Contents

Contributors xiii
Preface xxi
Preface to Second Edition xxii
Preface to First Edition xxiii

PART A HISTORICAL BACKGROUND 1

1 A Conceptual History in the Nineteenth Century 3
German E. Berrios
2 The Development of Old Age Psychiatry in the UK 7
Claire Hilton and Tom Arie
3 Commentary on 'In the Beginning' by Felix Post 12
Claire Hilton

PART B NORMAL AND ABNORMAL AGEING 15

4 Changes in the Macrostructure and Microstructure of the Ageing Brain 17
Natalie M. Zahr, Adolf Pfefferbaum and Edith V. Sullivan
5 Functional Imaging of the Ageing Brain 28
Robert Perneczky, Christian Sorg and Hans Förstl
6 Neurophysiology of the Ageing Brain 36
Paolo Maria Rossini and Laura Parisi
7 Potential Regeneration of the Ageing Brain 42
Stephen B. Dunnett
8 Neuroendocrinology of Ageing 45
Marcus Simmgen
9 Genetic Aspects of Ageing 51
Ben Pickard and Douglas Blackwood
10 The Clinical Pharmacology of Ageing 55
Brian Clarke and S. H. D. Jackson
11 Cognitive Gerontology 60
Patrick Rabbitt
12 Chronological and Functional Ageing 65
David Melzer and Iain Lang
13 Successful Ageing 70
Ann Bowling
14 Sexuality, Non-Traditional Relationships and Mental Health in Older People 74
Ian Peate
15 The Care Home Experience 78
Alisoun Milne
16 Ageing: International Statistical Trends and Prospects 83
Fiona E. Matthews and George M. Savva
17 Economics of Ageing and Mental Health 90
Anders Wimo
18 The Influence of Social Factors on Mental Health 97
Donna D. McAlpine and David Mechanic

PART C DIAGNOSIS AND ASSESSMENT 103

19 Classification of Dementia and other Cognitive Disorders in ICD-10 and DSM-IV 105
A. Jablensky and J.E. Cooper
20 Taking a Psychiatric History from Elderly Patients 109
Sunita Sahu and Monica Crugel
21 Mental State Examination in the Elderly 113
Joanne Rodda and Zuzana Walker
22 The Physical Examination: A Guide for Old Age Psychiatrists 117
Stephen Todd, John O'Hare, Bernadette McGuinness and A. Peter Passmore
23 Investigations in Old Age Psychiatry 122
Sujatha Merve and Robert C. Baldwin
24 Bedside Assessment of Cognitive Functioning 129
Richard Perry
25 Neuropsychological Assessment 135
Linda Clare
26 Overview of Rating Scales in Old Age Psychiatry 141
Kenneth C. M. Wilson, Ben Green and Pat Mottram
27 The Mini-Mental State Examination: A Brief Cognitive Assessment 145
Marshal Folstein, Susan Folstein and Jonathan Folstein
28 The Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE) 147
Nicolas Cherbuin and Anthony Francis Jorm
29 Geriatric Depression Scale 152
Meghan A. Marty, Renee Pepin, Andrea June and Daniel L. Segal
30 Dementia Care Mapping 157
Dawn Brooker

31 Staging Dementia 162
Barry Reisberg, Imran A. Jamil, Sharjeel Khan, Isabel Monteiro, Carol Torossian, Steven Ferris, Marwan Sabbagh, Serge Gauthier, Stefanie Auer, Melanie B. Shulman, Alan Kluger, Emile Franssen and Jerzy Wegiel

32 The Clinical Dementia Rating 170
Rawan Tarawneh, B. Joy Snider, Mary Coats and John C. Morris

33 GMS-HAS-AGECAT Package and the Global Mental Health Assessment Tool (GMHAT): Epidemiology and Closing the Treatment Gap 174
John R. M. Copeland

34 Assessing Life Skills 176
Colin Depp, Veronica Cardenas, Ashley Cain and Thomas L. Patterson

35 Quality of Life Measures in Old Age 183
Juanita Hoe, Martin Orrell and Gill Livingston

PART D DEGENERATIVE AND RELATED DISORDERS 193

36 Delirium 195
Barbara Kamholz

37 The Nosology of Dementia 201
Kenneth Rockwood

38 Epidemiology of Dementia 207
Mary Ganguli

39 An Introduction to the Medical Research Council Cognitive Function and Ageing Studies (CFAS) I and II 213
Fiona E. Matthews and Carol Brayne

40 The Lundby Study 222
Mats Bogren, Cecilia Mattisson and Per Nettelbladt

41 Clinical Features of Alzheimer's Disease: Cognitive and Non-cognitive 226
Oludamilola Salami and Constantine G. Lyketsos

42 Neuropsychological Assessment of Dementia and Alzheimer's Disease 232
David Aaron Maroof and Cynthia A. Munro

43 Genetics of Alzheimer's Disease 238
Lynn M. Bekris, Chang-En Yu, Thomas D. Bird and Debby Tsuang

44 Mouse Models of Alzheimer's Disease 252
Esther Oh, Constantine Lyketsos and Philip Wong

45 Physiological Neuroimaging in Ageing and Dementia: Metabolic and Molecular Scanning 257
Markus Donix, Susan Y. Bookheimer and Gary W. Small

46 Computational Anatomy in Alzheimer's Disease 262
Alex D. Leow, Liana G. Apostolova and Paul M. Thompson

47 Alzheimer's Disease: Risk Factors and Preventive Strategies 271
JoAnn T. Tschanz and John C. S. Breitner

48 Down Syndrome: Genetic and Clinical Overlap with Dementia 281
Giles M.Y. Tan and Declan G.M. Murphy

49 The Molecular Neuropathology of Alzheimer's Disease 287
Orly Lazarov

50 Neurochemistry of Alzheimer's Disease 295
Paul T. Francis

51 Antemortem Markers 299
Susan J. van Rensburg, Felix C.V. Potocnik, Maritha J. Kotze and Dan J. Stein

52 Pharmacological Therapies in Alzheimer's Disease 304
Martin Steinberg and Constantine G. Lyketsos

53 Behavioural Management in Alzheimer's Disease – Pharmacology 312
David A. Merrill and David L. Sultzer

54 Behavioural Management: Non-Pharmacological 324
Jiska Cohen-Mansfield

55 Emerging Applications of Gene and Somatic Cell Therapy in Geriatric Neuropsychiatry 330
Eric Wexler

56 Vascular Dementia 342
Ingmar Skoog

57 The Frontotemporal Dementia Syndromes 348
Mario F. Mendez

58 The Lewy Body Dementia Spectrum (Alpha Synucleinopathies) 360
J.-P. Taylor and I. G. McKeith

59 Prion Diseases 372
Brian S. Appleby

60 Alcoholic and Other Toxic Dementias 378
Eileen M. Joyce

61 Reversible Dementias 383
Michael Philpot

62 Cognitive Domains Affected by Conditions of Ageing and the Role of Neuropsychological Testing 389
Heather R. Romero, Scott M. Hayes and Kathleen A. Welsh-Bohmer

63 Memory Training for Older Adults 397
Karen Miller, Linda Ercoli, Jeanne Kim and Gary W. Small

64 Complementary and Alternative Medicine Approaches to Memory Improvement in the Elderly 403
Helen Lavretsky

65 Ethics of Dementia Care 410
Eran Klein and Jason Karlawish

66 Successful Interventions for Family Caregivers 415
L. McKenzie Zeiss, Yookyung Kwon, Renee Marquett and Dolores Gallagher-Thompson

67 The Role of Alzheimer Societies in the United States 421
Ruth O'Hara and Bevin Powers
68 Psychiatric Manifestations of Nervous System Infections 426
Jeffrey T. Guptill and E. Wayne Massey
69 Magnetic Resonance Imaging and Computed Tomography 433
Howard Aizenstein and Vijay Venkatraman
70 Functional MRI Studies in Ageing and Early Alzheimer's Disease 437
Ottavio V. Vitolo and Reisa A. Sperling
71 Magnetic Resonance Spectroscopy 446
Olusola Ajilore, Brent Forester, Matthew R. Woodward and Anand Kumar

PART E AFFECTIVE DISORDERS 455

72 Nosology and Classification of Mood Disorders 457
Dan Blazer
73 Genetics of Affective Disorders 460
Carolina Aponte Urdaneta and John L. Beyer
74 Environmental Factors, Life Events and Coping Abilities 464
Toni C. Antonucci and James S. Jackson
75 Vascular Disease and Late-Life Depressive Disorder 468
Robert Baldwin
76 Mood Disorders in Parkinson's Disease 473
John V. Hindle
77 Epidemiology of Depression: Prevalence and Incidence 479
Ruoling Chen and John Copeland
78 Neuroimaging in Geriatric Depression 489
Faith M. Gunning
79 Clinical Features of Depressive Disorders in the Elderly 495
Davangere P. Devanand and Steven P. Roose
80 The Outcome of Late-life Depressive Disorders 502
Aartjan T.F. Beekman, Harm W.J. van Marwijk and Max L. Stek
81 Physical Illness and Depression 508
Mavis Evans
82 Depression After Stroke 515
Peter Knapp and Allan House
83 Cross-Cultural Variation in the Experience of Depression in Older People in the UK 518
Vanessa Lawrence, Joanna Murray, Anthony Klugman and Sube Banerjee
84 Treatment of Late-Life Depression In Community Settings 524
Carolyn Chew-Graham
85 Electroconvulsive Therapy (ECT) 529
David G. Wilkinson
86 Pharmacological Treatment of Depression 537
Mohammed T. Abou-Saleh and Cornelius Katona
87 Psychotherapy of Depression and Dysthymia 543
Philip Wilkinson
88 Acute Management of Late-Life Depression 552
V. Gardner and D.C. Steffens
89 Bereavement 555
Robert J. Kastenbaum
90 Suicidal Behaviour 559
Brian Draper
91 The Assessment of Depressive Syndromes 565
Adriana P. Hermida and William M. McDonald
92 Mania: Epidemiology and Risk Factors 573
Susan W. Lehmann
93 Acute Mania and Bipolar Affective Disorder 576
M. Sajatovic, N. Herrmann and K.I. Shulman

PART F SCHIZOPHRENIC DISORDERS AND MOOD-INCONGRUENT PARANOID STATES 589

94 Late-Life Psychotic Disorders: Nosology and Classification 591
Nicole M. Lanouette, Lisa T. Eyler and Dilip V. Jeste
95 Schizophrenic Disorder and Mood-Incongruent Paranoid States: Epidemiology and Course 596
Cynthia D. Fields and Peter V. Rabins
96 Clinical Assessment and Differential Diagnosis 599
David N. Anderson
97 Treatment of Late-Life Psychosis 604
Peter Connelly and Neil Prentice

PART G NEUROSES (ANXIETY DISORDERS) 609

98 Nosology and Classification of Neurotic Disorders 611
David Bienenfeld
99 The Epidemiology of Depression and Anxiety 616
Robert Stewart and James Lindesay
100 Psychopharmacological Treatment of Anxiety 624
John L. Beyer
101 Obsessive-Compulsive Disorder 632
James Lindesay
102 Somatoform Disorders and Unexplained Physical Symptoms 636
Bart Sheehan
103 Other Neurotic Disorders 640
Jerome J. Schulte, C. Michael Hendricks and David Bienenfeld

PART H PERSONALITY DISORDERS 647

104 Personality Disorders: Description, Aetiology, and Epidemiology 649
Victor Molinari and Daniel L. Segal

105 Diagnostic and Treatment Issues Regarding Personality Disorder in Older Adults 655
Richard A. Zweig and Dana Scherr Parchi

PART I MENTAL AND BEHAVIOURAL DISORDERS DUE TO PSYCHOACTIVE SUBSTANCES 663

106 Alcohol Abuse and Treatment in the Elderly 665
Helen H. Kyomen and Benjamin Liptzin
107 Epidemiology of Alcohol Problems and Drinking Patterns 671
Celia F. Hybels and Dan G. Blazer
108 Drug Misuse in the Elderly 679
Martin M. Schmidt and Mohammed T. Abou-Saleh

PART J LEARNING AND BEHAVIOURAL STUDIES 687

109 Old Age and Learning Disability 689
Oyepeju Raji and Asim Naeem
110 The Elderly Offender 694
Graeme A. Yorston
111 Sleep and Ageing: Disorders and Management 700
Helen Chiu and Joshua Tsoh
112 Sexual Disorders 706
Walter Pierre Bouman

PART K CULTURAL DIFFERENCES, SERVICE PROVISION AND TRAINING IN OLD AGE PSYCHIATRY 711

113 Assessing Mental Health in Different Cultures 713
Rob Butler, Sati Sembhi and Melanie Abas
114 The Cross-Cultural Epidemiology of Mental Illness in Old Age 717
Martin Prince
115 Mental Illness in the Elderly in South Asia 730
Vikram Patel and K. S. Shaji
116 Dementia and Depression in Africa 734
Olusegun Baiyewu
117 Dementia and Depression in China 737
Helen Chiu and Cindy Tam
118 Spirituality and Mental Illness in Old Age 741
Susan Mary Benbow and David Jolley
119 Development of Health and Social Services in the UK from the Twentieth Century Onwards 745
John P. Wattis
120 The Pattern of Psychogeriatric Services 749
John P. Wattis
121 The Multidisciplinary Team and Day Care Provision 753
Martin Orrell and Kunle Ashaye
122 NHS Continuing Care 759
Clive Ballard, Ramilgan Chitramohan, Zunera Khan and Jean Beh
123 Overview of Law, Ethics and Mental Health in Old Age 766
Julian C. Hughes
124 The US System of Geriatric Mental Health Care: Financing and Future Challenges 770
Stephen J. Bartels
125 Geriatric Psychiatric Outpatient Care: The Private Practice Model in the USA 777
Elliott M. Stein and Gary S. Moak
126 The Medical Psychiatry Inpatient Unit 785
Maria I. Lapid and Teresa A. Rummans
127 Psychiatric Services in Long-Term Care 790
Marc E. Agronin, Stephen M. Scheinthal and Ashok J. Bharucha
128 Geriatric Psychiatry Care in the Private Psychiatric Hospital Setting 796
Brent P. Forester, Robert Kohn, Susan Kim and Thomas Idiculla
129 Liaison with Medical and Surgical Teams 803
David N. Anderson
130 Rehabilitation 810
Rob Jones
131 Anaesthetics and Mental State 817
Andrew Moore Severn and David Gwyn Seymour
132 Nutritional State 824
David N. Anderson and Mohammed T. Abou-Saleh
133 Caregiver Support 829
Kathleen C. Buckwalter, Mary Ellen Stolder, Charlene S. Aaron and Catherine Messinger
134 Elder Abuse – Epidemiology, Recognition and Management 835
Alexander M. Thomson and Martin J. Vernon
135 Care of the Dying 838
Adrian Treloar, Monica Crugel and Waleed Fawzi
136 Prevention of Mental Disorders in Late Life 844
Pim Cuijpers, Filip Smit, Barry D. Lebowitz and Aartjan T. F. Beekman
137 The Principles of UK Mental Health Law: A View from the Clinic 850
Julian C. Hughes
138 Training Requirements for Old Age Psychiatrists in the UK 854
Susan Mary Benbow and Aparna Prasanna
139 Training Requirements in North America 857
Paul D. Kirwin and Kirsten M. Wilkins
140 Education in Old Age Psychiatry: Recent and Future Developments 860
Hugo de Waal

Subject Index 864

Preface

It has been eight years since the second edition of *Principles and Practice of Geriatric Psychiatry* was published. During this time there has been substantial progress in the science and practice of geriatric psychiatry. This third edition attempts to capture these advances and provide an up-to-date summary for trainees and practitioners.

Two of the Editors of the previous editions, John R M Copeland and Dan G Blazer, decided to withdraw and two new Editors (one from the UK and one from the US) have been recruited. We wish first of all to express our grateful thanks to John and Dan for their remarkable stewardship over the production of the two previous editions. We would also like to acknowledge the invaluable contribution of the six Associate Editors in bringing this third edition to completion.

The previous edition received good reviews as well as some helpful criticisms. We therefore decided to maintain the textbook's overall scope, structure, headings, list of contents and international authorship. The majority of the textbook's chapters have been updated by the original authors. We have, however, recruited several new authors who are internationally recognized experts in their fields and commissioned substantial completely new material.

We believe that the value and the strengths of this textbook rest in its comprehensive coverage of the basic and clinical sciences of normal and abnormal ageing, of the full range of psychiatric disorders in the elderly, and of the organization of psychogeriatric services in the UK and the US as well as chapters on prevention, training and education.

We hope that this third edition is well received by its readers and that it proves to be a useful and readable way for them to update their knowledge of the science and practice of geriatric psychiatry.

Mohammed T Abou-Saleh
Cornelius L E Katona
Anand Kumar

Preface to Second Edition

The editors were very gratified that the first edition of this textbook was generally well received and that a second edition has been called for. It is now seven years since the original book appeared, and there have been many more advances in the subject. In spite of new sections and some wholesale rewriting, it has been possible once again, to contain the information in one volume. Very sadly some of our original contributors have died. New authors have replaced them while others have been added in an endeavour to keep the text authoritative and up-to-date. The helpful criticisms of the first edition have been carefully considered in the preparation of this one. Having so many distinguished authors with such a breadth of interest, while greatly enhancing the book, has led to a long gestation period, but we believe that it has been worthwhile. Much of the original format has been retained in order to continue to stimulate lively debate and exchange of views. If the book contributes to the growing strength of Geriatric Psychiatry internationally, it will have done its work.

John R. M. Copeland
Mohammed T. Abou-Saleh
Dan G. Blazer

Preface to First Edition

The discipline of the psychiatry of old age has moved rapidly in recent years and the number of practitioners has expanded worldwide. An authoritative text is required which draws on the knowledge of these experts and which reflects both new scientific advances and innovations in service development.

In a comparatively new subject many of the issues are still contentious and on some of these we have tried to provide the opportunity for the expression of different points of view. Readers are asked to judge the issues for themselves from the evidence set out.

Here and there short, special articles have been commissioned which present research findings in more detail and describe new aspects of care.

They are intended to enliven the text and their choice has been dependent on timing and opportunity.

We have also tried to give a "feel" for what is happening in developing countries and the scope of the problems experienced by local practitioners.

