countries where psychogeriatric services exist, which themselves are mature and established. On the contrary, education tends to be poorly structured, educationally isolated and occurring in an ad hoc fashion in those countries where psychogeriatric services are either non-existent, or are an 'afterthought' featuring in other medical specialties.

[i]Old Age Psychiatry is recognised in the UK by the Postgraduate Medical Education and Training Board as a subspecialty, carrying its own Certificate of Completion of Training.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

In 2001 the World Psychiatric Association (WPA) section on old age psychiatry surveyed the level of development of medical education in geriatric psychiatry in 93 countries. A total of 48 countries responded, which in itself at 52% was a worryingly low response rate – even for a postal questionnaire – given that the survey was particularly aimed at those clinicians who were known to have a special interest in and affinity to the subspecialty. Of the responders, 40 countries reported the existence of old age psychiatric services and 44 formal teaching at undergraduate level, but only 13 full recognition of the discipline as a subspecialty. The member societies furthermore considered support for the development of postgraduate training as their most pressing need[8].

In those countries where there is a drive to develop both services and education, there is often the problem of how to tackle the 'chicken and egg' phenomenon: it is, perhaps predictably, quite difficult to get education going when clinically there is no defined basis for that to occur in, although it must be pointed out that in the case of geriatric psychiatry some lessons have been learned from geriatric medicine. The same survey found that chairs in geriatric medicine – as a reasonable indication of structured advanced educational activity – only exist in countries where geriatric medicine is recognized as a subspecialty. This appeared not to be the case for geriatric psychiatry; several countries reported chairs in geriatric psychiatry to be in existence, even when the discipline was not yet formally recognized.

Subspecialty Recognition

The process of developing services when there are only a few appropriately skilled and motivated medical specialists pushing the psychogeriatric agenda is understandably a laborious exercise. But even when there are such interested parties present, the response from the wider professional body may be felt to be less than supportive. For example, in Canada Herrmann[9] pointed out that there exists a very active geriatric psychiatric subspecialty. The Canadian Academy of Geriatric Psychiatry counted in 2004 more than 190 members and organizes annual academic meetings, residency training programmes, numerous undergraduate and postgraduate training programmes and fellowship awards. It developed the Canadian Coalition for Seniors' Mental Health (CCSMH), which – among many activities and initiatives – co-hosted and organized the 9th Congress of the International Psychogeriatric Association. Yet the Canadian Royal College of Physicians and Surgeons did not demand any particular clinical and training time requirement in geriatric psychiatry until 2008, when it incorporated a mandatory six months' placement in geriatric psychiatry into its junior residency training programme[10] and to this day it does not recognize geriatric psychiatry as a subspecialty, while it does list geriatric medicine as such[11]. Hermann points out that such subspecialty recognition is vitally important to 'strengthen the awareness and profile of geriatric psychiatry, increasing the likelihood of recruitment into the practice'. If such recognition is not forthcoming in a country such as Canada, then how difficult will it be in countries that do not feature highly regulated professional bodies and training accreditation processes?

With or without such support from regulatory bodies, there is no doubt that high-level insistence on guidelines and standards has a positive effect on further developments. The earlier mentioned WHO consensus statement has led to a number of initiatives with immediate impact. In Europe it led to a consensus curriculum on Skill-Based Objectives in Old Age Psychiatry in 2002 (the so-called Lausanne statement). Apart from formulating a comprehensive list of areas of competence and learning objectives, Gustafson *et al*. express the hope that implementation of the curriculum 'should help ensure that . . . each European country has a number of specialists who can provide leadership in clinical service development, training and research'[12]. In the USA Lieff *et al*. formulated core competencies for geriatric psychiatric training and certification; their list appears equally inspired by the WHO consensus statement[13].

Implicitly they may be considered to base such expectations on the experience in the UK, where geriatric psychiatry managed to become a fully-fledged, mature and sophisticated subspecialty on the back of the energetic advocacy from initially only a few 'pioneers', such as Sam Robinson, Felix Post, Klaus Bergmann, Tom Arie, David Jolley, Brice Pitt, Elaine Murphy, Gordon Langley and John Wattis, to name the most prominent ones. Their inspirational efforts span across close to three decades, and to gain some understanding of how such pioneers and champions went about creating a new subspecialty, the Guthrie Trust Witness Seminar, entitled *The Development of Old Age Psychiatry from the 1960s until 1989*, provides a unique account and an important insight into how enthusiasm on one hand and tenacity on the other proved to be essential cornerstones of the process of establishing and developing old age psychiatry in the UK[14].

FUTURE DEVELOPMENTS

Research

Apart from the obvious and regularly reported demographic projections, which in themselves are likely to lead to increased attention and professional interest in geriatric psychiatric services on one hand, and subspecialty medical education on the other, there are other – very interesting – factors that may lead to a more fertile appreciation of the subspecialty within the medical profession at large. While historically geriatric psychiatry was quite limited in its therapeutic arsenal with respect to its most prominent disease category, i.e. dementia, the relatively recent availability of cholinesterase inhibitors, particularly in the developed countries, has served to improve its perceived status within the younger generations in medicine. This is likely to be further enhanced by the accelerated production of other therapeutic medications coming out of a research establishment which until fairly recently would have found it difficult to spend much time and energy on an illness category it considered to be largely beyond therapy or profit. The International Conference on Alzheimer's Disease (ICAD) in July 2009 in Vienna featured no fewer than eight distinct therapeutic target areas. Progress appears to be being made, for instance, in pyroglutamate-related pathways, tau aggregation inhibition, protection against tau hyperphosphorylation via activity-dependent neuroprotective protein (ADNP), normalization of metal–protein interactions via so-called metal protein attenuating compounds (MPAC), β-secretase inhibition, prevention of neuronal re-entry into the cell cycle, and so on (see www.alz.org/icad/overview.asp). Although many of these projects are some considerable time away from leading to clinically relevant therapeutic agents, there is little doubt that over time a more varied therapeutic arsenal will lead to more interest from all sorts of corners, including budding specialists.

Service Development

The link between such therapeutic power on one hand, and the ongoing development of a speciality and related focus on training and

education on the other, was recognized by Foucault, who described and analysed such links as cornerstones of a more or less mature specialist discourse, even if he then goes on to critique such discourse[15]. One unpredictable issue at this stage is the possibility that a superspecialty may develop within geriatric psychiatry, solely devoted to dementia: the inexorable and fast accelerating progress of therapeutic research into this area, combined with projections of an ageing population, would potentially lead to segregation between such a service and services for older patients with so-called functional illnesses. Such a path would follow Foucault's analyses of the medical discourse: whenever medicine is able to pinpoint causative pathophysiological processes it has a tendency to devote specialist attention to them, and this is further reinforced when therapeutic interventions become feasible and prove to be efficacious. Should this occur, then a new threat may be surfacing to the integrity and cohesion of geriatric psychiatry: one should be guarded if such a development leads to a decrease of specialist attention to the functional illnesses of old age, and it could be considered a negative and unintended consequence if the functional side of geriatric psychiatry winds up being reabsorbed into more generic psychiatric services.