Even a book of this size can never be complete and no doubt gaps in the coverage of subjects will be identified. We would be glad to have them pointed out. The more comprehensive a book aims to be the longer it takes to come to publication and in a fast-moving area of knowledge this can be a problem. Many of our authors have been kind enough to update their contributions at a late stage, which we hope has overcome this difficulty to some extent.

In the early stages of the development of a subject there is insufficient corpus of knowledge to assemble in book form. This situation has changed dramatically for geriatric psychiatry in recent years. We hope that the knowledge gathered here from our distinguished international panel of authors bears this out.

John R. M. Copeland
Mohammed T. Abou-Saleh
Dan G. Blazer

Part A

Historical Background

1

A Conceptual History in the Nineteenth Century

German E. Berrios

Department of Psychiatry, Addenbrooke's Hospital, Cambridge, UK

The history of geriatric psychiatry can be written from two viewpoints. The 'externalist' approach focuses on the social and political variables that have controlled attitudes towards abnormal behaviour in old age, and on the professionalization of those charged with the care of the mentally infirm elderly. The 'internalist' approach – to be followed in this chapter – concentrates on the origin of the scientific language of psychogeriatrics. An adequate historical account should include information on theories of ageing, both physical and mental, brain sclerosis and the formation of a viable concept of mental illness. On the first rubric much research has been done[1–9]; far less work exists on the other two. On psychogeriatric care before the nineteenth century[10,11] there is very little: this may simply reflect a historical reality.

VIEWS ON AGEING BEFORE THE NINETEENTH CENTURY

Like most other aspects of human life, ageing has also been portrayed in terms of metaphors. Classical views, following the nature–nurture controversy, conceived of ageing as resulting from either internal instructions or from the buffeting of foreign factors[4,8].

The 'wear and tear' view happened to be popular during the early nineteenth century, the period on which this chapter will concentrate. It was based, as it had always been, on the ageless observation that all natural objects, whether animate or not, are subject to the ravages of time. Surprisingly enough, the 'wear and tear' view has not always generated an understanding attitude. In fact, across times and cultures great ambiguity has existed in regard to the treatment of old folk. Fortunately, a realistic acceptance seems to have predominated although there is plenty of evidence of hostility. The Hebrew tradition, and indeed its Christian offshoot, encouraged much reverence towards the wisdom and value of old age. But even in societies that have made great play of this view, veneration has been reserved for those in positions of power or influence[12]. Little is known about attitudes towards elderly women or old men in humbler stations[11].

So, it can be concluded that, all in all, a view seems to have predominated that ageing was undesirable and that the identification of wear factors was important to devising ways of prolonging life[5,13].

A second ambiguity can be detected in these earlier writings. It concerns the extent to which the ageing process necessarily involves the human mind. While it was a palpable fact that all human frames decayed, not everyone accepted that this had necessarily to affect the soul or mind. Extant descriptions of the psychological changes brought about by old age suggest that people were aware that the mind also underwent a decline. However, theory and religion encouraged the view that the spirit could or did escape wear and tear, and that human beings grew ever more wise and useful, thanks to the accumulation of experience and knowledge. This belief must have been available in all those societies that felt the need to create adequate spaces for all manner of intellectual and/or sociopolitical gerontocracies[2]. Some seem even to have separated chronological age and functional age in order to justify such concessions. From the point of view of the history of psychogeriatrics, it would be useful to know to what extent this belief was undermined by the occasional case of dementia among those elderly in positions of power[1]. Historical evidence seems to show that these situations were neither more nor less perturbing than mental illness occurring at other periods of life. Indeed, fail-safe devices seem to have been available in these societies to cope with the upheavals created by such occurrences.

Men like Buffon, Darwin and Goethe reshaped ideas on ageing during the eighteenth century. Buffon[14] wrote: 'All changes and dies in Nature. As soon as it reaches its point of perfection it begins to decay. At first this is subtle and it takes years for one to realise that major changes have in fact taken place' (p. 106). Buffon put this down to an 'ossification' process similar to that affecting trees: 'this cause of death is common to animals and vegetables. Oaks die as their core becomes so hard that they can no longer feed. They trap humidity, and this eventually makes them rot away' (p. 111).

Erasmus Darwin's views resulted from the application of yet another metaphor, namely that ageing results from a breakdown of 'communication' between man and his environment[15]. Darwin suggested that such breakdown followed a loss of irritability (a property of nerve fibres) and a decreased response to sensation:

> It seems our bodies by long habit cease to obey the stimulus of the aliment, which support us . . . three causes may conspire to render our nerves less excitable: 1. If a stimulus be greater than natural, it produces too great an exertion of the stimulated organ, and in consequence exhausts the spirit of animation; and the moving organ ceases to act, even though the stimulus is continued. 2. If excitations weaker than natural be applied, so as not to excite the organ into action, they may be gradually increased, without exciting the organ into action, which will thus acquire a habit of disobedience to the stimulus. 3. When irritative motions continue to be produced in consequence of stimulus, but are not succeeded by sensation. (p. 365)

VIEWS ON AGEING DURING THE NINETEENTH CENTURY

In 1807 Sir John Sinclair[16] published a major compendium on ageing and longevity, which included references to most pre-nineteenth century sources. It was, in a way, the last grand glance to the past. Soon afterwards work started by those who, like Léon Rostan (1791–1866), based their claims on empirical findings. Rostan, one of the most original members of the Paris school, published in 1819 his *Recherches sur le Ramollissement du Cerveau*[17], where the view commenced that vascular disorders might be as important as parenchymal ones in brain ageing. Even more important was his uncompromising anti-vitalistic position enshrined in the claim that all diseases were related to pathological changes in specific organs[18,19].

During the 1850s Reveillé-Parise[3] saw his task as writing on 'the history of ageing, that is, mapping the imprint of time on the human body, whether on its organs or on its spiritual essence' (p. v). In regard to ageing itself he wrote: 'the cause of ageing is a gradual increase in the work of decomposition ... but how does it happen? What are the laws that control the degradation that affects the organization and mind of man?' (p. 13). Reveillé-Parise dismissed the toxic view defended by the Italian writer Michel Lévy[20] according to which there was a gradual accumulation of calcium phosphates that led to petrification, to an 'anticipation of the grave'. This view, he stated, had no empirical foundation and was based on a generalization from localized findings. Reveillé-Parise supported the view that ageing results from a negative balance between composition and elimination, which equally affected the cardiovascular, respiratory and reproductive organs.

Finally, the views should be mentioned of J. M. Charcot, who in 1868 offered a series of 24 lectures on the diseases affecting the elderly[21]. Charcot dedicated Lecture 1 to the 'general characters of senile pathology'; he started by saying that all books on geriatrics up to his time had 'a particularly literary or philosophical turn [and had been] more or less ingenious paraphrases of the famous treatise De Senectute' (p. 25). He praised Rostan for his views on asthma and brain softening in the elderly, and predictably also mentioned Cruveilhier, Hourman and Dechambre, Durand-Fardel and Prus. He criticized Canstatt and other German physicians because in their work, 'imagination holds an immense place at the expense of impartial and positive observation' (p. 26). Charcot's own contribution was based on the general principle that 'changes of texture impressed on the organism by old age sometimes become so marked, that the physiological and pathological states seem to merge into one another by insensible transitions, and cannot be clearly distinguished' (p. 27).

THE DEVELOPMENT OF THE NOTION OF BRAIN SCLEROSIS

When in 1833 Lobstein[22] described the basic pathology of arteriosclerosis, he did not imagine that it would, during the second half of the century, become the mechanism of 'senility' par excellence[14,23,24]. Motor and sensory deficits, vertigo, delusions, hallucinations and volitional, cognitive and affective disorder were all attributed to the effect of arteriosclerosis[25,26]. They related to the brain via a two-stage speculative pathophysiology: parenchymal and/or vascular disorders could affect the brain, and the distribution of the lesions could be diffused or focal. Vascular changes included acute ischaemia (on which clinical observation was adequate)[27,28] and chronic ischaemia, invented as a separate syndrome by extrapolating from the symptoms and signs observed during the acute states[24]. The role of arteriosclerosis as a causal and prognostic factor in relation to the involutional psychoses was challenged early in the twentieth century[29] but this paper remained unnoticed. Hence, some of the old notions, such as that of 'arteriosclerotic dementia', remained active well into the 1960s[30].

Alienists during the same period, however, were already able to distinguish between states where a putative chronic and diffuse reduction in blood supply had taken place from focalized damage, i.e. what they called 'multifocal arteriosclerotic dementia' and was equivalent to what is currently called multi-infarct dementia[24,31,32].

NINETEENTH CENTURY VIEWS ON MENTAL DECAY IN THE ELDERLY

It is against this background that the history of the language and concepts dedicated to understanding mental disorders in the elderly must be understood. In addition to these neurobiological frameworks, a psychological theory that explained the manner of the decline was required. Such a psychopathology was provided by the heuristic combination of associationism, faculty psychology[33], and statistics[34] that characterized the early and middle parts of the nineteenth century.

Yet another perspective, originating in clinical observation, was added during the 1830s. It led to the realization that, in addition to the well-known forms of mental disorder, the elderly might exhibit specific forms of deterioration, and that these could be related to recognizable brain changes. There is only space in this chapter to deal with two examples: one typifying a 'specific' disorder of old age, namely the history of chronic cognitive failure or dementia; the other illustrating the effect of a general mental disorder (melancholia) on the elderly.

THE FORMATION OF THE CONCEPT OF SENILE DEMENTIA

The history of the word and concept of dementia before the nineteenth century has been touched upon elsewhere[35]. Suffice it to say here that, at the beginning of the nineteenth century, 'dementia' had a 'legal' and a 'medical' meaning and referred to most acquired states of intellectual dysfunction that resulted in serious psychosocial incompetence. Neither age of acquisition nor reversibility was part of its definition. These two dimensions were only incorporated during the nineteenth century and completely changed the semantic territory of the dementia concept.

Anecdotal observation of cases of senile dementia abound both in the fictional literature and in historical documents[36], but the concept of 'senile dementia', as it is currently understood, only took shape during the latter part of the nineteenth century. Indeed, it could not have been otherwise, as the neurobiological and clinical language that made it possible only became available during this period[37,38]. But even after the nosological status of senile dementia had become clearer, there were many who, like Rauzier[39], felt able to state: 'it may appear either as a primary state or follow most of the mental disorders affecting the elderly' (p. 615). Following Rogues de Fursac[40], Adrien Pic – the author of one of the most influential geriatric manuals during this period[41] – defined senile dementia as: 'a state of intellectual decline, whether or not accompanied by delusions, that results from brain lesions associated with ageing' (pp. 364–365). It was against this background that the concept of Alzheimer's disease,

which became the prototype for all senile dementias, was created during the first decade of the twentieth century[37]. Recent work has shown that its 'discovery' was controlled by ideological forces well beyond what could be described as 'scientific'[37,42]. These forces also introduced unwarranted clinical strictures, such as the exclusion of non-cognitive symptoms[43,44] and false age boundaries, which took many years to disappear.

THE FORMATION OF THE CONCEPT OF INVOLUTIONAL MELANCHOLIA

The concept of 'senile or involutional psychoses', which featured so prominently in Kraepelin's early classification, included presenile delusional insanity, senile dementia, late catatonia and involutional melancholia[45,46]. The reasons that led Kraepelin to separate this group were mostly theoretical, to wit, that they appeared during a period of life when 'sclerotic' changes were beginning to occur; the same factor accounted for their bad prognosis[46].

The general history of melancholia and depression has been analysed elsewhere[47–49]. Suffice it to say here that by the 1860s depression was considered to be an independent syndrome resulting from a primary disorder of affect. This meant that hallucinations, delusions and cognitive impairment were secondary to the pathological feelings. This conviction was particularly strong towards the end of the century, when emotional mechanisms became popular in the explanation of most forms of mental disorder[50]. By the end of the century the metaphor of depression as a form of 'reduction' or 'loss' had become firmly established. No better example can be found than the fact that up to 1893 (fourth edition) Kraepelin felt obliged to classify all forms of agitated depression as mania![51]

KRAEPELIN AND INVOLUTIONAL MELANCHOLIA

Much of the current confusion on the meaning of involutional melancholia can be explained if attention is given to the circumstances of its historical development (for a full analysis of this process and list of references, see Berrios[52]). The conventional story[53–56] is that up to the seventh edition of his textbook Kraepelin considered involutional melancholia as a separate disease, and that when confronted by the evidence collected by Dreyfus[57], he decided to include it, in the eighth edition, under the general heading of manic depressive insanity. Indeed, this account was first offered by Kraepelin himself (see Dreyfus, p. 169).

The story is, however, more complex and it is unlikely that the findings of Dreyfus alone caused Kraepelin's change of heart. For example, Thalbitzer[58] claimed that his own work had also been influential (p. 41). In the eighth edition Kraepelin abandoned not only involutional melancholia but the entire group of 'senile psychoses'. A recent statistical analysis of Dreyfus's old series has also shown that his conclusion that the natural history of involutional melancholia was no different from that of depression affecting younger subjects was wrong[51].

CONCLUSIONS

This short chapter, providing a historical vignette on the origin of the language of old age psychiatry, suggests that it was born during the nineteenth century from three conceptual sources: theories of ageing, neurobiological hypotheses concerning brain sclerosis, and the realization that specific forms of mental disorder might affect the elderly. Two clinical illustrations were provided, one pertaining to the origins of the concept of senile dementia, and the other to the notion of involutional melancholia.

The Development of Old Age Psychiatry in the UK

Claire Hilton[1] and Tom Arie[2]

[1]*Central and North West London NHS Foundation Trust, Harrow, UK*
[2]*University of Nottingham, Ageing and Disability Research Unit, Nottingham, UK*

Old age psychiatry in Britain was born in the 1960s and 1970s, and came of age at its recognition by the government as a distinct specialty in 1989.[i] Yet the need for it had been recognized as far back as the 1940s. Why was the gestation so long, and how has it developed in the last twenty years since its recognition? What can we learn from this history?

THE EARLIEST DAYS

The likelihood that older people would become major users of psychiatric services was identified during the Second World War. Increasing longevity meant there were more, and even older, old people. Falling birth rates increased the proportion of old people and since more women were in employment it was harder for them to take on traditional caring roles. Some of the more frail older people were cared for in 'chronic sick' and mental hospitals, which might be needed for war casualties.

Until the 1940s mental and physical ill health in old age had been considered largely irremediable. In the 1940s Marjory Warren, the pioneering geriatrician, demonstrated the scope for rehabilitating old people[1], psychiatrist Felix Post wrote on psychiatric differential diagnosis and multidisciplinary approaches to treatment[2], and Willi Mayer-Gross described how severely depressed old people could improve with electroconvulsive therapy (ECT)[3ii]. Despite the evidence of successful treatment, older people were not given priority in health policy. In 1942 the Beveridge Report laid the foundations of the 'welfare state' and a National Health Service (NHS). However, it stated, 'It is dangerous to be in any way lavish to old age, until adequate provision has been assured for all other vital needs'[4].

After the war, at the instigation of Professor Aubrey Lewis, a psychiatric 'geriatric unit' was opened at the Bethlem Hospital in South London, part of the Bethlem-Maudsley postgraduate psychiatric teaching hospital (see Chapter 03). This unit was for functionally ill patients regarded as treatable. Patients with dementia, especially those requiring long stay care, were excluded, in part because of opposition from academic psychiatrists who did not see their care as being worthy of study and investigation.

We shall touch on matters relating to these early influences, since all run throughout the development of the specialty. In addition, each generation rediscovers the demography of ageing as if it were a new phenomenon. Yet unlike, say, trends in fertility, or in transportation, which cannot be predicted with certainty, we always know the size of prospective populations of older people and the epidemiology of the crucial illnesses[5]. Repeatedly, the government has laid plans and failed adequately to implement or fund them, and then has 'discovered' afresh the scale of need. In 1950 we hear, 'It is recognised that the present conditions of financial stringency limit opportunities for action at this time'[6]. In 2001, a national service 'framework' for older people had no allocated new funding for mental health[7], whereas a parallel framework for mental health for younger people was substantially funded[8].

Another initiative in 2007 to improve access to psychological therapies has followed an economic model and has been targeted towards getting unemployed younger people into work, although this may well be changing to become more inclusive across all ages[9]. A contrast exists even within Britain: since 2002, Scotland provides both free personal and nursing care, if deemed appropriate after assessment, while England and Wales do not.

WORKING WITH GERIATRICIANS

Working with geriatricians is crucial in view of the multiple and interlinked disorders of old people, yet at times this has been erratic. Although active treatment, both physical and mental, was being advocated by the 1940s, geriatrics developed much earlier than psychogeriatrics. This was in part because many early geriatricians saw themselves as holistic practitioners for older people, therefore requesting little psychiatric assistance. The advocacy of Lord Amulree, a civil servant and geriatrician, and the other founders of geriatrics drew the successes of rehabilitation, including emptying hospital beds, to the attention of the government[10]. Such a phenomenon did not occur in old age psychiatry until around 1970 when new local services, such as that established at Goodmayes Hospital in 1969[11], were drawn to the attention of the Department of Health and Social Security[12]: only then it was recognized that a modern approach could reduce bed occupancy, improve outcomes and save money. Until the 1970s old age psychiatry in the UK was

[i]Originally called 'psychogeriatrics', 'old age psychiatry' is now more commonly used. However, the former is retained in some contexts, e.g. journal titles such as *International Psychogeriatrics*. The Royal College of Psychiatrists has a Faculty of the Psychiatry of Old Age, while many clinical departments refer to themselves as 'Mental Health Services' for older people or older adults.
[ii]Before antidepressants, ECT was the only effective physical treatment.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

characterized by research in clinical treatment, nosology, pathology and epidemiology, with only small pockets of local service innovation.

In 1970 there were 200 geriatric medicine consultants[13] but only a handful of psychogeriatricians[14,15]. By 2006 there were 700 psychogeriatricians[16]. Where enthusiastic geriatricians and psychiatrists existed in a particular locality they collaborated. In addition, collaboration between the Royal College of Psychiatrists and the British Geriatrics Society[17] since the 1970s has led to the development of guidelines for good practice and working collaboratively[18]. Moving services away from isolated mental and 'chronic sick' hospitals and their coming together in district general hospitals has given better access to each other's services. Sometimes this facilitated joint working, but formal joint services were rare. In 1977, a department of Health Care of the Elderly, comprising both medicine and psychiatry working together, along with other relevant disciplines and professions was set up in Nottingham. There was an orthopaedic-geriatric unit, a stroke unit and a continence service, and joint research, along with extensive teaching of medical students and postgraduate trainees of relevant disciplines, and of overseas workers[19–21].

'Memory clinics' are another development, now widespread, with their roots in both psychogeriatric and geriatric practice in the mid-1980s[22]. More recent developments include psychiatric liaison services for patients with acute physical illness in district general hospitals[23]. Jointly run 'intermediate care' or 'convalescent' rehabilitation units for confused older people, especially those recovering from both delirium and physical illness, are also new. Geriatricians and psychiatrists still have much to learn from each other, and 'seamless' services remain the ideal. 'Guidelines for collaboration' have recently been updated[24].

WORKING WITH PSYCHIATRISTS CARING FOR YOUNGER PEOPLE

Before the establishment of the specialty, mentally ill old people requiring secondary care were the responsibility of general psychiatrists, but they rarely showed interest in actually working with them, especially those with dementia. However, some of the pioneering psychogeriatric services, such as Sam Robinson's in Dumfries (1958)[25], or Brice Pitt's at Claybury, Essex (1966)[26], emerged in part due to the far sightedness and encouragement of general psychiatrists who were medical superintendents of mental hospitals. Despite such early developments, it took until 1989 for the Royal College of Psychiatrists and the government to agree officially to the creation of the new specialty of old age psychiatry. Until then, lack of recognition meant that it had often been impossible to extract from official statistics adequate data on older people's use of services, and hence to establish the scale of need for services and for training.

Competition for resources is inevitable, so long as resources are limited. The low status of the aged, the perceived needs of people of working age, and the common misperception that young severely mentally ill people are frequently dangerous have generally resulted in funding for services for younger people disproportionately exceeding that for older people.

A CENTRAL BODY FOR COORDINATING DEVELOPMENT

A powerful national focus for securing improved recognition and better resources has been the flourishing Faculty of the Psychiatry of Old Age at the Royal College of Psychiatrists (since 1988), and its predecessor bodies (from 1973). It has, among other things, encouraged research, innovation, multidisciplinary working, and links with voluntary and statutory organizations and with the government, and has taken an interest in architecture and design for elderly confused people[27]. A first series of newsletters in the 1980s served as a constructive means of communication among clinicians. A second series since 1996, available online since 2000 (www.rcpsych.ac.uk/college/faculties/oldage/newsletter.aspx), often expresses thoughtful comment related to current clinical and policy dilemmas. Faculty meetings have remained a source of debate, education, inspiration and problem solving. The Faculty's website is a mine of information (www.rcpsych.ac.uk/college/faculties/oldage.aspx).

RESEARCH AND ACADEMIC DEVELOPMENT

Research on older people's mental health has flourished and has helped the development of evidence-based practice. Sir Martin Roth in the 1950s defined the major diagnostic categories in older people[28], rather as Emil Kraepelin had done 50 years earlier for younger people. Felix Post undertook follow-up studies of treatment of depression and psychotic disorders. Nick Corsellis[29] followed by Bernard Tomlinson, Martin Roth[30] and Elaine and Robert Perry unpicked the neurochemical and neuropathological features of Alzheimer's disease[31]. Early research by Raymond Levy into lecithin and later tacrine was a forerunner of today's evidence-based antidementia drugs[32].

Difficulty in obtaining funding for research has been characteristic[15]. But the growth of the neurosciences, along with the influence of bodies such as the Alzheimer's Society, has enhanced the scale of funding for research into the dementias, and has attracted able workers.

Research has also grown through the development of academic departments of old age psychiatry. The first old age psychiatrist to be appointed professor became head of the joint department of Health Care of the Elderly in Nottingham in 1977. The first professor of old age psychiatry, at Guy's Hospital, London, was appointed in 1983. The *International Journal of Geriatric Psychiatry* was started in 1986. In 1989 there were half a dozen professorial departments[33]; now most medical schools have an academic presence for old age psychiatry, and many NHS consultants are involved in teaching medical students and postgraduates. Many other departments in universities are now conducting relevant research, and there are further thriving journals.

TEACHING AND TRAINING

Biographical information reveals that many colleagues did not envisage becoming old age psychiatrists, but were *inspired* by others to do so; they saw and experienced what could be done to help old people. Such effective teaching is crucial[15].

Sharing our knowledge with other specialties and disciplines can change the way colleagues respond to elderly mentally ill people – in primary care, in management, in palliative care, social services, learning disability services, voluntary organizations, Citizens Advice Bureaux, and within the multidisciplinary teams within which we work. Other groups that have sought teaching include architects, designers, lawyers and the police.

Structured training for old age psychiatrists has also evolved over the years. The earliest psychogeriatricians in the 1960s and 1970s had little or no specific training. Six months' experience in old age psychiatry is considered valuable for trainees in psychiatry and in

general practice. Specialized training for career old age psychiatrists is during the last three years of a six-year psychiatry training scheme. There is a competency-based curriculum[34], and at least two years (full-time equivalent) old age psychiatry in recognized training posts are usually required.

CLINICAL INNOVATION

The demise of the vast Victorian mental hospitals, the coming of community care, more liberal mental health legislation and new effective psychopharmacology have all helped to shape the progress of psychiatry since the 1950s. The psychogeriatricians have consistently fought to prevent older people being left behind younger people in new developments. Important classic texts of innovation in old age psychiatry such as *In the Service of Old Age* by Tony Whitehead (1971)[35] deserve particular mention, as do the reports in the 1960s and 1970s of abuses in the unfashionable sectors of care. The Ely Hospital Report (1969)[36] was also instrumental in bringing about the Hospital (later Health) Advisory Service (HAS), which advised on the neglected areas of the health service. The HAS was a valuable ally of the early old age psychiatrists, encouraging and spreading good practice. Its first director became an old age psychiatrist upon demitting office[37].

Home assessment and support by consultants and other team members was the norm: in some services this is still the usual first point of contact. Initial assessment at home was introduced in the 1960s, in order to evaluate, in the light of knowledge of the home setting, who could be helped without hospital admission, or who might need a medical or a surgical bed rather than psychiatric help. Often the entire management of the patient could be undertaken in the patient's home. Home assessment and treatment is valued by patients, carers and staff, and it helps to build a close working relationship with the local community, and is popular with medical students.

The importance of support for carers of people with dementia has long been recognized. Respite admissions[38], social services day care, help with personal care at home and the Admiral Nurse service established in 1994 (www.fordementia.org.uk/admiral.htm) are important in delivering such support.

Psychotherapy, including family therapy with old people and their adult children, dates from the 1960s[39] but is still not widespread, despite pockets of enthusiasm[40]. In a very few places psychiatric intensive care units, in particular providing care for elderly men with dementia and disruptive behaviours, have evolved, such older people being excluded from similar services for younger people[41]. Elsewhere, intensive home treatment teams are appearing for even those with severe mental illness such as would traditionally require admission.

Old age psychiatry day hospitals date from the 1950s onwards. They were often a substitute for long stay care for people with chronic mental illness living at home or with their family. More recently they have developed to offer assessment, treatment, rehabilitation and support such as might be beyond the capacity of a social care day centre. They enable some with particularly disruptive behaviours unmanageable by a social care day centre to remain in the community[42].

More recently as 'ethnic minority' populations have aged, understanding cultural and religious customs and attitudes to mental illness and ageing has become important in many local communities.

Other disciplines have developed in parallel to old age psychiatry. The British Psychological Society, for example, established a special interest group for psychologists working with older people in 1980 (www.psige.org/index.php).

Without evaluated creativity, we would not have the rich array of services that, despite constraints of limited funding, serve our patients, their relatives and carers. But by no means every service for older people yet has all the components described above (see Table 2.1).

Table 2.1 Core features of a service in 2009

Core features are likely to include:
Community: assessment, diagnosis, treatment, rehabilitation
Inpatients: acute assessment and continuing care
Day hospital
Memory service
Support for carers
Liaison service to geriatric, medical and surgical wards
Other:
planning
teaching
research
liaison with related professions and organizations
advocacy for patients
advice on medico-legal matters, e.g. mental capacity

LONG STAY CARE

Up to the 1980s, most long stay care for dementia, along with that of aged people with chronic psychosis, took place in hospitals. Local authority residential homes were intended to care for frail old people, but with the passage of time they too increasingly became facilities for demented people, but lacking nursing skills and facilities appropriate to their residents' needs. During the Thatcher era of the 1980s, long stay care in hospitals was replaced by care in commercial, or, less often, charitable homes. Surveillance of standards in multiple dispersed units became very difficult. Third party inspection and definition of 'minimum standards' was instituted by the Blair government[43]. Education and training of care home staff, long virtually absent, is now becoming more prevalent. But 'scandals' in the care of old people continue, and although they often achieve publicity, they generally evoke less indignation and less remedial action than similar scandals in child care. Fortunately, architects and designers often now devote special skills to the needs of old people.

THE FUTURE

Old age psychiatrists, like workers in other health specialties, practise within the context of the structure and culture of society. At the time of writing we enter a recession, with uncertainty about the future, but with ever more evidence of the effectiveness of our interventions.

There are more government initiatives. The *National Dementia Strategy*, emphasizes raising awareness, early diagnosis and intervention, and improving quality of care in dementia, and is welcome on that account. However, the government's initial financial backing for the strategy amounts to less than 1% of the total annual cost of dementia care. It is hard to believe that this will make any significant impact. In addition it states, 'Decisions on funding for subsequent years will only be made once we have had the opportunity to consider

the results from the initial demonstrator sites and evaluation work. There is no expectation therefore that all areas will necessarily be able to implement the Strategy within five years'[44]. This resonates with previous policies advocating good practice, which are neither mandatory nor adequately funded.

A new Mental Capacity Act seeks to provide a statutory framework to protect vulnerable people who are not able to make their own decisions[45]. There is also new legislation relating to 'deprivation of liberty', significantly affecting people with dementia who lack capacity to decide on their place of care, to determine whether and how they can be confined to a care home or hospital in their best interests. The new Equality Bill should prevent discrimination in services on the basis of chronological age[46]. However, it also carries the paradoxical risk that a separate service for old people may be regarded as discriminatory. Challenges to our special services have long arisen from this viewpoint, and we must continue to show that special services for an inherently low status and thus usually neglected group make for better care, and to point to the reasons why.

Legal and medical changes, and changes in society, will raise new questions, but the 1970s adage for an old age psychiatrist will continue to be 'occasional militancy . . . to gain for the elderly a fair share of scant resources, to put them to best use, to make do with too little while wheeling, dealing, and fighting for more'[47].

Commentary on 'In the Beginning' by Felix Post

Claire Hilton

Central and North West London NHS Foundation Trust, Harrow, UK

INTRODUCTION

Felix Post was probably the first dedicated old-age psychiatrist anywhere in the world. 'In the Beginning' is his autobiographical account of the earliest days of old-age psychiatry in Britain. Such accounts are valuable primary sources for understanding the development of the specialty. We are now reaching a point in time when our earliest pioneers like Felix Post (1913–2001) and Martin Roth (1917–2006) have died. It is important that we remember the contributions of our teachers from the past who have set the foundations for our specialty, just as Phillipe Pinel, Emil Kraepelin, Sigmund Freud and many others are celebrated for their contributions to the mental well-being of mainly younger people.

This short chapter by Felix Post has been described as 'pure Felix'. It characteristically reveals his humility and modesty, and his praise of others, attributing little achievement to himself. A brief biographical note and commentary are therefore warranted to set it in context.

'IN THE BEGINNING' BY THE LATE FELIX POST

In 1943, after a year's early training as one of the war-time refugees of the Maudsley Hospital, Professor Aubrey Lewis passed me on to Professor D.K. Henderson and the Royal Edinburgh Hospital for Nervous and Mental Diseases, where I initially worked in the private department. During one of his rounds, Henderson said to me: 'Post, do you see all these old people here? Why don't you write 'em up?' This I obediently did, and my article appeared in the *Journal of Mental Science*[i]. The article started by demonstrating that the admission rate of patients over 60 to the Royal Edinburgh Hospital had risen between 1901 and 1941 more steeply than the proportion of this age group in the Scottish population. Interestingly, at this early date, I had found no difficulties in the differential diagnosis of my colleagues' and my own patients. There were 22 senile, arteriosclerotic and presenile dementia patients, 20 manic–depressive patients, 25 patients suffering from involutional or senile melancholia and 51 patients with schizophrenia. Assuming that the functional psychoses were the concern of general psychiatry, the rest of the paper dealt with the dementias and with an attempt to link the type associated with delusions and hallucinations to earlier personality characteristics. I noted that a high proportion of dementia admissions had been precipitated by terminal confusional states, and that of 111 patients admitted over the preceding four years with organic psychoses, only 23 were still occupying beds. I made the false prediction that in the future the main burden of the hospital services would be represented by the chronicity and survival of melancholic and paranoid patients. I did not anticipate that electroconvulsive therapy (ECT) and antidepressive drugs, while producing lasting recoveries in only 25% of cases, would make at least temporary discharge from inpatient care possible in most cases.

Aubrey Lewis was more farsighted. He had published, with a psychiatric social worker[ii] a paper describing the psychiatric and social features of the patients in the Tooting Bec Hospital for Senile Dementia, London, UK, and in 1946 predicted, in the *Journal of Mental Science*[iii] that ageing and senility would become a major problem of psychiatry.

After army service, I consulted Lewis about possible positions and he recommended me for the post of assistant physician at the Maudsley Hospital. I flattered myself that in me Lewis had seen a future brilliant psychiatrist, but was soon to be disillusioned. Even before the Bethlem Royal and Maudsley Hospitals were united in 1948, Lewis had conceived the idea of using some of the Bethlem beds to establish a unit for patients over the age of 60. After a heated discussion with the Bethlem matron, Lewis obtained agreement for the admission of senile patients to a hospital which, like the Maudsley, had previously admitted only patients thought to be recoverable. Uncovering his batteries, he asked me to take on the development of this Geriatric Unit. Once again, I obeyed (to say without enthusiasm would be an understatement) and, right up to my retirement, I continued also to run a unit and outpatient clinic for younger adults.

A report in the *Bethlem Maudsley Gazette*[iv] demonstrated that both the Bethlem staff and I had 'caught fire'. The article started with a tribute to Professor Aubrey Lewis and his almost revolutionary idea of including experience in geriatric psychiatry within postgraduate training. The article went on to describe how patients over 60 had gradually infiltrated the Bethlem wards to emerge as a unit for 26 women and 20 men. The two wards were staffed by the same number of senior and junior nurses as the other adult wards, with two trainee psychiatrists changing every six months to other departments. There was one psychiatric social worker, later usually assisted by a trainee. The occupational therapy department had collaborated with the nursing staff to devise and carry out a daily occupational programme as well as socializing activities. The psychiatric social worker ran a weekly afternoon of handicrafts, tea and talk near the Maudsley, where throughout my tenure I conducted a weekly follow-up and

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

supportive clinic. The first year during which the unit had been in full swing was 1952, and it was recorded that during that year there had been 3.00 admissions to each geriatric bed compared to 3.74 admissions to each general psychiatric place. Patients who had been dementing, but whose home care was no longer possible had been excluded from admission, though not rigidly, as well as patients with recurring illnesses that had been adequately treated at the Bethlem-Maudsley or other hospitals. Of 133 patients, nine died, only four had to be transferred to their regional mental hospitals, seven were resettled in homes for the elderly, while 113 could be returned to family care. One year after discharge, information was successfully obtained about 121 of 124 cases. Seven patients had died, including one suicide of a woman who had discharged herself. Thirty ex-patients had to be readmitted to our or other hospitals, 35 were still outside hospital but by no means symptom-free, but 45 patients would be classified as recovered. These relatively favourable results were due to 89 patients having suffered from affective illnesses: 24 had symptoms associated with brain damage, 10 were mainly paranoid and 10 were regarded as having psychoneurosis. In spite of 4–6 weeks of conservative management 52 patients had to be given ECT. I concluded the article by pointing to research needs and by opining that with 30–40% of patients admitted to British mental hospitals being over the age of 60, training in the special problems of this age group was essential for all entrants to general psychiatry.

The history of the beginning would be incomplete without a brief account of further developments. My little textbook (rightly out of print) and publications on the long-term outcome of affective, paraphrenic and schizo-affective illnesses were largely my own work, but many of the junior psychiatrists made contributions and they and clinical psychologists, as well as social workers, instigated their own researches. Many later made a name for themselves, and some became leading psychogeriatricians. Among them were Tom Arie, the late L.K. Hemsi, David Jolley, Robin Jacoby, David Kay, Kenneth Shulman and, last but certainly not least, Raymond Levy. After the Bethlem-Maudsley had accepted a district commitment and the admission of involuntary (sectioned) patients, Raymond Levy and my successor, Klaus Bergmann (not a Bethlem trainee), managed to move the Geriatric Unit to the Maudsley, so much closer to the patients' family homes. Raymond Levy succeeded in establishing an Academic Department of Old Age Psychiatry, which has continued to conduct research into the dementias of late life, that most important subject, previously neglected on account of admission restrictions before the hospital abandoned its ivory tower to accept a district commitment. With similar developments elsewhere, psychogeriatrics became a world movement, and Sir Aubrey Lewis would be pleased.

COMMENTARY

Felix was a refugee from Nazi Germany[1]. He enrolled at St Bartholomew's Hospital in 1934, qualifying in 1939. He entered medicine in an era when it was widely assumed that older mentally ill people were 'senile' and therefore nothing could be done for them.

Felix refers to his 1944 paper[2]. He commented on his 'false prediction' for older people requiring long-stay care in hospital, that those with chronic functional illnesses would numerically exceed those with organic illnesses. However, he did not emphasize the real significance of his paper, his observations that 'Old age alone does not produce mental illness', that appropriate diagnoses can be made, and that a multidisciplinary approach is important in treating older people. The possibility of differential diagnosis from a hopeless mass of mental symptoms in old age was not widely recognized until Martin Roth's classic paper in 1955[3]. Felix was a decade ahead. His conclusions were radical. Felix's paper caught the attention of Professor Aubrey Lewis (1900–1975); he referred to it in his own landmark paper[4]; they shared a common, new and challenging belief that something *could* be done to treat elderly mentally ill people.