Postgraduate Schools

From 2007 in the UK postgraduate training in all medical specialties is being commissioned and quality assured by newly established Postgraduate Schools, on behalf of the longer established Postgraduate Deaneries. Such Schools function through operational boards, which are almost exclusively manned by medical trainers and educationalists, with additional representation of senior management, Royal College officers, trainees, and patients and carers. These Schools are proving quite powerful in developing, driving and improving postgraduate training, and this is particularly important for those subspecialties that otherwise might wind up in a 'Cinderella position'. The British concept of the Postgraduate Schools may well prove an excellent mechanism through which other countries might try to foster such subspecialty developments. If so, it would be a rare example of a situation in which a high intensity of political interference with educational structures (as is the case in the United Kingdom) actually turns out to be beneficial to the profession and its training and education.

CONTENT OF TRAINING, ASSESSMENT AND APPRAISAL PROCESSES

With the establishment of Postgraduate Schools in the UK, the Royal College's role became more specifically focused on curricular development and the setting of standards for training and education. This gave the College the opportunity to formulate detailed, competency-based curricula, which directly link to assessment and appraisal processes, and these in turn form the core evidence on which specialist accreditation is based. The curricula undergo regular revision, and the latest version with respect to geriatric psychiatry can be accessed at www.rcpsych.ac.uk/PDF/Old_Age_Feb09.pdf.

Additionally the College took the lead role in developing workplace-based assessments particular to psychiatric training, which shifted the training experience from an apprentice model to a 'managed learning' model. These assessments replaced in part the traditional knowledge-testing function of the Royal College membership examination; workplace-based assessments specifically test clinical and professional competencies through direct observation and feedback, the latter being particularly important in providing a learning tool to the trainee, with increased levels of self-reflection on performance.

Already in 2003 Gustafson *et al*. called for training programmes to:

- be rooted in evidence-based practice
- be clinically relevant
- have explicit evaluation criteria
- include feedback from trainees
- be reviewed regularly.

He also highlighted that 'training program participants should have both formative (constructive feedback) and summative assessments'[11]. The former is thus now a crucial component of specialist training in the UK (as it has been for some time in the USA and Canada), while the latter is particularly important if one is to expect such training programmes and assessment processes to be linked to accreditation of specialists. Gustafson calls for the setting up of geriatric psychiatric accreditation through national systems in all European countries. All of this flows directly from the Lausanne statement[11], in turn the result of the WHO/IPA consensus statement[2].

It is worth noting that in the UK, with the implementation of the new streamlined postgraduate curriculum and assessment processes in 2007, totally new workplace-based assessments have been developed. These were to some degree based on the tools already in use in the USA and Canada, but they underwent extensive adaptation and re-validation for the purposes of psychiatric training. More recently a further assessment tool has been developed, particularly aiming to test for higher, non-clinical skills (the so-called Direct Observation of non-Clinical Skills, or DOnCS); it tests and assesses the trainee's skills in competencies not directly related to the clinician–patient interaction, but more to do with higher, so-called 'meta-level', skills. The categories are taken from CanMEDS, the Canadian framework, which organizes core competencies around seven key physician roles:

- medical expert
- communicator
- collaborator
- manager
- health advocate
- scholar
- professional.

It aims to provide formative and summative learning opportunities to the trainee in their post-membership training, and is expected to aid in their preparation for their subsequent role as consultant old age psychiatrists. In the British National Health Service there is a strong appreciation that the consultant role must exceed the provision of clinical, patient-centred care, and should incorporate a variety of roles, such as team leader, service developer, inter-agency negotiator, strategic planner etc. Given that particularly in geriatric psychiatry there is a relatively strong emphasis on collaboration with other agencies and an ensuing interest in strategic service and educational development, the DOnCS could be particularly powerful in fostering such skills in specialists being educated and trained in geriatric psychiatry, were it to be adopted elsewhere. More information about this assessment tool can be found at https://training.rcpsych.ac.uk/doncs-assessor-guidance.

CONCLUSION

With the large variety of political, cultural and economic factors on one hand and the huge diversity of service configuration and related

existence of medical education on the other, combined furthermore with the varying levels of governmental interest or disinterest in either, the way forward will at least have to be a two-pronged one: top-down with the involvement and guidance of institutions such as the World Health Organization and the International Psychogeriatric Association and bottom-up through 'champions and pioneers'.

The role of champions and pioneers should start with undergraduate training. One noteworthy initiative, recently started by the UK Royal College and led by its Psychiatric Trainees' Committee, is designed to engage with medical students: in medical schools up and down the country undergraduate Psychiatry Societies are starting up, linked into a network in which a new College grade of Student Associate of the Royal College features prominently. The UK Royal College website now has a dedicated section for medical students who are interested in psychiatry and who want to find out more about the specialty, the training and education, career options etc. (www.rcpsych.ac.uk/specialtytraining/students.aspx). It provides an opportunity for interested medical students to enrol as a Student Associate of the Royal College. Further information on the Old Age section of this website can be found at www.rcpsych.ac.uk/specialtytraining/students/subspecialties/oldagepsychiatry.aspx.

In short, one can discern a number of factors that should lead to a higher profile for geriatric psychiatry and its training and education:

1. continued efforts by international and national professional organizations
2. increased efforts to provide the relevant exposure to medical students
3. enthusiasm and active 'proselytizing' by clinicians and educators
4. the projected increase in the size of the older age groups
5. an expected increase in therapeutic options.

Subject Index

Abbreviations
  AD - Alzheimer's disease
  APP - amyloid precursor protein
  DLB - dementia with Lewy bodies
  DTI - diffusion tension imaging
  FAST - Functional Assessment Staging
  FTD - frontotemporal dementia
  GDS - Global Deterioration Scale
  LBD - Lewy body dementias
  MCI - mild cognitive impairment
  MMSE - Mini Mental State Examination
  MTL - medial temporal lobe
  NAA - *N*-acetylaspartate
  OCD - obsessive-compulsive disorder
  PDD - Parkinson's disease dementia
  SSRIs - selective serotonin reuptake inhibitors (SSRIs)

Note: All index entries relate to older people and psychiatric disorders unless otherwise indicated. *vs* denotes differential diagnosis or comparisons.