Lewis had three contemporaries writing constructively on mental illness in older people. Two were relatively senior refugee psychiatrists: Willi Mayer-Gross[5] and Erwin Stengel[6]. The third, Felix, was earmarked by Lewis for a clinical role with older people. However, Felix had no intentions of becoming a psychiatrist, let alone one working with older people. But he was aware that refugee doctors were having difficulty in securing senior appointments, especially in traditional elitist teaching hospitals. Lewis offered him a post in 1947 at the Maudsley Hospital, London, a psychiatric teaching hospital. Henceforth, he regarded himself as owing Lewis a huge debt, and thus when Lewis asked him to be consultant on the new Geriatric Unit he could not refuse. Felix's ambivalence to working there stemmed from the prevailing belief that nothing could be done therapeutically to help the old and mentally ill[7], despite his own published work.

Lewis's objective was to make the Bethlem-Maudsley Hospital a great centre of postgraduate psychiatric teaching and research, of which mental illness of older people would be part[8]. Once established, the Geriatric Unit for functionally ill old people was sufficient for the teaching purposes envisaged by Lewis. With this objective fulfilled, Lewis and his colleagues offered Felix no further support for developing additional services for older people. 'In the Beginning' rightly attributes the founding of the Geriatric Unit to Lewis, but it would be inaccurate to attribute any further developments to him. The rest should be Felix's accolade.

Felix also modestly reported the outcome of treatment of his first inpatients in 1952 as 'relatively favourable'[9]. However, his results could perhaps better be described as 'spectacular'. This is for two reasons. First, at that time most mentally ill old people requiring mental hospital admission would have been admitted to long-stay wards without any assessment, let alone treatment, for their apparent all encompassing label of 'senility'. The expectation of any recovery was extremely low. Second, the only effective therapeutic tools were electroconvulsive therapy (ECT) and psychotherapeutic approaches; antidepressants, antipsychotics and mood stabilizers were yet to be introduced. Sadly, however, this outcome study was published in a journal with only a small circulation; had it been published in a more widely read journal it might have had a greater impact. For Felix himself, however, such results began to produce a sense of 'therapeutic optimism'[10].

Felix also referred to 'my little textbook (rightly out of print)'. This is a valid statement, but fails to reflect on the importance of the 'little textbook', *The Clinical Psychiatry of Late Life*[11]. It was the first book of its kind to emphasize an evidence-based approach to actively treating older mentally ill people. Highly readable, its philosophy remains at the foundations of good clinical practice today. It ends with the words:

> Sometimes, we may effect cures; frequently, we may be able to ameliorate the patient's condition; we shall always endeavour to give him and his family sympathetic support . . . *Quelquefois guérir; soulager souvent; consoler toujours*.

Why, one may ask, did so many of Felix's junior doctors go on to become leading psychogeriatricians? It was not chance, but likely to be related to his inspiring and enthusiastic teaching. Felix's personal career experience, moving from ambivalence to optimism to conveying his enthusiasm to others raises another contemporary lesson: we need to engage our medical students and junior staff and let them experience what can be done in order that they may carry with them the knowledge and ideals of the specialty, and possibly enter the field themselves. Felix's widespread influence lay largely in his clinical acumen, his meticulousness, his wisdom and his teaching skills[12].

Felix's autobiographical sketch ends with the words 'psychogeriatrics became a world movement, and Sir Aubrey Lewis would be pleased'. Lewis would undoubtedly have revelled in such lasting recognition, and hopefully the more unassuming Felix Post would also be pleased to have his legacy remembered.

Changes in the Macrostructure and Microstructure of the Ageing Brain

Natalie M. Zahr[1], Adolf Pfefferbaum[2] and Edith V. Sullivan[1]

[1]*Department of Psychiatry and Behavioral Sciences, Stanford University School of Medicine, CA, USA*
[2]*Neuroscience Program, SRI International, Menlo Park, CA, USA*

MACROSTRUCTURAL CHANGES IN NORMAL AGEING DETECTED WITH CONVENTIONAL MRI

Conventional brain structural magnetic resonance imaging (MRI) produces images of protons, with contributions primarily from water and some from fat. Tissue contrast is possible because of the fundamental differences in water content in the primary tissues of the brain: white matter consists of about 70% water, grey matter 80% and cerebrospinal fluid (CSF) 99%. Tissue contrast also depends on differences in the degree to which water is bound and differences in the local environment. By judicious choice of imaging acquisition parameters that yield high conspicuity between grey and white matter (e.g. Figure 4.1a), segmentation of brain tissue is possible. Segmentation provides the basis for volumetric and morphological quantification of brain structure[1,2]. In addition to manual delineation of specific structures, methods for quantitative survey of the brain include voxel-based morphometry, as is widely used with spatial parametric mapping (SPM)[3,4], parcellation[2,5] and deformation morphometry[6–8]. The achievement of quantitative analysis was an essential step for rendering MR images useful in the quest for reliable identification of age-related macrostructural change.

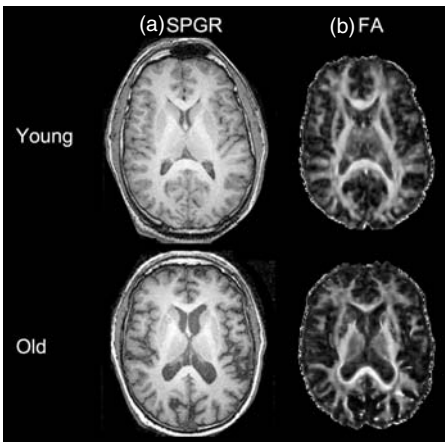

Figure 4.1 (a) Structural magnetic resonance imaging (spoiled gradient recalled, SPGR), and (b) diffusion tensor imaging (fractional anisotropy, FA) images from a young (32 year old) and an elderly (73 year old) male volunteer. SPGR images exemplify those that yield conspicuity between grey and white matter permitting brain tissue segmentation. Fractional anisotropy images facilitate fibre tracking

In vivo structural MRI reveals age-related increases in the volume of CSF-filled spaces primarily at the expense of cortical grey matter (cross-sectional[9–14], longitudinal[15–19]).

Despite evidence for widespread thinning of the cerebral cortex as a feature of normal ageing[16,20,21], specific grey matter structures of the brain exhibit differential patterns of ageing. A preponderance of data indicates an excessive vulnerability of the frontal lobes, and in particular the prefrontal cortex, as documented cross-sectionally[22–25]. Other grey matter structures demonstrating cross-sectional decline in volume with age include, but are not limited to, segments of the temporal[20,25] and parietal cortices[20], thalamus[12,26], and cerebellum[11,21,27]. Longitudinal studies, although less frequently reported, support cross-sectional results by revealing disproportionate effects of age on frontal grey matter regions[15,17,28], entorhinal[28,29], temporal[17,28], parietal[17] cortices, and cerebellum[21]. Some[30], but not all[27,31] MRI studies of subcortical structures report little shrinkage of basal ganglia structures. Similarly, although some reports are equivocal[16,28,32], it is generally accepted that hippocampal volume shrinks little with age[20,33,34]. That hippocampal volume shrinkage is not a reliable marker of healthy ageing makes it a robust marker of age-related diseases affecting this structure, notably, Alzheimer's disease.

The relevance of structural MRI findings to age-related decline in function is underscored by correlations with selective behaviours. For example, smaller prefrontal volume predicts poorer performance on the Wisconsin Card Sorting test[35] and other tasks involving inhibitory control[36,37]. Deficits in the working memory that occur in normal ageing correlate with frontal system volume[38], whereas episodic memory deficits that occur in Alzheimer's disease correlate with medial temporal lobe/hippocampal volume[39–41]. Such findings support a double dissociation between normal ageing and Alzheimer's disease: frontal brain volume reductions and executive dysfunction mark normal ageing, whereas volume reductions in the medial temporal lobe/hippocampus and the corresponding memory deficits indicate Alzheimer's pathology[20,42,43].

MICROSTRUCTURAL CHANGES IN NORMAL AGEING DETECTED WITH DTI

Whole-brain white matter volume shrinkage is small, estimated at no more than 2% per decade[27] (but see [31,44]). Yet postmortem investigations, in contrast to macrostructural approaches, have provided fruitful leads to age-related changes in white matter by revealing microstructural white matter compromise[45] including degradation of microtubules, myelin and axons[46–48]. *In vivo*, white matter microstructure is detectable with DTI, which has successfully revealed evidence of regional white matter disruption in normal ageing even in regions appearing normal on bulk volume imaging.

Quantification of DTI Data

Water molecules in the brain are in constant Brownian motion. Although movement of water protons affects conventional structural imaging to some degree, DTI allows quantification of this microscopic movement *within* each voxel, providing a depiction of local water molecular movement in terms of the preferred orientation of the motion. Along a white matter fibre, the path of a water molecule is constrained and this movement is called 'anisotropic', because diffusion along the long axis of a fibre (axial diffusion) is greater than diffusion across the fibre (radial diffusion[49]). Conversely, regions with few or no constraints imposed by physical boundaries such as CSF in the ventricles allow water movement to be random in every direction; this is therefore 'isotropic'. Disruption of white matter microstructure detectable with DTI can reflect compromise of cytoskeletal structure, myelin or axon density[50,51].

DTI quantification requires computation of a tensor, a mathematical description of a three-dimensional ellipsoid depicting the magnitude and orientation of diffusion in individual voxels. The tensor is associated three eigenvalues, with three corresponding orientational vectors (eigenvectors, $\lambda_1, \lambda_2, \lambda_3$), describing the diffusion ellipsoid by its major axes. The eigenvalue average, or trace, reflects the magnitude of diffusion, referred to as mean diffusivity or the apparent diffusion coefficient. The extent to which one eigenvalue, λ_1, dominates the other two, λ_2 and λ_3, determines the degree of anisotropy, that is, the degree of orientational preference within a voxel, typically measured as fractional anisotropy, ranging between 0 and 1 on a normalized scale (Figure 4.1b[52]). The largest eigenvalue, λ_1, is the longitudinal or axial diffusivity, λ_L, and reflects axonal integrity, whereas λ_2 and λ_3 quantify transverse or radial diffusivity, $\lambda_T = (\lambda_2 + \lambda_3)/2$, and reflect myelin integrity[49,53]. For both clinical and research studies, most DTI data sets are reduced to an anisotropy image and a diffusivity image. (For more information about DTI, see[54].)

Regional Quantification of DTI Data

A variety of approaches have been developed for quantification of DTI data; each has strengths and weaknesses that should be considered when critically evaluating published reports. Approaches for regional quantification of the DTI metrics of anisotropy and diffusivity include manually placing small, geometric samples (cubes, ovals, circles) onto selective white matter bundles, manually identifying anatomically based regions of interest (ROI, e.g. midsagittal corpus callosum), application of whole-brain analysis using SPM or other voxel-based morphometric methods, or tract-based spatial statistics (TBSS[55]). Geometric ROIs have the advantage of yielding rarefied samples of white matter with minimal effects from partial voluming (i.e. inclusion of grey matter, CSF or both) but the potential disadvantage of under-representing the condition of the full extent of the fibre system under study. Manual identification of the entire fibre tract has the advantage of providing an anatomically based sample of the target fibre with the possibility of examining subdivisions for regional variation; a disadvantage can be its susceptibility to partial voluming artefact because of the extended region sampled[56]. Voxel-based morphometry is attractive because it provides an automated, whole-brain survey of fractional anisotropy or diffusivity, but more often than not, has the under-appreciated cost of inadequate registration[6]. Such misregistration can disproportionately bias results and conclusions drawn from data, especially of the elderly[57], who have dilated CSF-filled spaces invading targeted white matter samples[58]. TBSS is another survey approach that does not actually track fibres but is used to quantify the whole-brain fractional anisotropy skeleton[59].

AGEING EFFECTS ON DTI METRICS

With advancing age and senescence, a consensus maintains a decline in fractional anisotropy in brain white matter[56,60–65] (but see [66,67]). Furthermore, consistent evidence supports an anterior–posterior gradient of fractional anisotropy decline with age[57,58,60,61,65,68–74] that has been confirmed in a monkey model of ageing[75]. TBSS likewise substantiates an anterior–posterior gradient, namely by identifying lower fractional anisotropy values in the frontal, parietal and temporal lobes, corpus callosum (particularly the genu and body) and the internal capsule[76].

In complement to white matter fractional anisotropy decline in ageing, diffusivity in white matter increases[58,65,67,77–80]. As with fractional anisotropy, profile analysis reveals that the primary locus of the age effect is in anterior white matter[80]. This pattern of age-related decline of fractional anisotropy and increase in diffusivity mirrors postmortem observations with predominant age-related findings in anterior white matter systems[45,81].

QUANTITATIVE FIBRE TRACKING IN AGEING

The degree to which the diffusion orientation of a voxel is similar to its neighbours, or in other words, coherence of diffusivity measures between voxels[82,83], serves the conceptual basis for quantitative fibre tracking[55,84–87]. Connectivity and coherence between different brain regions on vector and fibre tracking maps is readily apparent on visual inspection[88]. Methods for quantitative analysis of structural connectivity of white matter include fibre-tract trajectories[89–91] and maps of the degree of 'alignment' among neighbouring vectors, on a voxel-to-voxel basis, resulting in a measure of intervoxel coherence[82]. Advantages of quantitative fibre tracking over focal ROI analysis include the ability to measure the entire extent of a fibre tract and to characterize its integrity along its full extent.

Quantitative fibre tracking confirms focal DTI measures of an anterior-to-posterior pattern of disruption of white matter integrity[92,93] as, for example, the elderly have lower fractional anisotropy and higher diffusivity than the young in anterior but not posterior sectors of the fibres coursing through the corpus callosum (Figure 4.2)[94–96]. Recent work also supports a superior–inferior gradient of ageing effects on white matter (Figure 4.3)[97–99], whereas pontocerebellar and cerebellar hemisphere white matter tracts are relatively preserved[97].

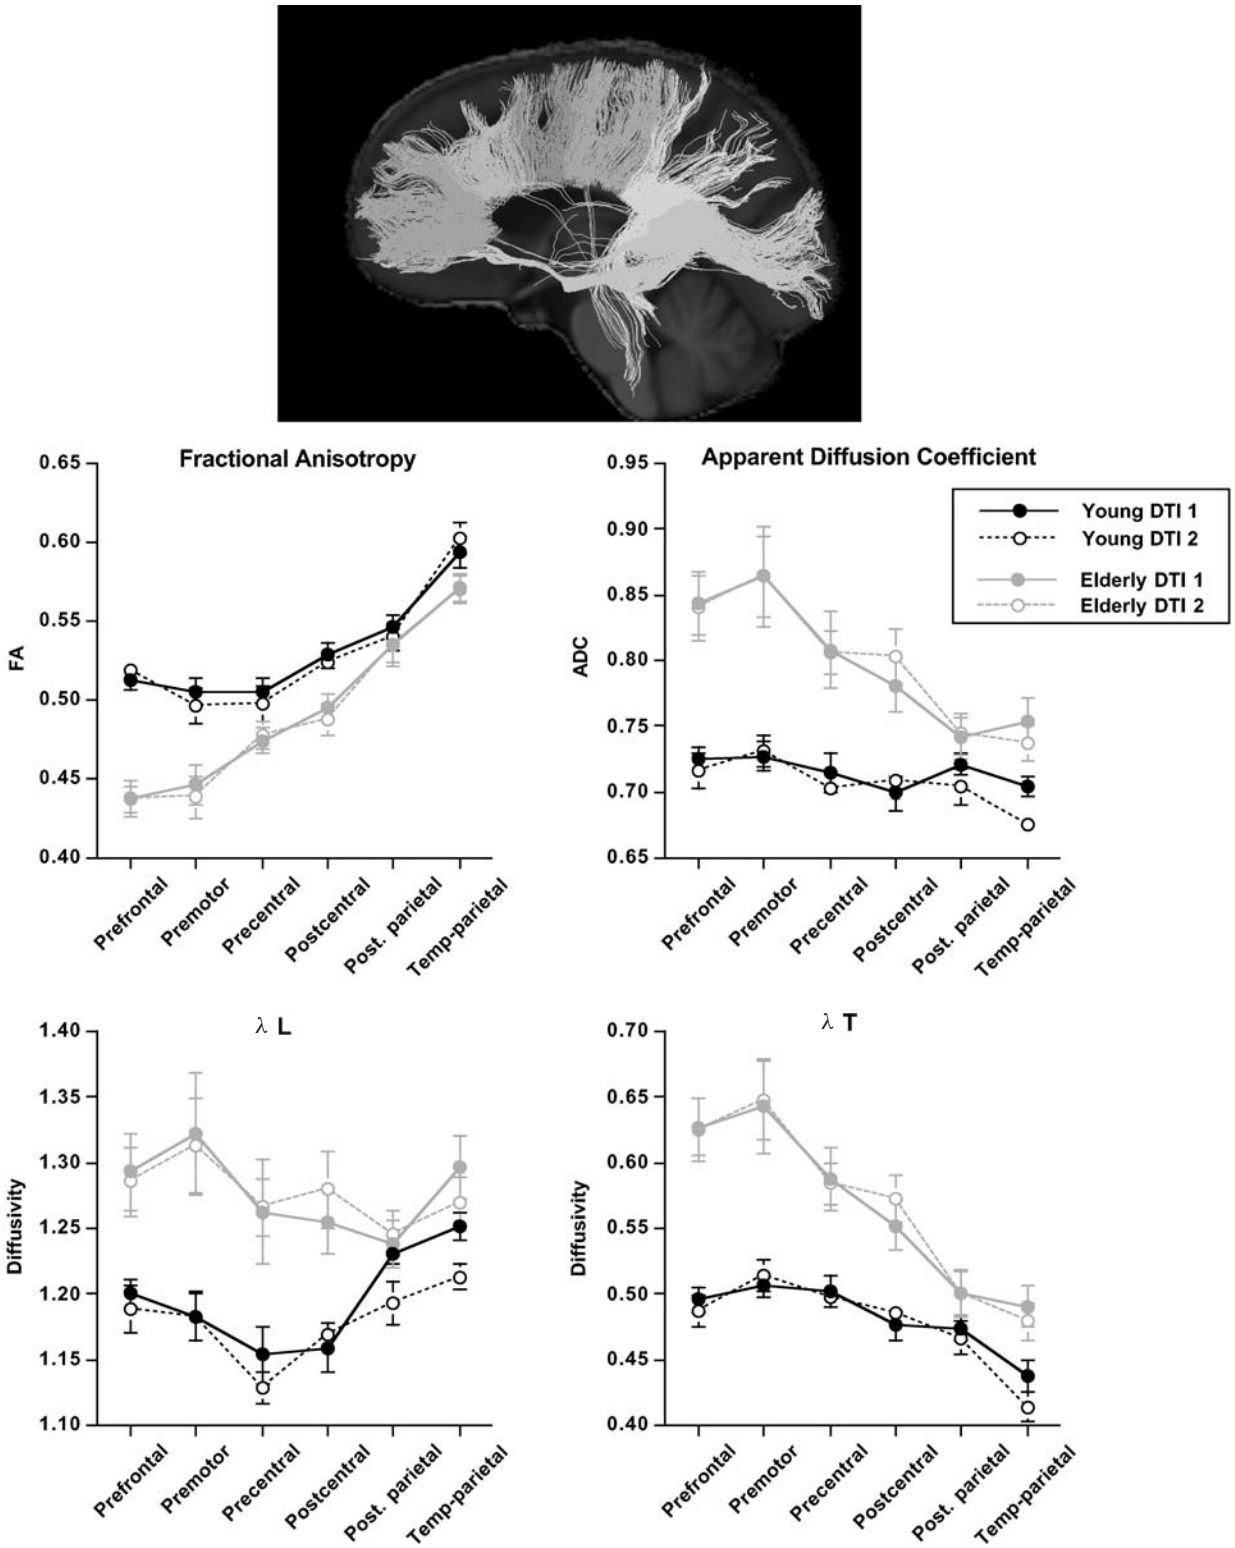

Figure 4.2 Top sagittal image: Example of fibre tracking of the corpus callosum of a 23-year-old healthy woman. The colours represent six different fibre bundles based on previously described divisions[148] identified with fibre tracking based on diffusion tensor imaging (DTI)-derived fractional anisotropy. From anterior (far left) to posterior (far right), the bundles are deemed prefrontal, premotor, precentral, postcentral, posterior parietal, and temporal-occipital. Bottom data figures: Mean ± SE of the six callosal sectors for the young and elderly groups at MRI sessions two years apart of the four principal metrics of DTI: fractional anisotropy, apparent diffusion coefficient (ADC), λ_1 and λ_t. The elderly group had lower fractional anisotropy and higher diffusivity than the young group at both scanning sessions, and the group differences were greatest in anterior sectors. Reproduced with permission from Sullivan *et al*.[105]