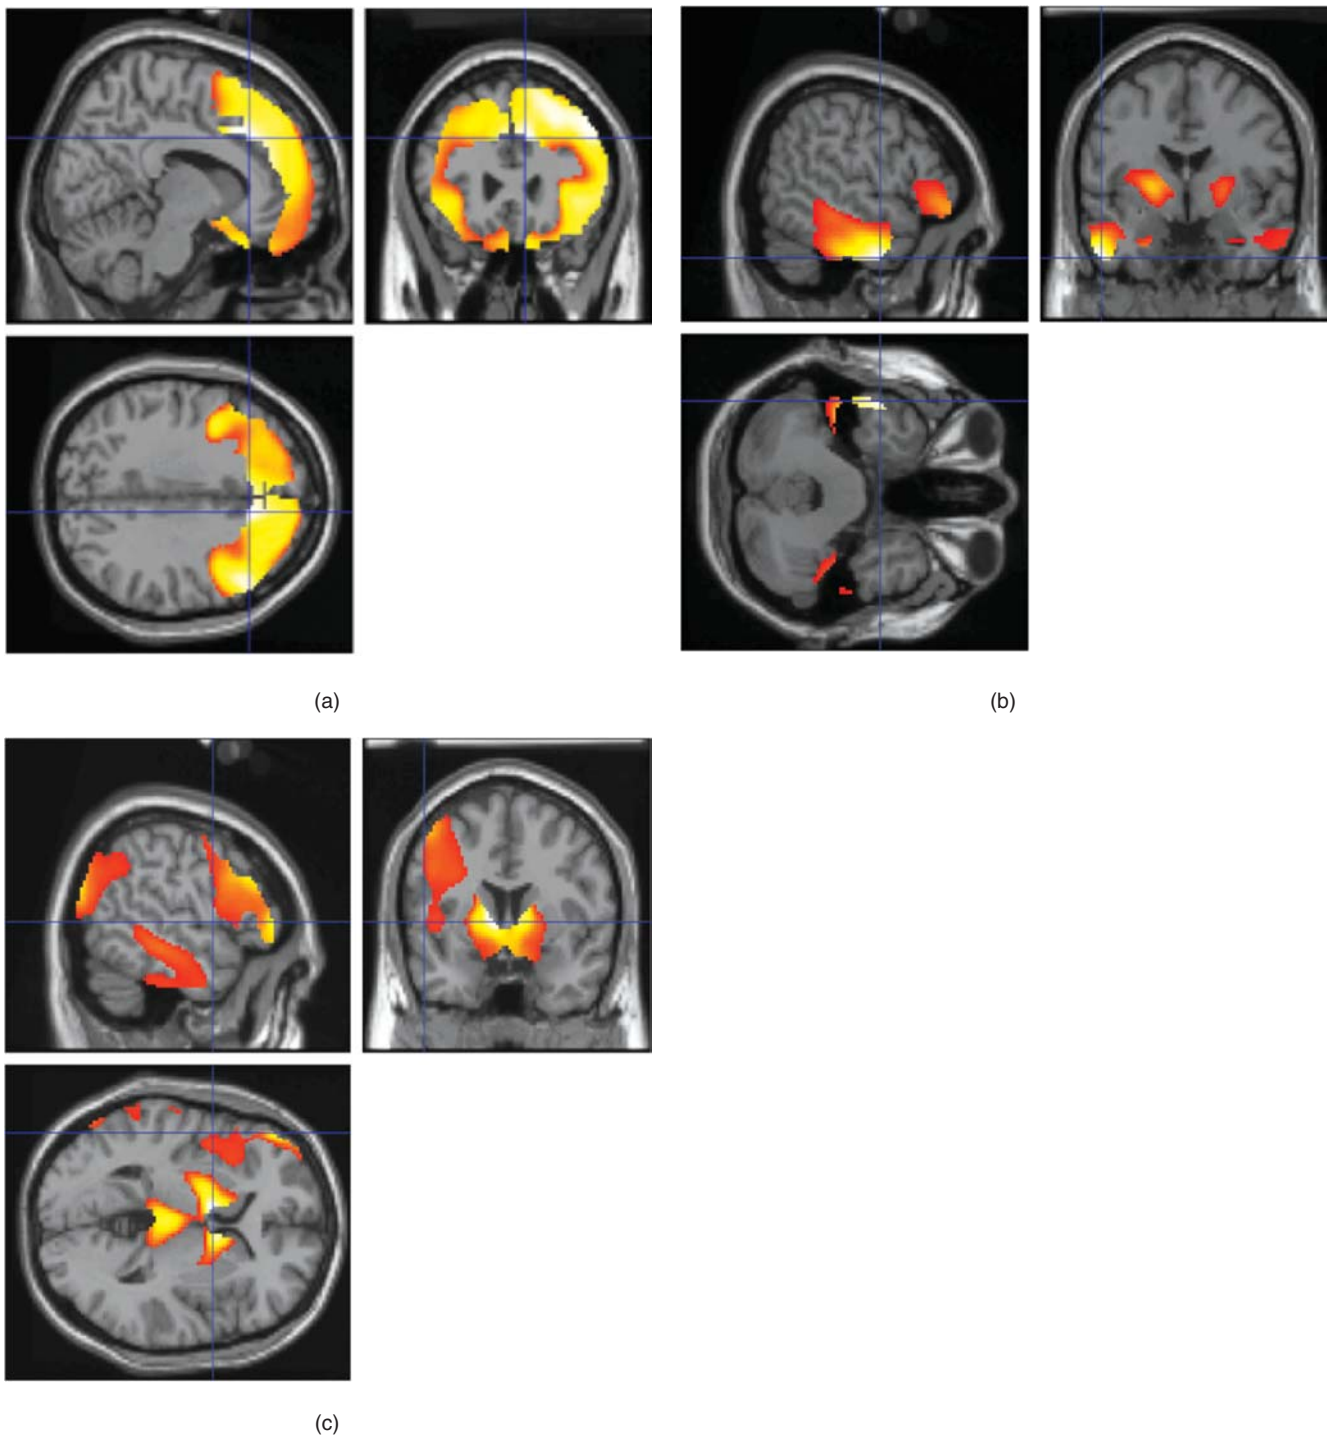

Figure 5.1 Reductions of regional cerebral glucose metabolism in ^{18}F-fluoro-2-deoxy-glucose positron emission tomography (FDG PET) studies of patients with (a) frontotemporal dementia, (b) semantic dementia and (c) progressive non-fluent aphasia compared with healthy control subjects (sagittal, axial, and coronal slices; areas with reduced metabolism are displayed in colour).

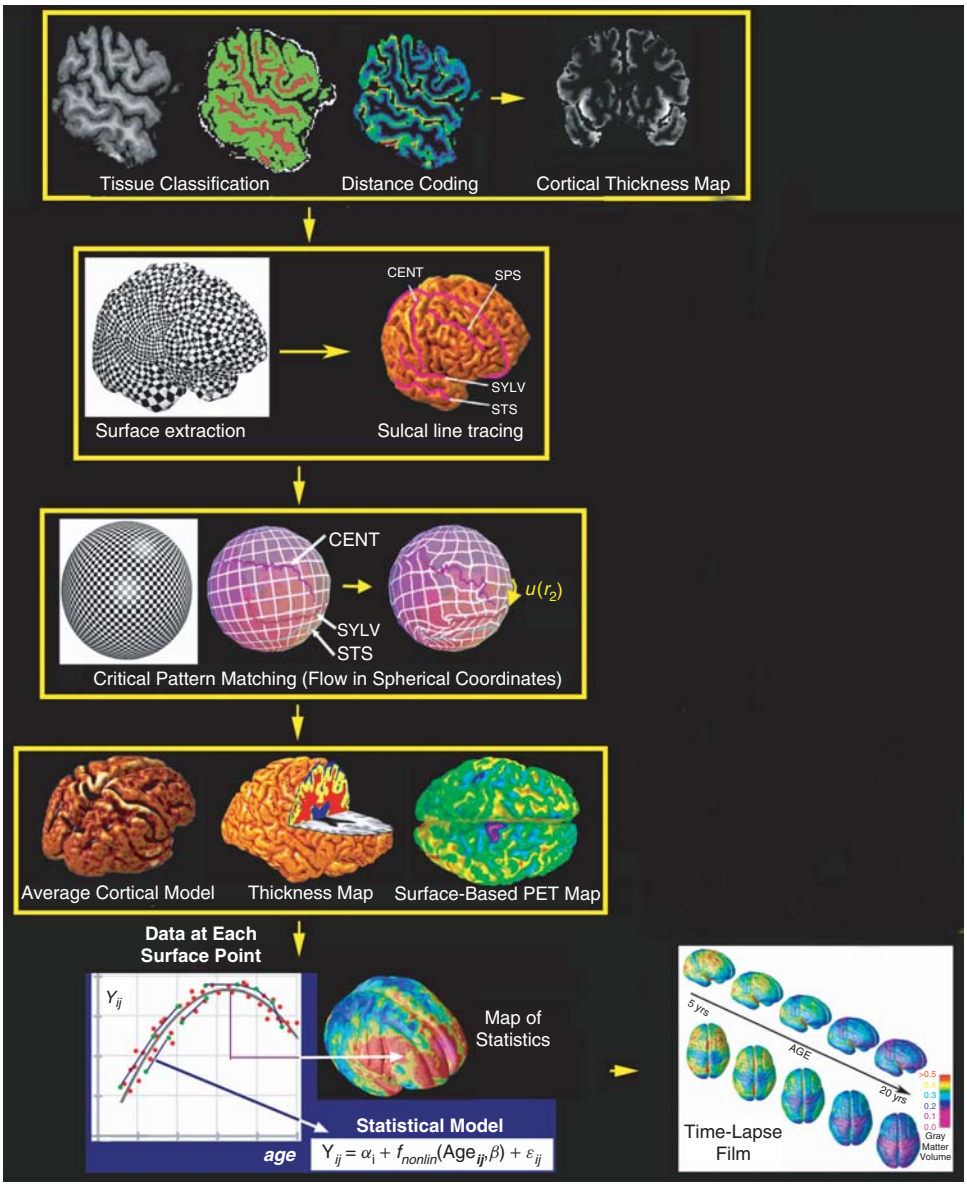

Figure 46.1 Flowchart showing an image analysis pipeline (adapted from[10]) that can map changes of various neuroanatomical measures in the cortex, such as grey matter atrophy. Cortical thickness profiles, for example, can be averaged across subjects or compared across time. Tissue classification techniques can be used to identify grey and white matter and to produce cortical thickness maps (row 1). The CPM approach can be applied by tracing sulcal landmarks on extracted brain surface models (row 2) that serve as anchors to guide a flow field matching gyral regions across subjects (row 3). Then maps of cortical thickness, or other cortical signals (such as co-registered PET images, shown here), can be fluidly aligned to an average cortical model (row 4). Statistical models are fitted to data from all the subjects at each cortical point. This can assess whether imaging signals are associated with age (bottom row), or other parameters of interest. Effects of ageing on cortical measures – or changes relative to baseline – may be animated as a time-lapse film to reveal the disease trajectory.

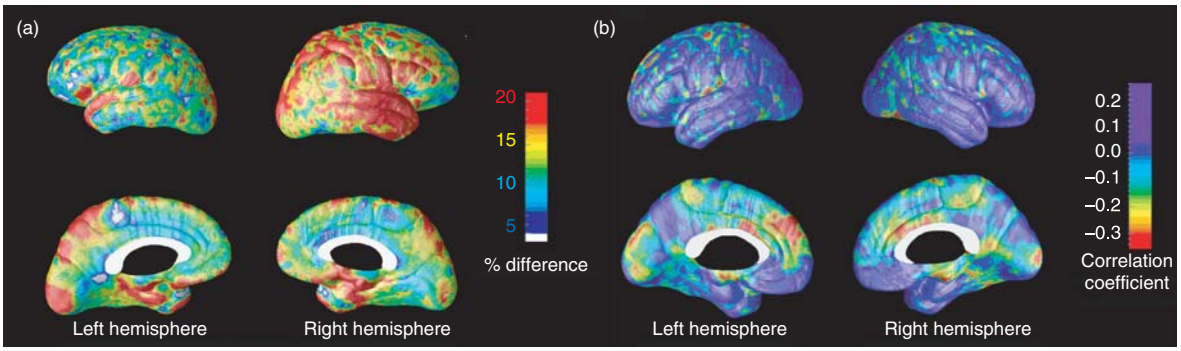

Figure 46.2 (A) Cortical thinning of up to 20% occurs between MCI and AD, in widely distributed cortical areas (greatest tissue loss is coded in red). (B). Grey matter atrophy in the anterior cingulate and supplementary motor cortices is correlated with the presence or absence of apathy in AD. Regions where structural variation correlates with clinical or behavioural differences can be identified using correlation maps such as these (strong associations are shown here in red colours). Data adapted from[21,22].

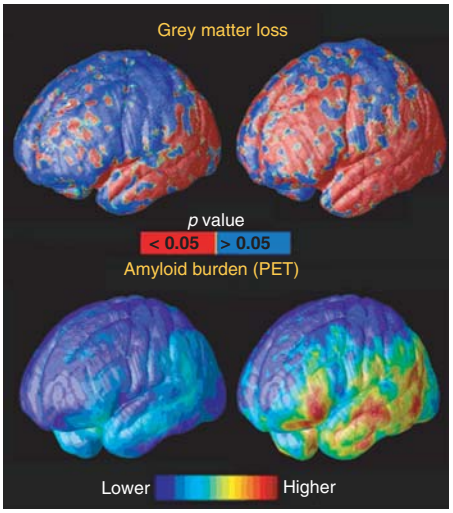

Figure 46.3 Progression of AD based on MRI and [^{18}F]FDDNP PET. On MRI (top row), the areas with grey matter deficits in mild AD (left panel) include primarily the temporal lobe, but in moderate AD (right panel) these deficits have spread to involve the frontal cortex (adapted from a longitudinal study by Thompson *et al*.[25]). Finally, cerebral amyloid estimated *in vivo* from the PET ligand FDDNP is low in controls, but higher in those with impaired cognition (bottom row; adapted from Braskie *et al*.[8]). The anatomical agreement is striking between these *in vivo* maps and the well-established postmortem maps for the staging of AD. In all maps, the sensorimotor cortex shows least disease-related degeneration.