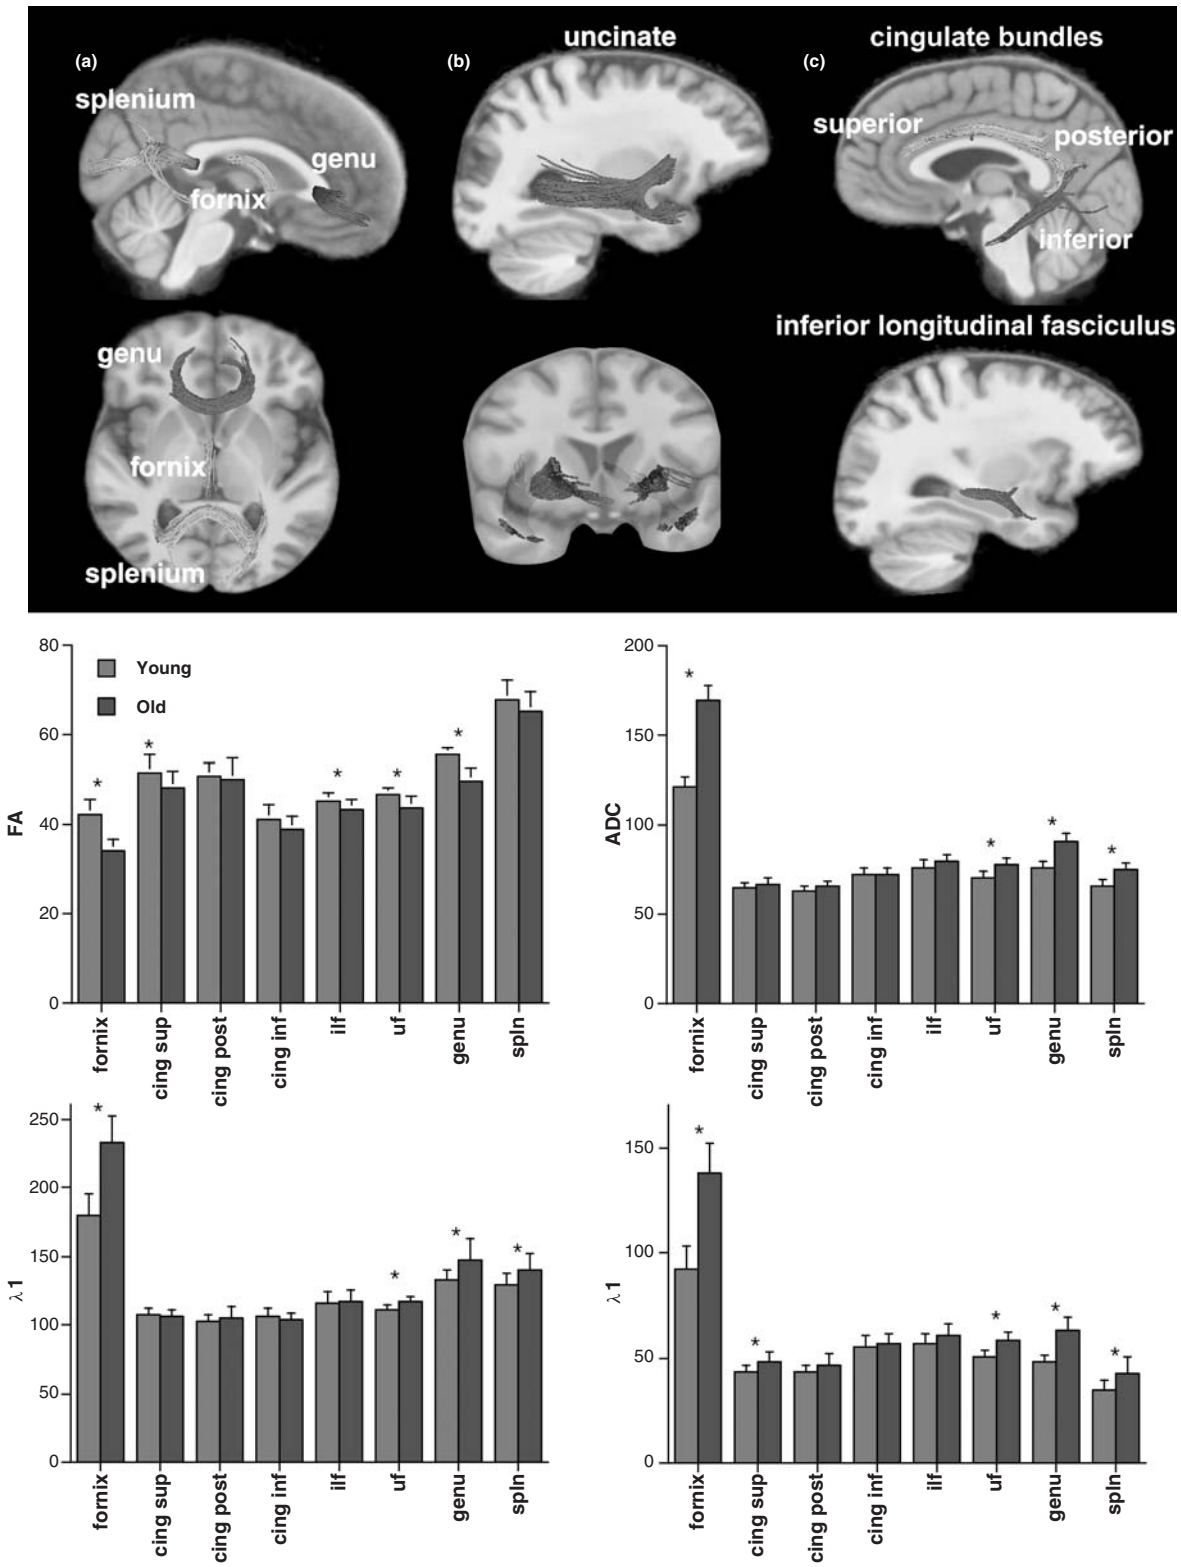

Figure 4.3 Images: Fibre tracts were identified on the group-average fractional anisotropy image in common space. (a) Sagittal (top) and axial (bottom) views of the genu, splenium and fornix. (b) Sagittal (top) and coronal (bottom) views of the uncinate fasciculus. (c) Sagittal (top) view of the cingulum (superior, posterior, inferior) and inferior longitudinal fasciculus (bottom). Bar graphs: Mean ± SD for fractional anisotropy, apparent diffusion coefficient (ADC), λ_1 and λ_t for young (grey) and elderly (white) subjects for each fibre bundle. *$P \leq 0.05$*t*-test. Modified from Zahr *et al*.[99]

LONGITUDINAL STUDIES OF AGEING BRAIN MICROSTRUCTURE

Longitudinal studies of normal, healthy men and women across the adult age range document normative age-related, DTI-detectable changes in brain white matter that are requisite for interpreting DTI data from individuals with neuropsychiatric disorders and other conditions affecting the brain. However, longitudinal studies have their own problems with respect to measurement reliability within and across research centres, selective attrition, and hardware and software system modifications and drift[100]. For example, a study of five normal adults imaged five times each resulted in 5% across-subject variation and a mean variation of 2.3 ± 1.2 SD% in diffusivity[78]. Another study measured the reliability of global and regional fractional anisotropy and diffusivity measurements in ten healthy young adults, imaged three times on two different 1.5-T scanners made by the same manufacturer[101]. When reliability was measured on a voxel-by-voxel basis or on a slice-by-slice basis, fractional anisotropy and diffusivity values were equivalently and significantly higher within than across scanners. In addition to reliability of a common measurement approach, substantial differences can arise when different analysis schemes are applied to the same data set[102].

Longitudinal DTI studies of healthy ageing are only now emerging. The few studies reporting longitudinal results in normal ageing do so secondarily, in that the target study groups were individuals with neurological conditions, including head injury[103] and amyotrophic lateral sclerosis[104]; in neither control group were age-related declines in fractional anisotropy or increases in diffusivity detected. One small prospective study followed eight young and eight elderly individuals over two years[105] but found no evidence of change in any of the six sectors of the corpus callosum examined; instead, the measurement was highly reliable across the interval (see Figure 4.2).

BRAIN WHITE MATTER STRUCTURE–FUNCTION RELATIONSHIPS

The functional ramifications of the DTI metrics have been regularly verified with observations of correlations between regionally specific low fractional anisotropy or high diffusivity and poor cognitive[61,62,71–73,106,107] or motor[68] test performance in humans and also a monkey model of ageing[75]. Lower whole-brain fractional anisotropy and higher mean diffusivity correlated with working memory performance[106,108]. The alternating finger-tapping task, a test of interhemispheric information transfer, revealed a relationship between splenium and parietal pericallosal white matter fractional anisotropy and finger-tapping output that was selective to the alternating condition, requiring interhemispheric motor coordination, and not unimanual conditions, free of transcallosal information exchange[68]. Task switching[61,109] and lower scores on tests of executive functions[63,109] correlated with low fractional anisotropy and greater diffusivity in anterior brain regions; lower verbal fluency scores correlated with lower fractional anisotropy in central samples of white matter[61].

Functional correlates of regional fibre tracking are also emerging. Correlations between fibre tracking quantification and the Stroop color-word reading were noted[94]. A large, multifactorial battery of neuropsychological tests reduced to three factor scores revealed that problem solving and working memory factor scores correlated with indices of callosal genu and fornix integrity, whereas the motor factor score correlated with a widespread set of fibre systems, likely reflecting the multiple brain loci required to execute the tasks, which included speed, dexterity and choice reaction time (Figure 4.4)[99].

LIMITATIONS OF DTI

DTI studies indicate widely varying fractional anisotropy across brain regions, with lower anisotropy and higher in diffusivity in older than younger healthy adults, that is prominent in the anterior supratentorial white matter but minimal to none in posterior cortical and corticospinal tracts. A caveat to this generalization is that selective deletion of uniformly orientated white matter fibres from a tissue sample of crossing fibres, as can occur with Wallerian degeneration, can cause abnormally high anisotropy[110]. Therefore, interpretation of fractional anisotropy results requires guidance by knowledge of the underlying regional architecture, especially white matter[111] and supplemented with non-human primate studies, affording the opportunity for *in vivo* examination and postmortem verification of imaging results (cf.[88]).

Furthermore, the diameters of axons, for example in the corpus callosum ranging from 0.4 to 5 μm, with most less than 1 μm, means that a cross-section of the genu of the human corpus callosum contains approximately 400 000 fibres per mm^2 and a single DTI voxel using relatively high resolution ($2 \times 2 \times 2\,mm^3$) for current standards could contain 1.6 million fibres in a cross-section[112]. Consequently, caution must be used when interpreting the anatomical meaning of observations made with radiological measures, which are coarse on the size scale of the underlying fibres.

Finally, the diffusion-weighted signal can also be influenced by iron accumulation with age, and the resulting effect is different among deep grey matter structures and white matter and needs to be considered, especially when using DTI to characterize structures known to accumulate iron (*in vivo*[113], postmortem[114]) or in conditions, such as stroke, that produce high ferritin deposition (cf.[115]).

OTHER STRUCTURAL MAGNETIC RESONANCE OBSERVATIONS IN AGEING

Convergent postmortem[114] and *in vivo* data indicate that deep grey matter brain structures accumulate ferritin at different rates throughout adult ageing[113,116,117]. Abnormal iron accumulation has been reported in neurological conditions involving the basal ganglia, including Parkinson's disease, multiple sclerosis and Huntington's disease (reviewed in: [113,118–122]), and suggests that iron burden contributes to age- and disease-related functional decline[123,124].

Iron can be measured *in vivo* with MR imaging because of iron's effect on signal intensity, causing signal darkening on T2* and T2-weighted images that is greater with increasing magnetic field strength. By estimating the transverse relaxivity increase across field strengths, the MR field-dependent relaxivity increase (FDRI) can be calculated[113,125,126]. For example, acquisition of spin-echo data with a constant TR and multiple echoes at 1.5-T and 3.0-T allows the computation of R2 (the inverse of T2) at each field strength with the difference between R2s divided by the field strength difference producing FDRI in units of s^{-1}/T (Figure 4.5a).

In addition to affecting relaxivity, local iron influences MR gradient-echo image phase, which forms the basis for another method for iron quantification, susceptibility-weighted imaging (SWI) (Figure 4.5b)[127]. The paramagnetic properties of tissue ferritin cause local field inhomogeneity that can also be quantified by examining the phase of the computed spins. The ferromagnetic

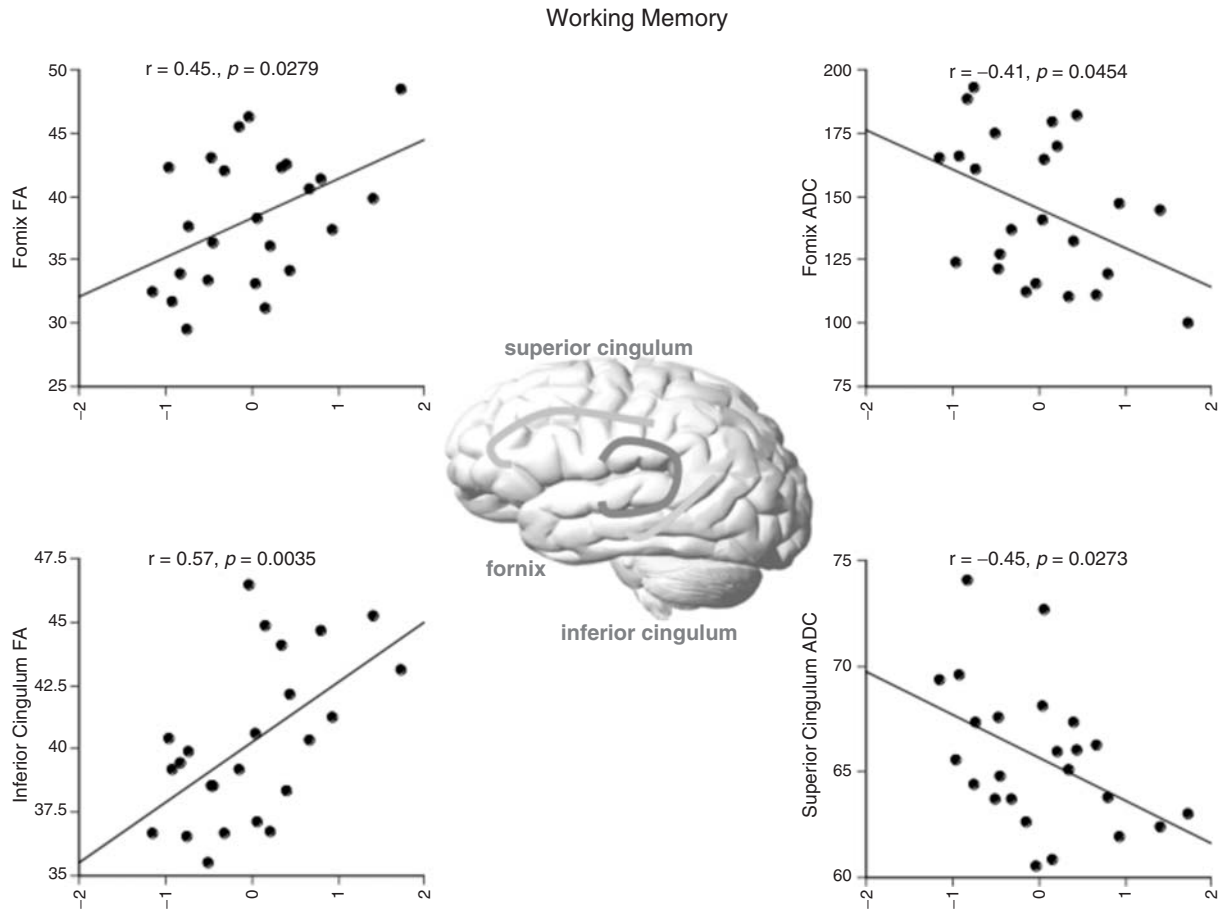

Figure 4.4 Correlations (Spearman rank and Bonferroni corrected) between a working memory domain isolated using principal component analysis and diffusion tensor imaging (DTI) metrics (fractional anisotropy and apparent diffusion coefficient) by tract. Modified from Zahr *et al*.[99]

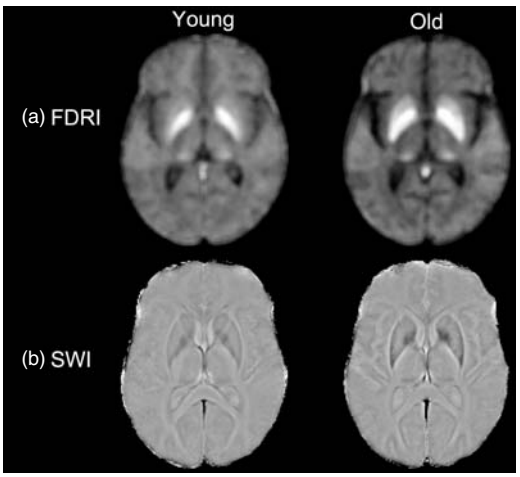

Figure 4.5 Group averages for 11 younger (mean= 24 years old, 5 men, 6 women) and 12 older (mean= 74 years old, 6 men, 6 women) participants for (a) field-dependent relaxivity increase (FDRI) and (b) susceptibility-weighted imaging (SWI) techniques for measuring brain iron. Greater iron concentration yields higher (brighter) FDRI signal but lower (darker) SWI signal. Modified from Pfefferbaum *et al*.[126]

property of iron causes protons to accrue more negative phase in iron-rich tissue. At optimal acquisition parameters, the more iron in a voxel, the lower will be the measured phase[127].

FDRI and SWI document increasing iron deposition with age in deep brain structures such as the caudate and putamen, globus pallidus, red nucleus, substantia nigra and thalamus[113,119,126,128]. In a recent comparison study between FDRI and SWI, both methods detected high globus pallidus iron concentration independent of age and significantly greater iron in putamen with advancing age[126].

Further senescent changes in brain tissue composition and emblematic of tissue degradation are the increases in presence and volume of white matter hyperintensities (WMHIs) (e.g. [129–131]), typically visible in T2-weighted and fluid-attenuated inversion recovery (FLAIR, Figure 4.6) images. WMHIs are associated, for example, with hypertension, stroke, traumatic brain injury and respiratory dysfunction[132–134]. The current controversy regarding WMHIs aetiology is whether a common pathophysiological mechanism underlies the formation of periventricular and deep white matter lesions[134–136]. It is thought that demyelination or ependymal lining damage commonly occurs periventricularly, whereas rarefication of myelin or cavitations from fibre loss, concomitant of ischaemic damage or arteriosclerosis, commonly occurs in deep white matter[130]. Depending on the location of WMHIs, different types of functional decline can ensue[136,137].

CONCLUSION

The twentieth century has seen a dramatic increase in life expectancy in developed countries. Estimates from the Health and Retirement Study, sponsored by the US National Institute on Ageing, indicate that ~10% of individuals aged 70 and older in the United States suffer moderate to severe cognitive impairment that rises to ~20% by age 85 years[138]. Therefore, expanding longevity coupled with declining CNS function will dictate the need for continued development of clinically practical and sensitive imaging modalities to assist in the differential diagnosis of age-related diseases.

Advances in neuroradiology have contributed to the neuroscience of normal ageing and to characterizing morphological and tissue changes that occur in the brain with age. Among these is the identification of previously underappreciated occurrence of decline in white matter integrity. The *in vivo* interrogation of the brain has also highlighted the dramatic, involutional brain tissue shrinkage and replacement with CSF, less apparent at the autopsy table as the brain collapses in on itself when removed from the skull[139].

Finally, a principal aim of this paper was to emphasize neuroradiological concomitants of apparent normal ageing, thereby providing an essential context in which to interpret radiological evidence for neurodegenerative diseases and other conditions of brain insult. Careful history taking and clinical description of presumed healthy men and women have proved essential in identifying factors that underlie departure from normality[28] or are categorized as 'normal variants'[140]. Factors increasing in prevalence with age and affecting brain tissue and potentially function include hypertension[141], cerebrovascular disease[135,142], and iron deposition[113]. DTI can be more sensitive than conventional MRI for detection of subtle and perhaps prodromal changes in tissue that occur with age (cf. [126,143,144]), including those characteristic of stroke[145–147]. Use and quantification of tractography may also enable monitoring white matter fibre regrowth[148] following trauma, disease or recovery from alcohol and drug dependence and to test models of white matter recovery in normal ageing, trauma and disease.

Functional Imaging of the Ageing Brain

Robert Perneczky, Christian Sorg and Hans Förstl

Department of Psychiatry and Psychotherapy, Klinikum rechts der Isar, Technische Universität München, München, Germany

INTRODUCTION

Modern imaging techniques such as functional magnetic resonance imaging (fMRI), positron emission tomography (PET) and single photon emission tomography (SPECT) provide the groundwork to test mechanistic hypotheses derived from basic neuroscience studies in healthy individuals and patients with neurological and psychiatric disorders. Apart from these scientific applications, functional imaging studies can also provide important diagnostic information in the field of geriatric psychiatry. Therefore, functional imaging scans are recommended by diagnostic guidelines to resolve certain differential diagnostic issues[1], and costs are also reimbursed for these special cases in selected countries (e.g. Medicare Coverage Criteria for FDG-PET for Alzheimer's disease, http://nps.cardinal.com/nps/PETFoundations/documents/PETADCovFinal.pdf). In addition to its benefits for the diagnosis and differential diagnosis of neurological and psychiatric disorders, functional brain imaging has also been shown to increase the confidence of experts in their clinical diagnosis. For example, Foster *et al*.[2] reported that visual rating of ^{18}F-fluoro-2-deoxy-glucose (FDG) PET scans after a short training period was more reliable and accurate in distinguishing Alzheimer's disease from frontotemporal dementia (FTD) than clinical assessment on its own. This was particularly true when the raters were uncertain with their clinical diagnosis. Hence, FDG PET is able to add important diagnostic information that appropriately improves diagnostic confidence.

Biomarkers including functional imaging are also gaining importance for the evaluation and monitoring of treatment effects. Modern, sensitive techniques are able to detect subtle brain functional changes resulting from therapeutic interventions, even if the therapeutic effect is not immediately mirrored by clinical improvement. This could lead to the identification of treatment responders in very early treatment phases[3] or before the actual treatment period has even started. Furthermore, for some potentially preventive treatments to have their greatest impact, patients need to be identified at the presymptomatic stage. This means that individuals with an increased risk for a certain disease, but who do not yet show any clinical signs, need to be identified. Persons at risk for Alzheimer's disease, for example, can already be identified on the basis of brain metabolic deficits in their FDG PET scans before first symptoms, such as forgetfulness, appear[4].

This chapter provides an overview of a selection of functional imaging techniques and brain functional changes associated with ageing, some prevalent neurodegenerative and psychiatric disorders, and those due to treatment. Important clinical aspects and future research perspectives will be discussed.

FUNCTIONAL IMAGING TECHNIQUES

Functional neuroimaging is broadly defined as techniques that provide measures of brain activity. Commonly used techniques are electroencephalography (EEG), magnetoencephalography (MEG), PET, SPECT and fMRI. Here we focus on PET and fMRI, which primarily aim at the regional mapping of mental processes. These techniques measure metabolic and haemodynamic brain processes closely linked with neuronal activity. PET and fMRI allow both the detection of regional activity changes in response to experimentally presented stimuli or cognitive tasks and the detection of synchronous co-activity changes across brain regions in response on stimuli or during rest. In this section we review the biological basis of functional neuroimaging signals, then we describe the physics of PET and fMRI signals, and finally we discuss two basic principles underlying functional neuroimaging data analysis: functional specialization and functional integration.

Behaviourally evoked changes in blood flow are at the heart of functional neuroimaging[5]. Blood flow changes reflect metabolic changes, which in turn reflect changes in neuronal activity. From a metabolic point of view neuronal activity is dominated by transmitter recycling. Eighty per cent of brain energy is used for glutamate recycling. Central to glutamate recycling are aerobic glycolysis and oxidative phosphorylation. These activity-dependent processes with their main substrates H_2O, O_2 and glucose provide the basis for[15] O-H_2O-PET, FDG PET, and blood oxygen level-dependent (BOLD) fMRI.

Oxygen-15 and fluorine-18 are isotopes with short half-lives that are introduced into the body incorporated into H_2O and glucose. As the tracers decay, emitted gamma rays are detected by the PET scanner and used for image construction. The spatial resolution is about 1.5 cm and the temporal resolution is about 60 s; both values strongly influence the experimental design of neurocognitive paradigms. The fundamental signal for BOLD fMRI comes from hydrogen atoms mainly bonded to H_2O within the brain. In the presence of a static magnetic field, these hydrogen atoms absorb energy that is applied at a characteristic radio frequency. After radiofrequency excitation,

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

hydrogen atoms emit energy at the same radiofrequency until they gradually return to their equilibrium state (resonance phenomenon). The MRI scanner measures the emitted radiofrequency energy. The measured radiofrequency signal decays over time, influenced by distinct factors, including the presence of inhomogeneities in the magnetic field. BOLD fMRI techniques are designed to measure primarily changes of inhomogeneity within a small volume of tissue that result from changes in blood oxygenation. Deoxy- and oxyhaemoglobin ($Hb\text{-}CO_2$, $Hb\text{-}O_2$) have different magnetic properties; $Hb\text{-}CO_2$ is paramagnetic and introduces an inhomogeneity into the nearby magnetic field, whereas $Hb\text{-}O_2$ is weakly diamagnetic with little effect. Hence, an increase in the concentration of $Hb\text{-}CO_2$ causes a decrease in image intensity, and a decrease in $Hb\text{-}CO_2$ causes an increase in image intensity (BOLD effect). The spatial resolution of BOLD fMRI is about 0.5 cm and temporal resolution about 1–4 seconds.

There are two key topics in the analysis of functional imaging data, reflecting the long-standing debate in neuroscience about functional specialization versus functional integration in the brain[6]. The first is brain 'mapping', where three-dimensional images of neuronal activation are generated showing which parts of the brain respond to a given sensory stimulus or cognitive task. This is also known as the study of functional specialization and generally proceeds using some form of statistical parametric mapping (SPM) based on a voxel-wise analysis. A classic example here is the identification of human V4 and V5, the areas specialized for the processing of colour and motion. The second topic is 'functional integration', where models are used to analyse how different brain areas interact. A classic example is the use of models to find increased connectivity between dorsal and ventral visual streams after subjects learn object–place associations. A large number of statistical techniques are used to detect interregional connectivity (e.g. independent component analysis, support vector machine, dynamic causal modelling).

AGE-RELATED FUNCTIONAL CHANGES

Brain Functional Decline

'Normal ageing' is associated with numerous biological deteriorations in the human body, which also include brain functional changes. However, 'normal ageing' is a rather fuzzy concept and it is sometimes difficult to separate age-related and disease-related brain changes. All the same, with age the brain undergoes both structural and functional changes that underlie subjective complaints. The pre-frontal cortex shows the most prominent functional deterioration in most studies, whereas other regions including the anterior hippocampus, the thalamus and the posterior cingulate cortex are affected to a much lesser extent[7]. These results support the theory that the first areas to emerge phylo- and ontogenetically are the most resistant to age effects and the last to emerge are the most vulnerable. Furthermore, the relative functional preservation of brain structures during 'normal ageing' that are affected early in Alzheimer's disease, such as the hippocampus and the posterior cingulate cortex[8], seems to mark the parting of the ways between ageing and brain disease. This is also supported by the finding that cognitively normal elderly individuals with a pathological brain metabolic pattern are more likely to experience memory decline[9] and are at elevated risk of developing symptoms of Alzheimer's disease[10]. Also in line with these findings, Alzheimer's disease-like brain functional patterns are also found in cognitively normal elderly individuals with an increased genetic risk for Alzheimer's disease (i.e. carriers of the apolipoprotein E allele $\varepsilon 4$ (*APOE4*)[11]). Alzheimer's disease-like changes are already present at even younger ages in pre-symptomatic individuals from families with known early-onset autosomal dominant Alzheimer's disease-carrying mutations in the *PRESENILIN1* gene[12]. Interestingly, a maternal history of Alzheimer's disease also predisposes cognitively normal individuals to progressive metabolic deficits in Alzheimer's disease-vulnerable brain regions, which may be related to a higher risk of developing the disease[4]. Although the exact causes of these abnormalities are not yet known, these results suggest the involvement of maternally inherited predisposition to brain metabolic failure, possibly connected to mitochondrial DNA. The facts that mitochondrial DNA is entirely maternally inherited in humans, and diseases associated with mitochondrial DNA mutations often present as sporadic disorders, support this hypothesis.

Adaptation and Compensation

Age- and disease-related changes are not only associated with functional deterioration but also with counteractive measures. Accessory neural networks are activated to solve increasingly difficult tasks (adaptation). Similar mechanisms are deployed if a task cannot be solved by the usual means because of damage to the brain regions normally involved due to age-related changes or neurodegeneration (compensation)[13]. To offset brain functional deterioration, networks and cognitive patterns less susceptible to interference are activated; furthermore, additional networks not involved in young healthy individuals for the same task are recruited. These activity adjustments are exemplified by two well-described phenomena. The PASA (posterior-anterior shift in aging) phenomenon describes one possible reaction of the human brain to age-associated cognitive impairment. An increased activation of pre-frontal areas in conjunction with a decreased activation of occipital areas is found for the same cognitive paradigm in elderly individuals compared to healthy young persons. The degree of this activity shift is positively associated with task performance[14]. The HAROLD (hemispheric asymmetry reduction in older adults) phenomenon, on the other hand, delineates a reduction of hemispheric asymmetry in elderly individuals[15]; compared to young individuals, elderly persons tend to activate additional contralateral and to deactivate ipsilateral brain regions for the same cognitive task. Again, task performance positively correlates with the degree of the activity change. Taken together, PASA and HAROLD are good examples of the three possible mechanisms of cerebral activity changes associated with efficient information processing during ageing: (i) increased activation of brain regions already involved at the same task difficulty level in young individuals; (ii) activation of additional networks in other brain regions; (iii) more efficient deactivation of interfering networks.

FUNCTIONAL CHANGES IN NEURODEGENERATIVE DISORDERS

Neurodegenerative disorders are associated with distinct brain functional patterns. These patterns help to separate different disorders and to identify patients at oligosymptomatic stages.

Mild Cognitive Impairment and Alzheimer's Disease

In Alzheimer's disease functional brain damage is typically found in the hippocampus, and the pre-frontal, temporoparietal and posterior

cingulate association cortices[8,16]. The hippocampus and the posterior cingulate cortex seem to be affected in very early disease stages; metabolic deterioration of these two regions is already present in patients with mild cognitive impairment (MCI)[17,18]. Furthermore, an FDG PET suggestive of Alzheimer's disease in patients with MCI is a strong predictor for progression to dementia, especially in the presence of other risk factors such as an *APOE ε4* allele[19]. The degree of posterior cingulate cortex hypometabolism is also positively correlated with clinical disease severity in MCI[20]. However, several studies show that there is no linear association between brain damage and clinical symptoms, and that individual characteristics related to cognitive reserve modify the association between neurodegenerative damage and clinical signs[21–23]. Therefore, clinical symptoms tend to be less severe in individuals with higher estimated cognitive reserve than would be predicted by the amount of their brain damage.

Frontotemporal Lobar Degenerations

The clinical syndromes FTD, semantic dementia (SD) and non-fluent progressive aphasia (NFPA) have distinct morphological and functional imaging correlates. Furthermore, associations between specific clinical symptoms and focal functional brain pathology can be established. For example, metabolic reductions in brain regions related to micturition can be found in patients with FTD who suffer from urinary incontinence in contrast to those patients who do not experience this distressing symptom[24].

In FTD, bi-hemispheric functional brain pathology, which predominantly affects the pre-frontal cortex, the anterior cingulate cortex, the caudate nucleus and the insula, is already present in early clinical stages[25]. As the disease progresses, the functional pathology crosses the boundaries of the pre-frontal cortex and spreads to temporal and parietal regions[26]. Davies *et al*.[27] recently reported a group of patients with FTD without any structural brain changes that seem to have a better prognosis. However, brain functional alterations and the clinical relevance of this finding have yet to be explored. It is interesting to note that the degree of functional brain pathology is also influenced by genetic characteristics[28] and cognitive reserve[29,30]. In SD, initially asymmetric, in most cases left-sided, functional lesions of the temporal cortex, more specifically the temporal pole, are found[25]. It was recently shown in a follow-up study that the metabolic deficit only worsened in the anterior cingulate cortex after 15 months; this limited worsening was, however, associated with a considerable clinical decline[31]. In NFPA, the asymmetric functional deficit is predominantly located in the left temporal and insular cortex, the caudate nuclei and the thalami[32–34]. However, right hemispheric functional pathology was reported in left-handed patients[35] (Figure 5.1).

Lewy Body-Associated Disorders

Parkinson's disease dementia (PDD) and dementia with Lewy bodies (DLB) probably both belong to a spectrum of Lewy body-associated disorders. This notion is supported by a similar pattern of functional cerebral pathology, which includes brain regions also affected in Alzheimer's disease, such as the pre-frontal, temporoparietal and posterior cingulate cortex, and additional areas in the visual association cortex[36,37]. In a direct comparison, patients with DLB had a significant metabolic reduction in the anterior cingulate cortex compared with patients with PDD[36]. Associations between focal metabolic deficits and typical neuropsychiatric symptoms were reported, for example between right pre-frontal metabolism and delusions[38], and metabolism in visual association areas and visual hallucinations[39,40]. Furthermore, the impairment of daily activities was also linked to focal functional brain pathology[41,42].