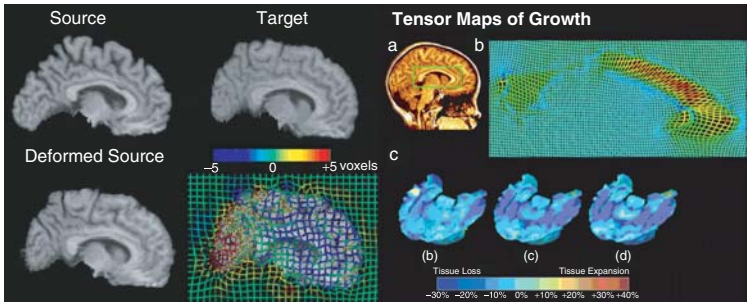

Figure 46.4 Tensor-based morphometry. In TBM, a fluid transformation (*deformed grid*) is applied to a baseline scan (*source*) to reconfigure it (*deformed source*) into the shape of a follow-up scan (*target*). The local expansions (*red colours*) or atrophies (*blue colours*) can be plotted in brain regions such as the corpus callosum (shown in the green box in [a]). Voxel expansions (*red colours*) or contractions (*blue colours*) can be plotted onto a sequence of scans collected from the same subject (shown here in axial view illustrating progressive temporal lobe atrophy in a subject with frontotemporal lobe atrophy) during a degenerative brain disease, emphasizing regions with progressive atrophy. These maps may be averaged across subjects or compared across populations to assess factors that influence degenerative rates in each region of the brain.

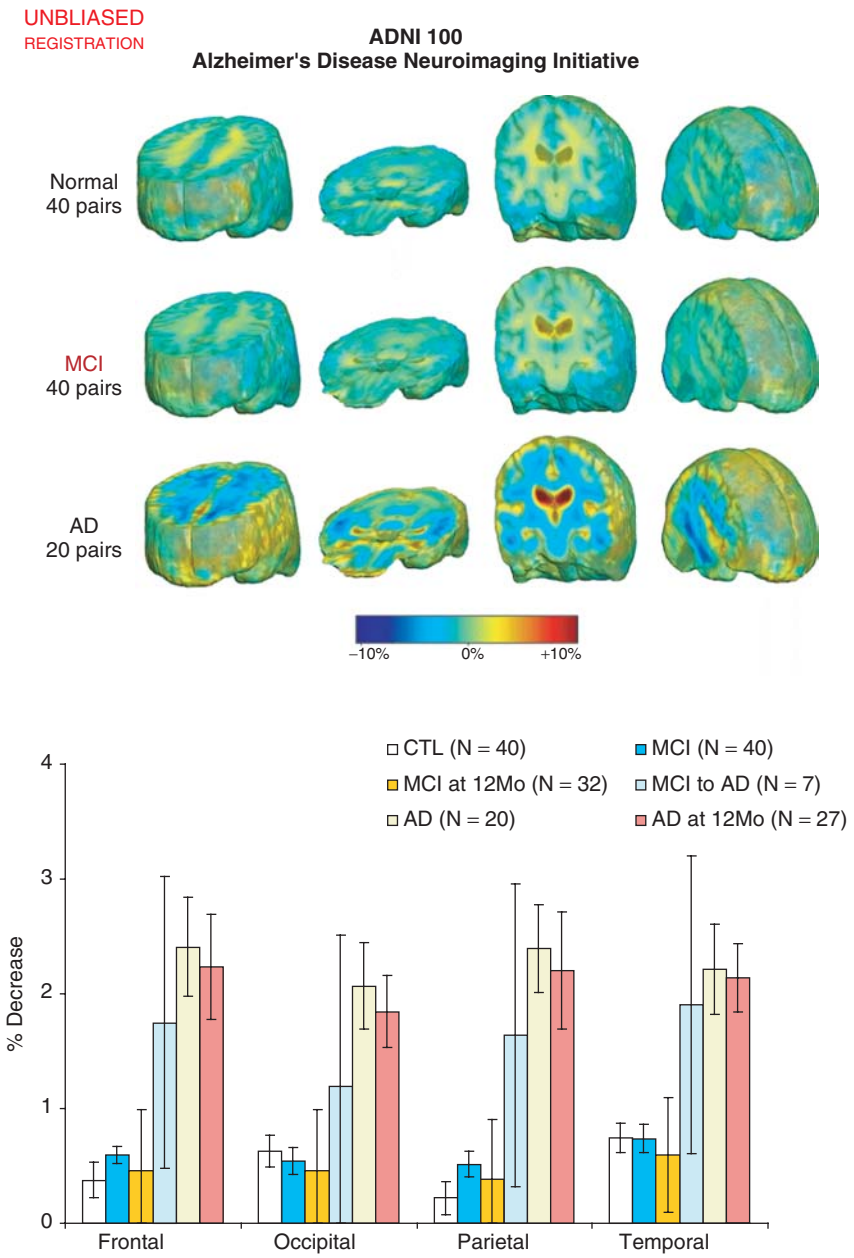

Figure 46.5 (Top panel) average longitudinal tissue atrophy/expansion rate for 40 normal, 40 MCI and 20 AD subjects, using serial MRI scans from the ADNI dataset scanned at 12 months apart. Ventricular expansion (third column) and temporal lobe atrophy (fourth column) are most prominent in the AD group. (Bottom panel) Percentage brain tissue loss from baseline to follow-up within each lobe can be computed by averaging the maps in the left panel for each region of interest (with CSF excluded). The diagnoses for the AD, MCI and CTL groups were determined at baseline. Here, MCI at 12Mo denotes subjects diagnosed as MCI at baseline who did not convert to AD at 12-month follow-up, whereas MCI to AD signifies those who had converted to AD at 12-month follow-up. One MCI subject's diagnosis converted back to control at follow-up, and thus was excluded from the MCI subgroups. The first bar in each group (coloured *white*) shows mild but significant progressive atrophy in controls. The second bar (*turquoise*) denotes MCI subjects at baseline, and is followed by bars denoting converters and non-converters. Mean rates are typically higher in the converters, comparable to subjects diagnosed as AD at both time-points, or AD at the last time-point (*last two bars*). This figure is adapted from the results in[33].