FUNCTIONAL CHANGES IN PSYCHIATRIC DISORDERS

Next we review some studies in major depression and in schizophrenia using fMRI and FDG PET. Since explicit neuroimaging studies exploring the effect of age on major depression and schizophrenia are rare, we focus here on some recent imaging studies in major depression and schizophrenia, providing some new insights in disease mechanisms and demonstrating the potential of neuroimaging techniques for a better understanding of disease-related symptoms by altered brain processes. For both disorders changes in the default mode network (DMN) will be of special interest. The DMN comprises the medial pre-frontal cortex, the posterior cingulate cortex, and the lateral parietal cortex (for review see[43]). Areas of the DMN show elevated metabolism at rest, they are functionally connected by synchronized co-activity at rest and they consistently deactivate across a wide range of attention demanding, goal-directed behaviours; since DMN activation is related to self-referential functions such as remembering the past, planning the future or perspective taking of the mental state of others, deactivations during goal-directed behaviour are suggested as an attenuation of self-referential processes in order to improve goal-oriented attention[43].

The first finding pointing at a potential role of the DMN in major depression was reported by Greicius and colleagues[44]; the authors observed increased synchronized co-activity of the medial pre-frontal cortex within the DMN in major depression during rest. Examining the relevance of this result, Sheline *et al*.[45] found that in major depression medial pre-frontal regions of the DMN exhibited failure to deactivate during both looking at negative stimuli and appraising them. Patients with major depression and healthy controls were instructed to look at pictures inducing negative emotions in a passive mode and to appraise them actively (making a negative picture positive by depersonalizing it such that it does not pertain to the viewer or that the picture is not real). For the passive viewing and the active regulating condition patients and controls demonstrated reduced activations compared to the baseline state (i.e. deactivations) in the DMN. However, compared with controls, depressed patients' deactivations were less distinctive in several areas of the DMN, notably in the medial pre-frontal cortex. This result suggests that patients with major depression might have problems in reducing self-referential processes both during emotion-related activity and also during subsequent emotion regulation.

In a similar design to that of Sheline *et al*. Grimm and colleagues[46] found that the degree of deactivation failure correlated with the severity of depressive symptoms and reported hopelessness. These results together point at the prominent role of the DMN in major depression: the DMN seems to be critically involved in some key deficits of major depression such as emotion regulation or increased self-focused cognitions.

Several recent studies have revealed substantial changes within the DMN of patients with schizophrenia. Garrity and colleagues[47] found reduced synchronized co-activity within superior parts of the posterior cingulate cortex and the precuneus and increased co-activity within the inferior posterior cingulate cortex and the

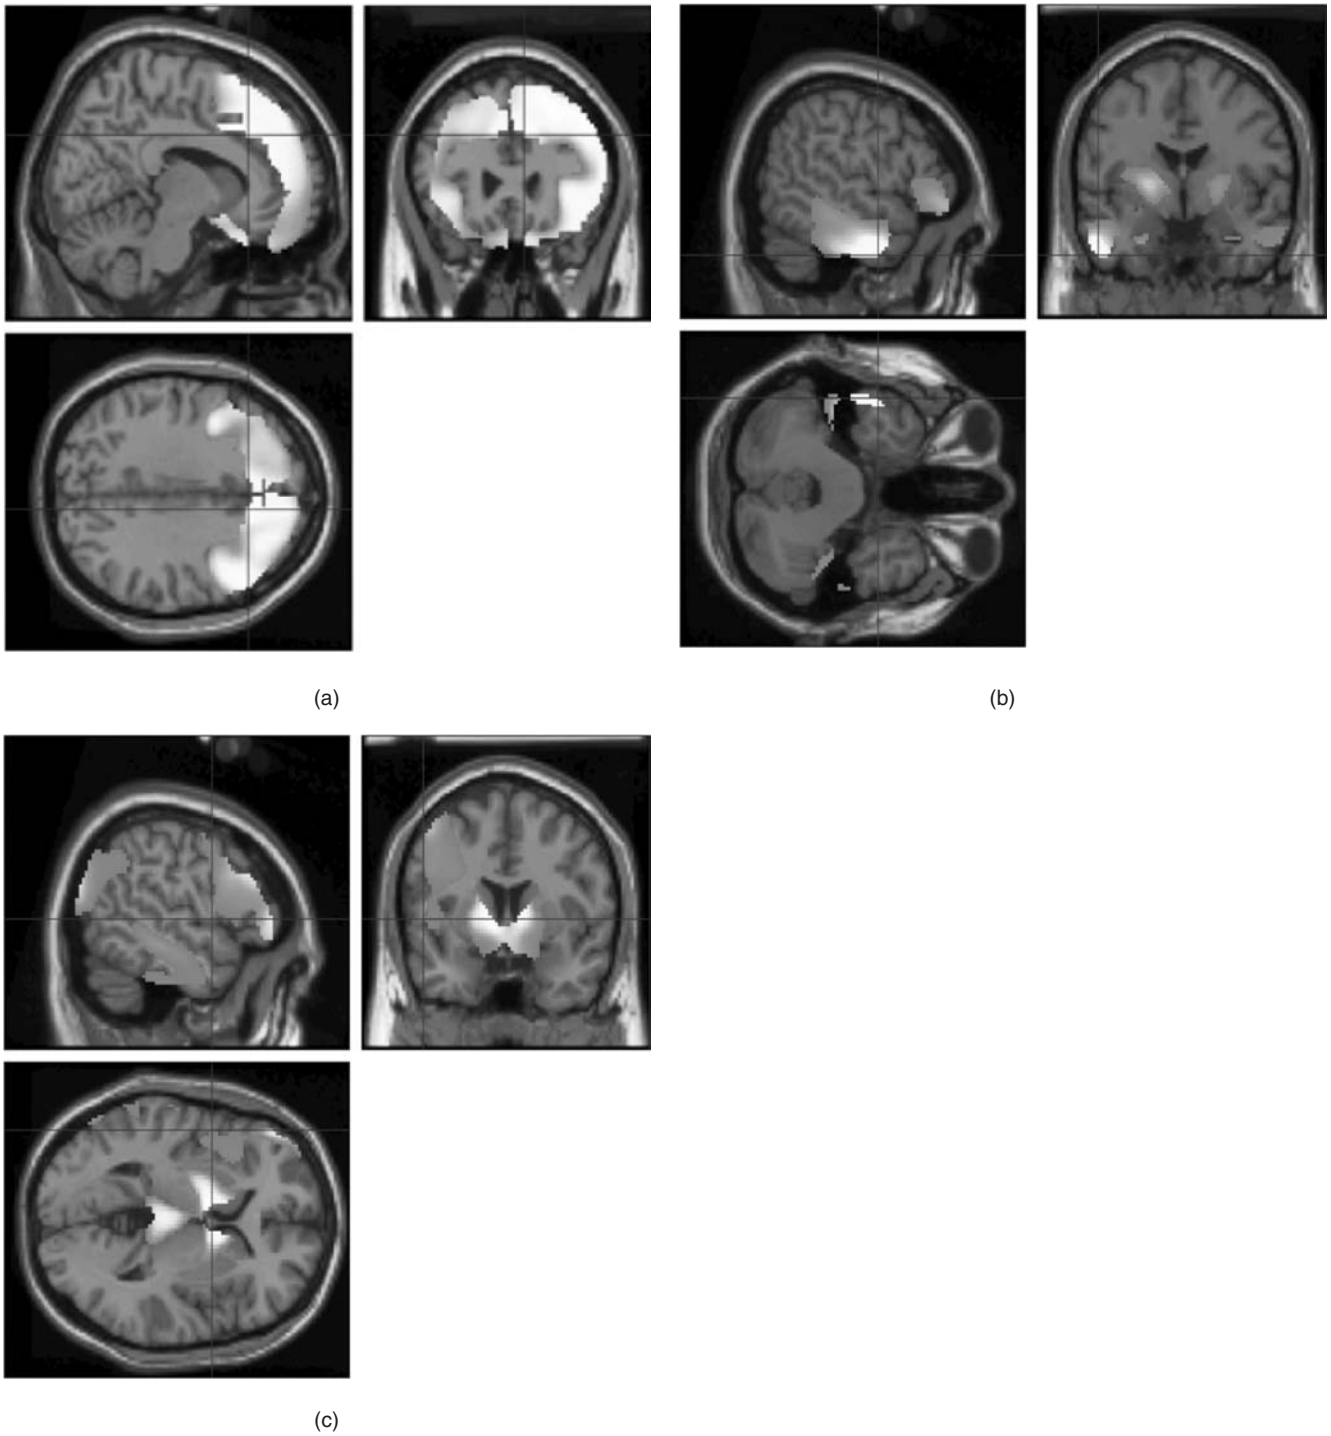

Figure 5.1 Reductions of regional cerebral glucose metabolism in ^{18}F-fluoro-2-deoxy-glucose positron emission tomography (FDG PET) studies of patients with (a) frontotemporal dementia, (b) semantic dementia and (c) progressive non-fluent aphasia compared with healthy control subjects (sagittal, axial, and coronal slices; areas with reduced metabolism are displayed in colour). *A full colour version of this figure appears in the colour plate section*

medial pre-frontal cortex in patients with schizophrenia during an auditory oddball attention task. In particular, increases in co-activity (i.e. functional hyperconnectivity) were correlated with positive symptoms. Looking at a potential relation between hyperconnectivity within the frontal DMN and already known hyperactivation of areas within and outside of the DMN in schizophrenia, Whitfield-Gabrieli *et al*.[48] instructed patients with early schizophrenia, first-degree relatives of patients with schizophrenia, and healthy control subjects to perform a working memory task during fMRI. They found gradually reduced deactivations of the medial pre-frontal cortex

across patients with schizophrenia, relatives of patients and controls with deactivations correlating with the cognitive performance. In the patient group deactivations were related to the severity of positive symptoms. Both patients and relatives hyper-activated in the dorsolateral pre-frontal cortex. With regard to functional connectivity, synchronized co-activity of the medial pre-frontal cortex during rest was highest in patients and lowest in controls. This hyperconnectivity of the medial pre-frontal cortex was related to both the hyperactivity of the dorsolateral pre-frontal cortex and the deactivation of the medial pre-frontal cortex, indicating an association between hyperactivation and hyperconnectivity in schizophrenia.

Hyperactivation of the DMN may blur the boundary between internal, self-focus-based thinking and external world-focus-based perceptions. Since many symptoms of schizophrenia involve an increased sense of self-relevance in the world or a smearing of internal reflection and external perception, hyperactivity and hyperconnectivity of the DMN may contribute to these critical symptoms of schizophrenia.

TREATMENT EFFECTS ON BRAIN FUNCTION

Including functional neuroimaging in clinical trials and clinical treatment monitoring procedures may identify neurochemical and anatomic differences between treatment responders and non-responders. These differences may serve as biomarkers for the prediction of treatment response and provide valuable information for treatment development by identifying mechanisms of treatment resistance.

Treatment Effects in Dementia

In Alzheimer's disease, cholinergic treatment with donepezil was associated with a stabilized regional cerebral blood flow in treatment responders, whereas blood flow declined in non-responders in a study by Nobili *et al*.[49]. Similar treatment effects of donepezil were also shown in patients with cognitive impairment after traumatic brain injury[50]. The binding of donepezil to acetylcholinesterase can also be directly measured *in vivo* with PET, allowing quantitative analyses of acetylcholinesterase and direct investigation of the pharmacokinetics of donepezil in the human brain[51]. Okamura *et al*.[52] reported that up to 60% of acetylcholinesterase donepezil-binding sites were occupied after the oral application of 5 mg donepezil. Cholinergic treatment with galantamine also caused sustained inhibition of acetylcholinesterase activity in patients with Alzheimer's disease; this effect was associated with attentional rather than memory improvement[53]. Brain functional changes were also demonstrated for drugs targeting transmitter systems other than the cholinergic system. Fellgiebel *et al*.[54], for example, reported clinical and brain metabolic improvements in a patient with FTD under treatment with aripiprazole, a newer antipsychotic with partial agonistic properties at serotonin 5-HT_{1A} and dopamine D_2 receptors, and partial antagonism at serotonin 5-HT_2 receptors. This study also suggests that common functional imaging techniques can be used to provide neurobiological evidence for the clinical effects of different psychotropic drugs.

Treatment Effects in Geriatric Depression

Most studies on antidepressant interventions in unipolar depression, including antidepressant drugs[3], total sleep deprivation[55], psychotherapy[56] and electroconvulsive therapy[57], focus on mid-life individuals. The available data in geriatric depression are limited. Nobler *et al*.[58] reported that after treatment with nortriptyline or sertraline, the study group as a whole did not show any blood flow changes; furthermore, there were no global blood flow differences between treatment responders and non-responders. However, the blood flow pattern differed significantly between treatment responders and non-responders: responders showed regional blood flow reductions in the pre-frontal and anterior temporal cortices. Brain metabolic reductions in the anterior cingulate cortex and the amygdalae were observed under chronic citalopram treatment by Liotta *et al*.[59]; the reductions were greater in responders than in non-responders. Wu *et al*.[60] showed that improvement under treatment with sertraline and after sleep deprivation was associated with a metabolic decrease in the orbitofrontal cortex, whereas clinical worsening was related to a metabolic increase in the dorsolateral pre-frontal cortex. Early metabolic decreases of the right cingulate gyrus after total sleep deprivation in combination with sertraline treatment were furthermore associated with clinical improvement[61]. However, these synergistic effects of antidepressant drug and sleep deprivation could not be replicated in a randomized, placebo-controlled study by the same group[62]. Taken together these results suggest that the state of severe depression is associated with increased functional activity, the reduction of which through different antidepressant therapies is linked to clinical improvement.

CLINICAL APPLICATION AND FUTURE PERSPECTIVES

Functional Neuroimaging in Clinical Practice

Structural imaging of the brain is an integral diagnostic procedure in psychiatry. It can provide indispensable information on possible organic aetiologies of psychiatric disorders, sometimes with immediate therapeutic consequences; furthermore, structural imaging can also support the clinical diagnosis in geriatric psychiatry, such as in the case of marked mediotemporal atrophy in Alzheimer's disease[63]. However, functional imaging techniques are experiencing increased popularity in the search for more sensitive and specific biomarkers for distinct psychiatric disorders. For a limited number of indications, functional imaging studies are already recommended by diagnostic guidelines. These indications include the assessment of regional cerebral blood flow or metabolism by means of PET or SPECT imaging for the differentiation of Alzheimer's disease and other neurodegenerative dementias such as FTD. Functional imaging should, however, never replace structural imaging; functional imaging should rather be used to provide complementary information in uncertain clinical cases. The added clinical value of functional imaging in several psychiatric and neurological disorders, including major depression and schizophrenia, is still to be determined. The identification of responders and non-responders in early treatment phases or even before starting a treatment would be especially desirable. Furthermore, novel imaging procedures such as resting state fMRI (rs-fMRI) could not only help to clarify the brain functional basis of neurodegenerative and psychiatric disorders but also serve as non-invasive biomarkers for the diagnosis and differential diagnosis in geriatric psychiatry[64].

Future Perspectives

Representing a new tool of functional neuroimaging research with some potential for reaching clinical relevance in psychiatric disorders, rs-fMRI focuses on changes of functional interactions between

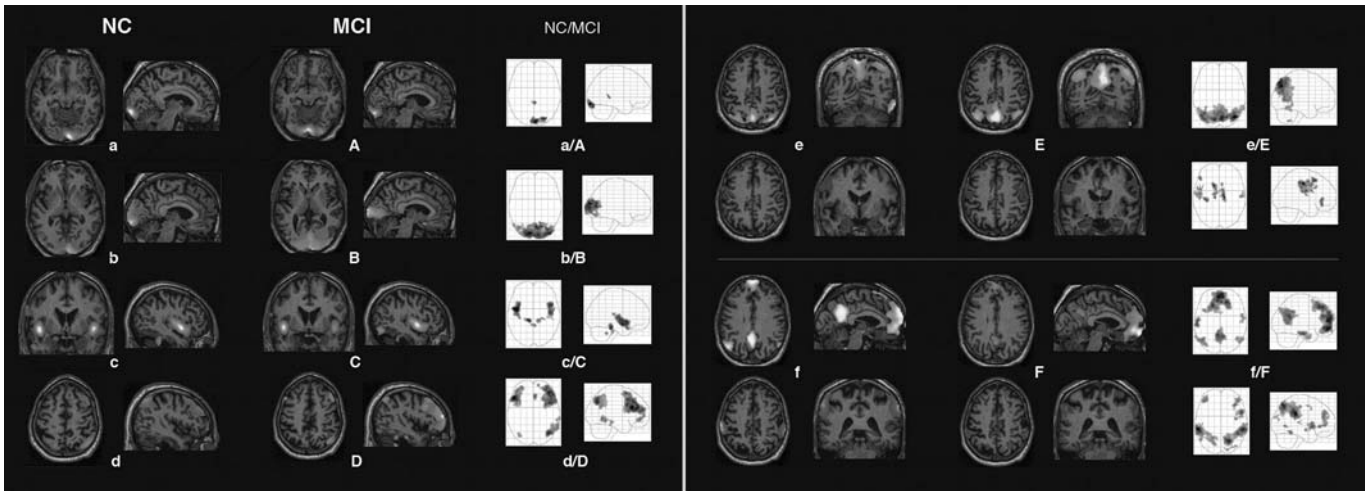

Figure 5.2 Brain networks characterized by synchronized co-activity during rest in normal controls (NC) and patients with mild cognitive impairment (MCI) detected by 4 min of resting state functional magnetic resonance imaging (fMRI). Brain networks correspond with networks found during characteristic cognitive task conditions such as seeing or attending. Selectively in both networks of part f/F patients had reduced co-activity compared with controls: the default mode network and an attention network

Figure 5.3 The functional connectivity at rest within the default mode network (DMN) correlates with psychopathology in patients with schizophrenia. Psychopathology reflects positive symptoms (composite Scale for the Assessment of Positive Symptoms (SAPS) score of positive symptoms); connectivity reflects whole brain functional connectivity with seed in the medial pre-frontal cortex. Adapted with permission from data published in Whitfield-Gabrieli *et al*.[48]

brain areas. Since it is performed at rest, rs-fMRI only needs minimal compliance of patients during imaging, making it appropriate for clinical purposes. Because it focuses on interactions between brain areas, rs-fMRI detects functional changes characteristic of several psychiatric disorders (Figures 5.2 and 5.3)[65].