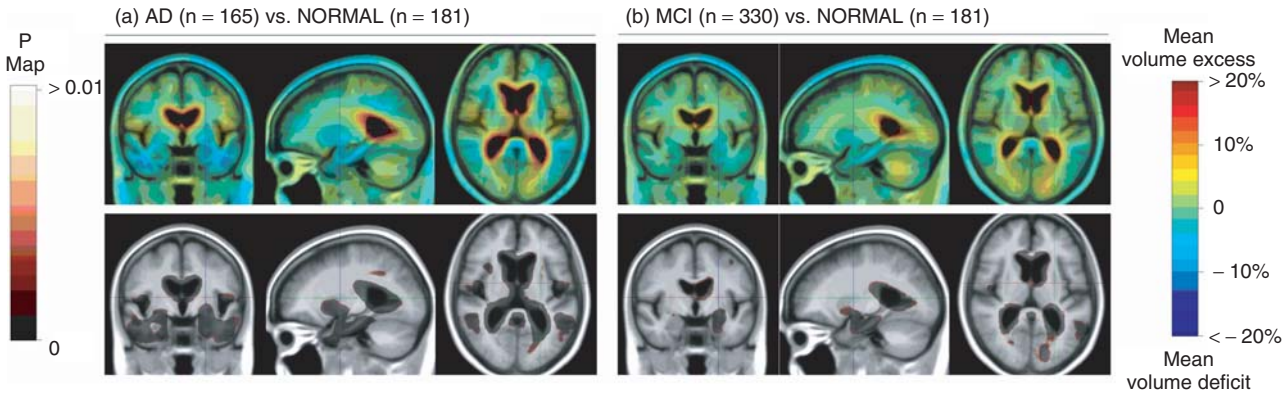

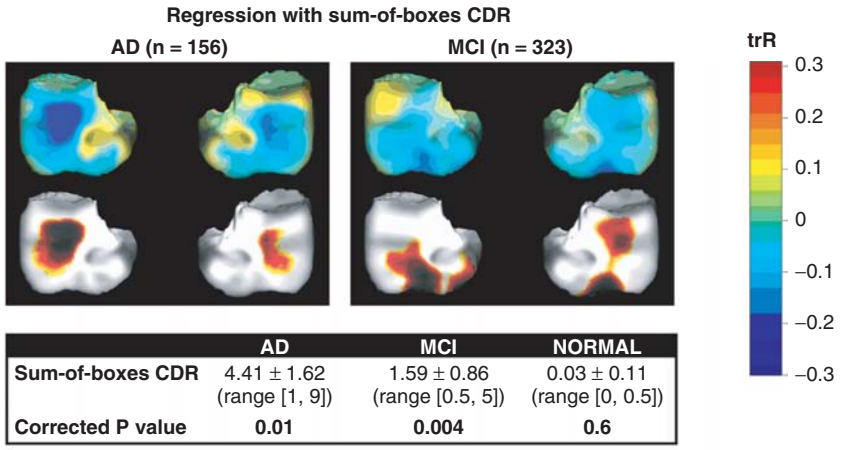

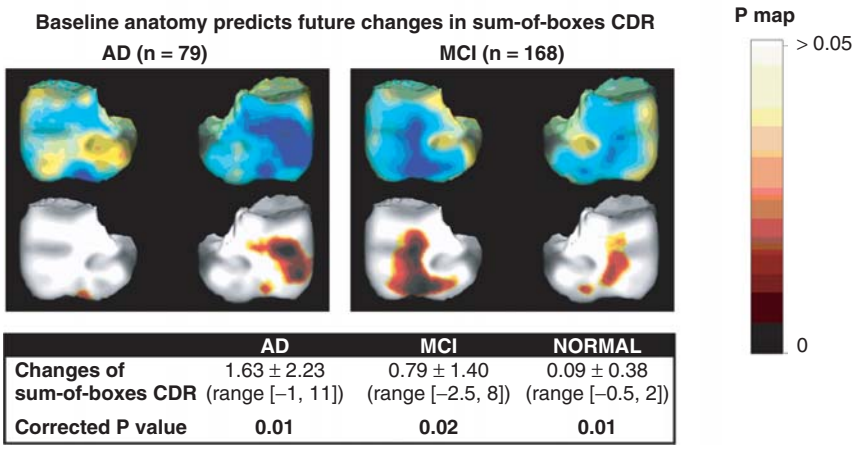

Figure 46.6 3D maps of brain atrophy comparing group differences between MCI ($n = 330$) versus normal ($n = 181$), and AD subjects ($n = 165$) versus normal. The top rows of panels (a) and (b) show the mean level of atrophy as a percentage reduction in volume. The bottom rows show the significance of these reductions, revealing highly significant atrophy in AD but a more anatomically restricted atrophic pattern in MCI. In MCI (b), atrophy is most prominent in the left hippocampus; ventricular expansion is also substantial. When AD is compared with MCI (not shown here), additional temporal lobe degeneration is evident. The overall level of ventricular expansion is about 10–15% for MCI and greater than 20% for the AD group. This figure is adapted from the results in[35].

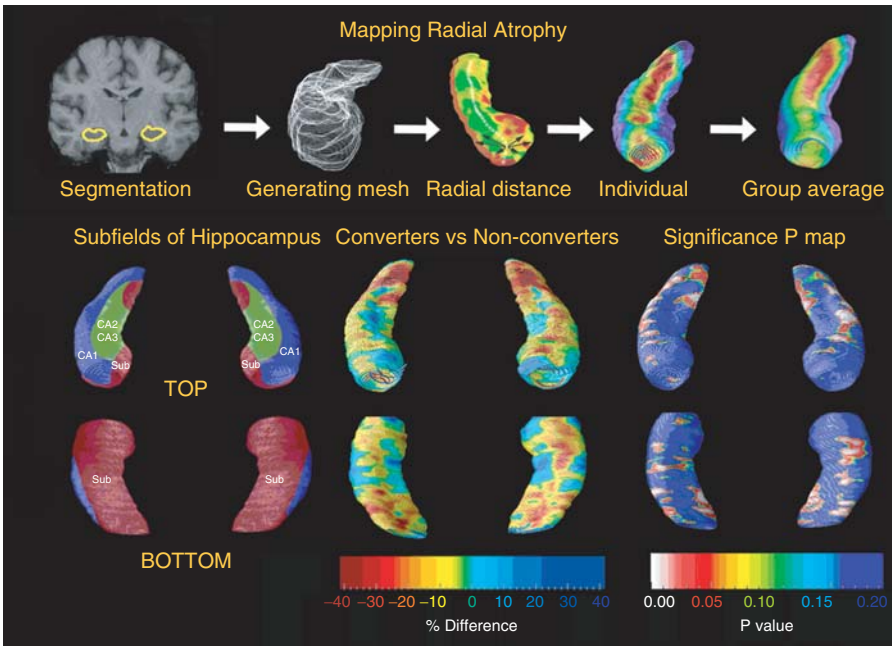
	AD	MCI	NORMAL
Sum-of-boxes CDR	4.41 ± 1.62 (range [1, 9])	1.59 ± 0.86 (range [0.5, 5])	0.03 ± 0.11 (range [0, 0.5])
Corrected P value	**0.01**	**0.004**	**0.6**

	AD	MCI	NORMAL
Changes of sum-of-boxes CDR	1.63 ± 2.23 (range [–1, 11])	0.79 ± 1.40 (range [–2.5, 8])	0.09 ± 0.38 (range [–0.5, 2])
Corrected P value	**0.01**	**0.02**	**0.01**

Figure 46.7 Temporal lobe atrophy correlates with sum-of-boxes clinical dementia rating and future clinical decline. Top row negative correlations are detected between temporal lobe atrophy and higher CDR scores at the time of the initial scan (i.e. a higher CDR score correlates with a faster rate of atrophy). The corrected P values in the table (inset) provide an overall estimate of significance, corrected for multiple comparisons. Bottom row atrophy of the temporal lobe also predicts future cognitive decline, as reflected by an increase in CDR scores, which indicates deteriorating cognitive function over the following year. trR denotes partial correlation coefficient. This figure is adapted from the results in[35].



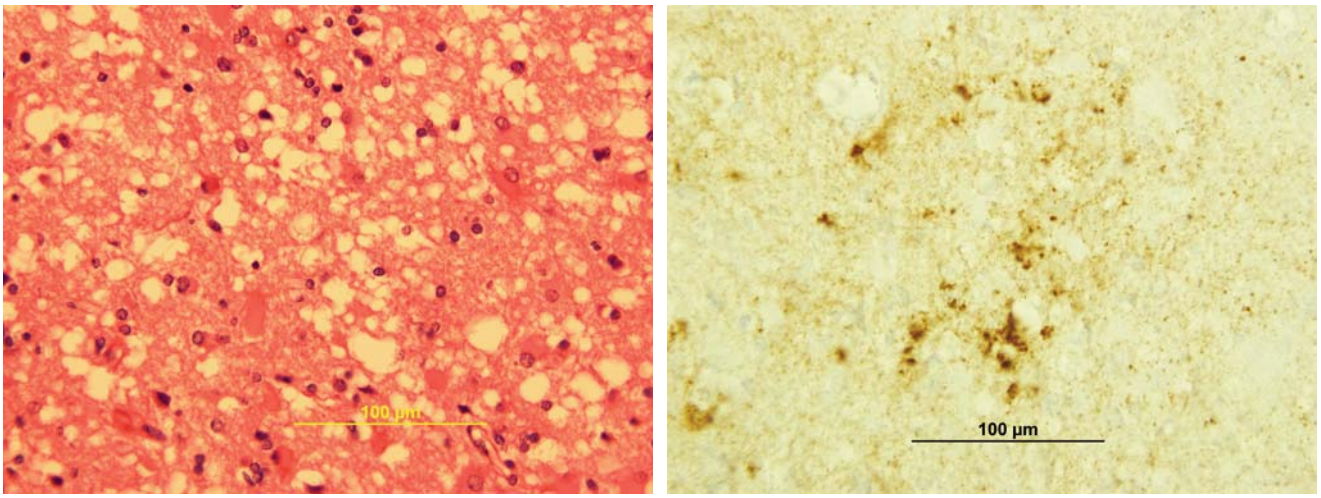


Figure 46.8 Mapping hippocampal atrophy. The radial atrophy mapping method (*top row*) relies on manually or automatically segmenting the hippocampus, computing a 3D parametric mesh model of the structure, estimating the distance between the central core of the structure to each surface point (i.e. the radial distance), and recording radial distance estimates at each surface point to create individual and group average colour-coded maps of the radial distance. These are then statistically compared between groups or conditions. One longitudinal 3D MRI study[50] compared baseline hippocampal atrophy in MCI subjects who converted to AD versus MCI subjects who remained stable or improved cognitively during three years of clinical follow-up. Greater atrophy at baseline was seen in the CA1 and subicular areas in subjects who subsequently convert to clinically probable AD (*bottom right panels*). The bottom panels show a schematic representation of the hippocampal subfields (*left*), the proportional difference in atrophy levels between converters and non-converters (in percentage points; *middle panels*), and the significance of these differences taking into account normal structural variation (*bottom right panel*).

(a) (b)

Figure 59.2 (a) Haematoxylin and eosin (H&E) stain of the temporal cortex and (b) monoclonal 3F4 antibody immunostaining of the hippocampus in a patient with Creutzfeldt–Jakob disease. The neuropathology is characterized by a spongiform appearance, astrogliosis and neuronal cell death. Immunostaining (b) reveals abnormal prion protein deposits (dark brown).

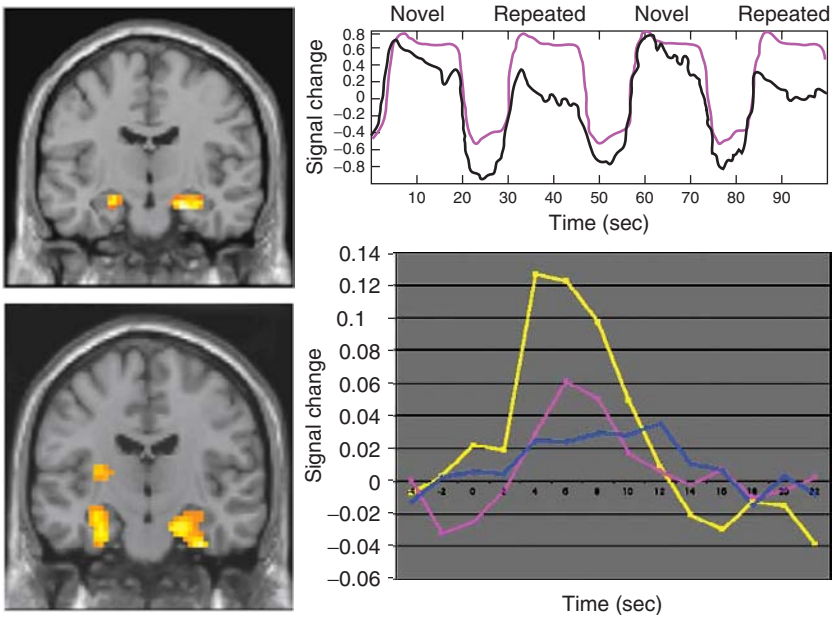

Figure 70.1 Functional MRI data during a face-name encoding paradigm. The top left figure demonstrates a statistical parametric map (SPM) of the hippocampus showing greater MR signal response to novel (N) face-name pairs compared to repeated (R) face-name pairs in a block-design fMRI paradigm. The top right shows a representative time course of the MR signal in the block-design paradigm, with marked increase in signal during novel blocks compared to blocks of visual fixation (+) or repeated blocks. The bottom left demonstrates significant hippocampal activation for an event-related face-name paradigm comparing successful vs. failed encoding. The bottom right graph shows the MR signal change in the right hippocampus for those face-name pairs correctly remembered with high confidence (yellow line), low confidence (pink line) or forgotten (blue line).

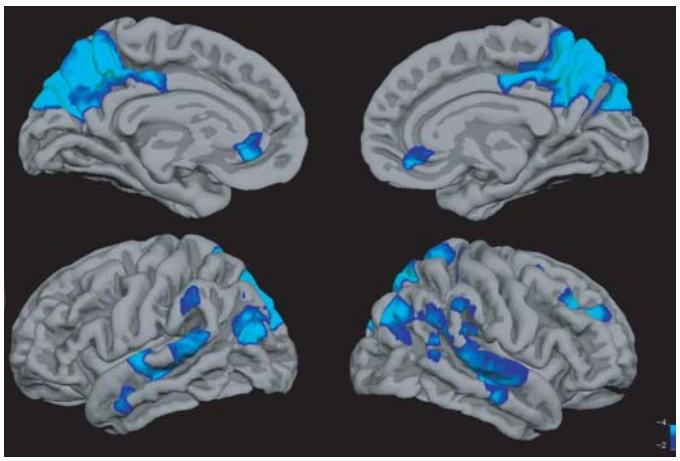

Figure 70.2 The default network, a set of regions that demonstrate higher fMRI activity during rest compared to challenging cognitive tasks. In this group fMRI data map, regions in blue demonstrate greater MR signal during rest (visual fixation) compared to novel face-name encoding.

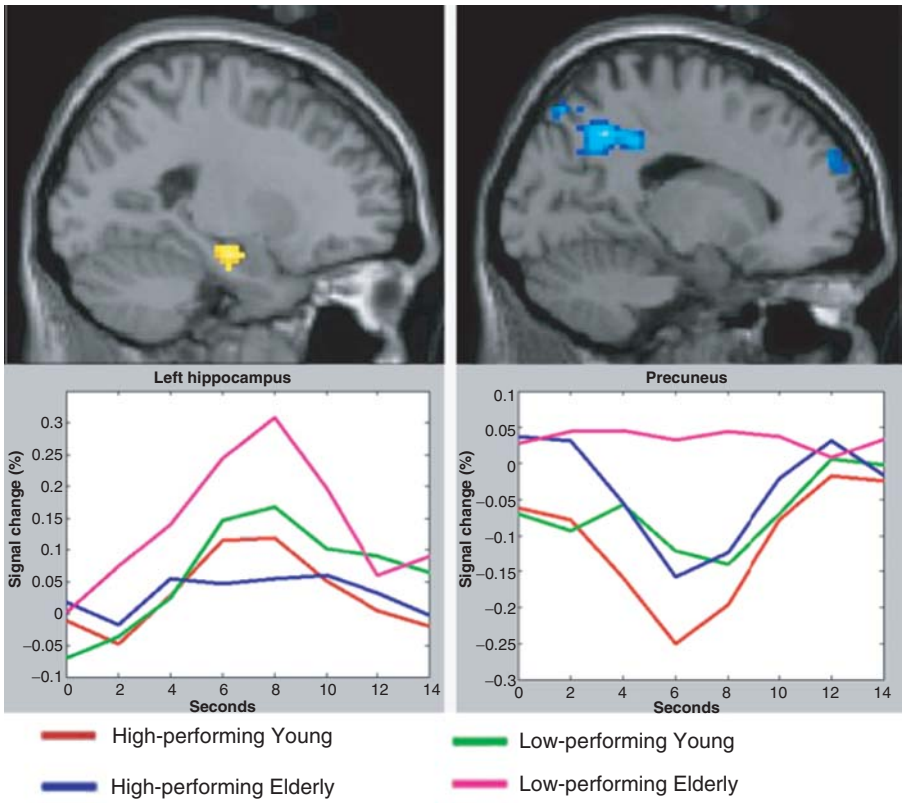

Figure 70.3 Group fMRI data maps (top) with MR signal time courses (bottom) for Young and Elderly controls show hippocampal activation (left) and precuneus deactivation (right) during the successful encoding of face-name pairs. Low-performing Elderly failed to deactivate the precuneus and demonstrated increased hippocampal and pre-frontal activation for successful but not failed encoding trials, perhaps as a compensatory response to failure of default network activity.

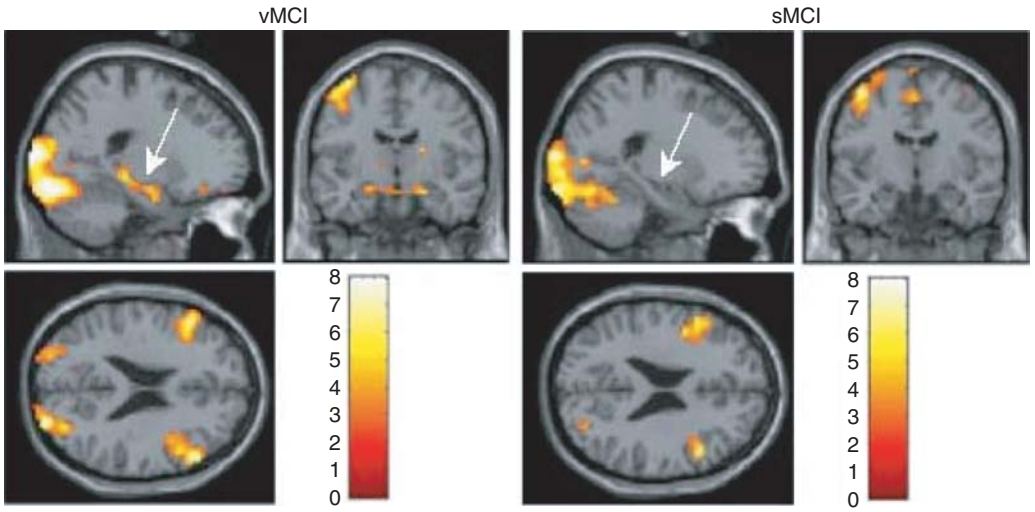

Figure 70.4 Group fMRI data from 15 very mildly impaired MCI (vMCI) and 12 significantly impaired MCI (sMCI) subjects on a face-name encoding task. The vMCI subjects showed evidence of hippocampal 'hyperactivation' compared to controls. The sMCI subjects showed significantly decreased hippocampal activation at levels similar to those seen in mild AD patients.