In addition to this new brain mapping tool, several other new approaches aim at the integration of distinct structural and functional imaging parameters. Of particular note, machine learning-related methods such as support vector machines and various clustering procedures have been used. The basic idea of these approaches is to identify distinct patterns that are specific for a set of patients[66]. However, further research is warranted to explore the real potential of these newer methods.

Neurophysiology of the Ageing Brain

Paolo Maria Rossini and Laura Parisi

Clinica Neurologica University Campus Bio-Medico, Rome, Italy

INTRODUCTION

The few individuals who reach very old age are called 'longevity outliers'. This particular group represents the fastest growing age group worldwide. For instance, the number of centenarians increases steadily in the US population and their numbers are expected to grow to more than 400 000 in the next 30 years[1].

Awareness of age-related diseases such as dementia has prompted considerable interest in the study of the ageing human brain to trace a clear boundary between physiological and pathological ageing, to carry out primary prevention on populations at high risk of developing dementia, to achieve secondary prevention and to apply eventual disease-modifying therapy to at-risk subjects. Results from these types of studies could be used to plan political and public health interventions. Recent investigations have prompted advancement in biochemical, structural, functional and neurophysiological fields.

Ageing is a physiological dynamic process due to a specific property of the central nervous system (CNS) known as neuronal plasticity. The concept of 'plasticity' applied to neurobiology typically denotes the *potential for change* in addition to the mechanisms of self-repair and/or of reorganization of neural connections. Neural plasticity underlies learning as well as endogenous brain function repair[2], including synaptic efficacy and *synaptic redundancy*; on this basis the functional status and distribution of a network depends on the balance between neural excitation and inhibition, with some areas appearing silent or 'masked' by a mechanism of active tonic inhibition, the latter being prone to alteration or removal, causing a rapid change of the functional network, a process termed 'unmasking'[3]. Additional mechanisms include *long-term potentiation* (LTP) and *long-term depression* (LTD), which contribute to the functional strengthening or weakening of existing synapses by which information is stored in the CNS. LTP has been regarded as the prototypic mechanism of modified synaptic efficacy, and it can differently occur via modification of the input to a postsynaptic cell, the concomitant synchronous input to the synapse from another cell, or postsynaptic depolarization. LTD stems from Na^+ or Ca^{2+} channels at least for short-term changes, while LTP-like mechanisms include glutamate-dependent NMDA receptor activation for long-term changes, a process that can be antagonized by GABA inhibition[4]. Another plasticity-related process is neuronal sprouting and formation of new synapses influenced by local neurotransmitter, neurotrophic factors and synaptic protein synthesis[5]. In particular, dendrites and related spines with synaptic connections undergo continuous remodelling most likely also modulated by interaction with neighbouring astrocytes[4].

Postmortem examinations show that brain ageing is characterized by the formation of neurofibrillary tangles and senile plaques in both cognitively intact individuals and patients with dementia, namely Alzheimer's disease[1]. The ubiquitous presence of these lesions and the steady increase of the prevalence of dementia up to 85 years have strongly supported a continuum between normal and pathological brain ageing.

Ageing is a physiological process that occurs asynchronously in different areas of the brain, its rate being also dependent on the style of life. The differential age-related changes produced in several regions of the brain in the anatomy of neurons, volume tissue, density and dynamics of several neurotransmitters give support to this suggestion[6].

From a macroscopic point of view, brain ageing becomes evident by atrophy. In 1955 Brody estimated that the neuronal loss was about 40%. In 1986 Braak and Braak specified that during the ageing, especially pyramidal cells of frontal lobes die. Some studies suggest that the *primum movens* is a functional and then a structural modification of synapses[7]. It is followed by a modification of the dendritic tree and then by the neuronal death, today known as *aposklesis*. Particularly, the hippocampus seems to be one of the most vulnerable structures in brain ageing.

Functional modifications precede the structural ones, so it is hoped that by integrating structural techniques with the functional ones it will be possible to better investigate brain ageing. Moreover, modern neurophysiological techniques (transcranial magnetic stimulation, TMS; electroencephalography, EEG; magnetoencephalography, MEG; event-related potentials, EPRs) could be helpful for this purpose, being of low cost and non-invasive[8]. Modern techniques of functional neurophysiological imaging allow investigation with high accuracy of the cortico-cortical 'connectivity' that is the base for synchronization and functional binding. These phenomena allow neuronal populations, even at a distance, to contribute to a specific task or to process a specific input working together only for a few milliseconds. Analysis of EEG and MEG signals and TMS techniques gives us worthwhile information about that.

TRANSCRANIAL MAGNETIC STIMULATION

TMS is a brief and intense magnetic field, created by a strong electric current circulating within a coil resting on the scalp; it penetrates human tissue painlessly and, if the current amplitude, duration and direction are appropriate, it induces in the brain (or in spinal roots, or in nerves) electric currents that can depolarize neurons or their axons. TMS can demonstrate causal relationships between the stimulated area and behaviour. It can be used to interfere with the neuronal activity underlying sensory processing, motor planning or execution, attention and visual processing or awareness, different forms of declarative and non-declarative memory, reasoning, mathematics, language and consciousness. This temporary disruptive effect of TMS on cortical function is often referred to as a 'virtual lesion' and is likely to occur because the stimulus transiently synchronizes the activity of a large proportion of neurons under the coil, thus inducing a long-lasting, generalized inhibitory postsynaptic potential that reduces cortical activity for the next 50 to 200 milliseconds, depending on stimulus intensity and duration. Moreover, repetitive TMS (rTMS) can produce changes – outlasting the period of stimulation – in cortical excitability[9].

rTMS studies are increasing knowledge about correlation between anatomic structures and their functions. For example, they showed that dorsolateral prefrontal cortex (DLPCF) is implicated in working memory and in verbal episodic memory tasks.

Lesions of frontal lobes cause a reduction of learning and memory abilities but they do not cause the same memory loss as bilateral hippocampal lesions do. So, it has been demonstrated that prefrontal cortex (PFC) is involved in episodic memory tasks and that during encoding or retrieval, there are different areas of PFC that are activated with different *patterns*. It has been demonstrated that left PFC is involved in encoding processes; instead right PFC is involved in retrieval processes. This theory is known as hemispherical encoding retrieval asymmetry (HERA)[9–11]. Nowadays, it is known that the HERA model is not so absolute but that there could be variations due to the nature of the presented stimuli, the strategies of memorization used and the grade of difficulty of the task. Recently, positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies have demonstrated that PFC activity tends to be less asymmetric in older than in younger adults (hemispheric asymmetry reduction in old adults, HAROLD). This change may help counteract age-related neurocognitive decline (compensation hypothesis) or it may reflect an age-related difficulty in recruiting specialized neural mechanisms (dedifferentiation hypothesis)[12,13]. Functional neuroimaging techniques could not be used to study whether the loss of asymmetry during ageing reflects compensatory mechanisms or dedifferentiation processes; in fact, they show only the activation of a specific area during a task, but this activation could be related to the performance of the task without being the cause. Instead, this issue was addressed by using rTMS to assess causal relationships between performance and stimulated brain regions. Rossi *et al*. studied the effects of rTMS applied to the left or right DLPFC simultaneously with the presentation of memoranda on visuo-spatial recognition memory task, in a population of healthy subjects divided into two classes by age (<45 and >50 years). In the younger subjects, rTMS of the right DLPFC interfered with retrieval more than left DLPFC stimulation. The asymmetry of the effect progressively vanished with ageing, as indicated by bilateral interference effects on recognition performance. Conversely, the predominance of left DLPFC effect during encoding was not abolished in the older subjects, thereby indicating its causal role for encoding along the life span. Findings with rTMS suggest that the bilateral engagement of the DLPFC has a compensatory role on episodic memory performance across the age span[13].

CORTICAL EXCITABILITY

Physiological ageing is associated with more complex activations of the motor system to compensate for the reduced skill in motor performance[14,15]. Therefore, TMS variables can provide useful clues to investigate causally subclinical changes of cortical excitability at the motor cortex level. Unfortunately, studies do not show converging findings, probably as a result of technical and experimental differences among them[13,16–18]. Apart from assessing cortical excitability, TMS can be used to measure intracortical facilitatory and inhibitory mechanisms resulting from the balance among neurotransmitters, and dynamic synaptic adaptations to progressive neuronal loss. Motor threshold is generally reduced in Alzheimer's disease compared to healthy age-matched controls and is similarly reduced in subcortical ischaemic vascular dementia[16,19,20], even if several reports have not found reduction of motor thresholds[21,22], with one study noting increased rather than decreased motor thresholds in Alzheimer's disease[23]. Global cortical hyperexcitability while the brain is 'at rest' in Alzheimer's disease is a consistent result[22], which seems to occur independently of GABAergic and cholinergic cortico-cortical mechanism dysfunction as reduced motor thresholds and intracortical inhibition (ICI) and short-latency afferent inhibition (SAI) are uncorrelated. Since TMS does not provide specific pathophysiological information but is sensitive to the 'global weight' of several neurotransmitters as well as subcortical and cortical motor inputs, interpretation of cortical hyperexcitability in Alzheimer's disease is not yet possible.

The majority of these TMS results indicate that the cortex of Alzheimer's disease patients is hyperexcitable, and that such hyperexcitability may offer clues for the differential diagnosis from other dementias in which the cholinergic deficit is not predominant. An intriguing issue that can be addressed by TMS is the study of cortical reorganization of the motor output in Alzheimer's disease. Indeed, motor cortex physiological organization is early involved in Alzheimer's disease, despite the lack of clinically evident motor deficits, which only appear later[24]. This observation is not surprising considering that the motor cortex, through muscarinic receptors and cholinergic terminals, receives a major input from the nucleus basalis of Meynert[25]. Mapping of motor output in mild Alzheimer's disease patients asymptomatic for motor deficits has demonstrated frontal and medial shift of the cortical motor maps for hand muscles. In healthy controls the centre of gravity of motor cortical output is coincident with the site of maximal excitability (hot spot[26]), whereas in Alzheimer's disease patients it shifts towards frontal and medial regions in the absence of changes in the hot spot[22]. An altered synaptic plasticity in Alzheimer's disease also has been demonstrated by applying brief trains of high-frequency rTMS to motor cortex and recording motor-evoked potentials (MEPs) from the contralateral hand muscles. This procedure can induce a progressive increase in MEP size in normal age-matched controls, but it produces opposite changes in Alzheimer's disease. This finding was interpreted as an altered short-term synaptic enhancement in excitatory circuits of the motor cortex. Additional assessment of these findings will be required by evaluating Alzheimer's disease patients after different pharmacological treatments (e.g. cholinergic versus drugs acting on NMDA glutamate receptors).

In summary, TMS assays of cortical disinhibition in Alzheimer's disease as a dysfunction of a single neurotransmitter in a single neural circuit or as the net effect of a complex involvement of more than one neurotransmitter system in several brain areas likely reflects a single facet of a pathological mosaic. A lasting preclinical condition under the attack of pro-degenerative agents could produce the Alzheimer's disease brain as alternative strategies of functioning belonging to the brain reserve even for the execution of simple motor tasks[15,22]. The emerging evidence indicates that the 'stressed synapses' may acquire a different function both in terms of effects and of utilized neurotransmitter and may be strongly dependent on the sampling time of the tested patients[27].

rTMS could be useful to improve cognitive performance in healthy subjects or in patients with mild cognitive impairment (MCI). These effects include selective shortening of picture naming[28] and action naming without changing verbal reaction times for naming objects[29], improving subjects' speed at finding the solution to a reasoning puzzle[30], and improving performance on a choice reaction task[31]. It can be hypothesized that rTMS – by shifting the level of cortical excitability – might allow either more or less access (by interfering, for example, with the functioning of local inhibitory circuits) to brain networks relevant to the experimental task. These effects might vary depending on the timing of the TMS stimulation and on the hierarchical role of the brain area stimulated within the whole functional network underpinning the function under investigation.

These findings reflect the potential of rTMS to recruit compensatory networks that underlie the memory-encoding process and suggest that rTMS is capable of transient and positive rehabilitative influences on brain function[9,32].

EEG/MEG RHYTHMS

Advanced EEG analysis techniques together with analysis of MEG signals contribute to the investigation of brain ageing. Among EEG analysis techniques, the most worthy are the surface Laplacian transformation or coherence analysis of EEG, which can illustrate changes in specific oscillatory frequencies over time and can provide quantitative measurements of individual rhythm[33]. Moreover, the low resolution electromagnetic topography algorithm (LORETA) technique computes three-dimensional linear solutions from multi-channel input to localize generators *in* the brain from the EEG field distribution on the scalp by employing a three-shell spherical head model of the scalp, skull and brain compartments[34]. LORETA solutions consist of voxel z-current density values that are used to predict EEG spectral power density at scalp electrodes. A normalization method yields current density at each voxel for the power density averaged across all frequencies (0.5–45 Hz) and voxels of the brain volume.

Instead, MEG is a non-invasive technique that permits spatial identification of neuronal activation from spontaneous cerebral or external stimulus presentation. MEG signal characteristics are not influenced by extracerebral tissue layers (i.e. meninges, skull, scalp, muscles). MEG signals originate from current flow of tangential dipoles in cortical gyri and sulci[35,36]. The signals reflect the spatial and temporal production of a dipolar source modelled as an equivalent current dipole (ECD). This method provides three-dimensional localization of dipolar field distributions over the scalp with time resolution of milliseconds. Hence, MEG signals can directly estimate the number of active neural pools and provide accurate measures of the intracellular currents in a limited shallow brain region below the recording sensor without influence from volume conduction.

Resting EEG changes across physiological ageing, with gradual changes in spectral power profile indicating a pronounced amplitude decrease of alpha (8–13 Hz) and a global 'slowing' of the background EEG, with increases in power and topographic location in the slower delta (2–4 Hz) and theta (4–8 Hz) frequency ranges[37–39]. Ageing effects on parieto-occipital alpha rhythms reflect the activity of dominant oscillatory neural network modulated by thalamo-cortical and cortico-cortical interactions facilitating/inhibiting the transmission of sensorimotor information and the retrieval of semantic information from cortical storage[40,41]. Low-frequency alpha is primarily related to the subject's global attentive readiness, whereas high-frequency alpha reflects the oscillation of neural systems for the elaboration of sensorimotor or semantic information[39]. Over the course of age, alpha power decreases combined with changes in cholinergic basal forebrain system and in the excitatory activity in the cholinergic brainstem pathway[42]. Despite the relative consensus on alpha decrease, there is no general agreement on the modulation of delta and theta activity in brain ageing[43].

Resting EEG changes in pathological brain ageing. When compared to healthy normal elderly (Nold) subjects, Alzheimer's disease patients exhibit high power for delta and theta and low power for posterior alpha (8–12 Hz) and/or beta (13–30 Hz) frequencies[44–47]. EEG abnormalities were associated with altered regional blood flow/metabolism and with impaired global cognitive function as evaluated by Mini-Mental State Examination (MMSE)[48,49].

MEG also has provided contributions to the understanding of the cortical rhythms in pathological ageing. Parieto-temporal delta and theta sources enhanced in power in Alzheimer's disease compared to Nold subjects in association with hippocampal atrophy[50]. Furthermore, Alzheimer's disease subjects demonstrated a decrease of alpha sources in parieto-occipital region possibly compensated by an increase of temporal alpha sources[51]. Finally, cortical theta and alpha rhythms as revealed by MEG have discriminated the severity level of Alzheimer's disease and distinguished it from Lewy body dementia.

EEG power *per se* does not capture one of the main features of Alzheimer's disease, namely the impairment of functional neural connectivity. It has been reported that Alzheimer's disease patients present an abnormal linear coupling of EEG rhythms among cortical regions, as revealed by spectral EEG coherence[52–56], suggesting a linear temporal synchronicity of coupled EEG rhythms from simultaneously engaged neural sources. Such findings imply that functional coupling of cortical rhythms is modulated by cholinergic systems, and that a decrease of cortical EEG coherence may be a fine-grained marker of Alzheimer's disease, since it is characterized by defective basal forebrain cholinergic inputs to cortex and hippocampus[57]. Most EEG studies of Alzheimer's disease have reported a prominent decrease of alpha band coherence[52,54–56,58–60]. This result also has been found to be associated with ApoE genetic risk, which is hypothesized to be mediated by cholinergic deficit[52]. However, delta and theta band coherence changes in Alzheimer's disease are not homogeneous, as some studies demonstrate a decrease of slow-band EEG coherence, whereas others find an increase[56,61].

MCI subjects present an intermediate magnitude of low-frequency alpha (8–10.5 Hz) activity from parietal, occipital and limbic areas, compared to mild Alzheimer's disease and normal elderly[62]. Increase of slow EEG power coupled with a decrease in alpha activity is linked to cognitive performance decline in MCI patients compared to Nold. More importantly, the magnitude of these sources is correlated negatively with MMSE scores across subjects of the three groups, suggesting that EEG evidence of alpha power decrease in MCI compared to normal subjects is related to behavioural cognition[60,63–65].

The relative decrement of posterior low-frequency alpha sources in MCI may be related to an initial selective impairment of the cholinergic basal forebrain, which could induce a sustained increase of the excitatory activity in the cholinergic brainstem pathway[42]. As a consequence, the increased excitability of thalamo-cortical connections would desynchronize the resting alpha rhythms and enhance the cortical excitability as seen in Alzheimer's disease. Hence, changes of low-frequency alpha power in MCI and mild Alzheimer's disease suggest a progressive impairment of the thalamo-cortical and cortico-cortical systems that govern visual attention. This hypothesis is consistent with clinical findings of increasing deficits of visuo-spatial abilities in MCI and mild Alzheimer's disease. Similarly, limbic sources imply a progressive impairment of thalamo-cortical and cortico-cortical systems regulating attention tone for memory functions.

Quantitative EEG is able to predict with a good approximation MCI progression to Alzheimer's disease in a short run; this was demonstrated by Rossini *et al*.[66], who investigated whether combined analysis of EEG power and coherence provides early and reliable discrimination of MCI subjects who will convert to Alzheimer's disease after a relatively brief follow-up.

EEG and MEG rhythms can change over time in relation to a specific event. Event-related desynchronization (ERD) and event-related synchronization (ERS) of EEG or MEG rhythms describe neuroelectric events preceding and following a task execution[39]. ERD/ERS is defined as reduction/increase in EEG power during event (sensory, motor, cognitive) when compared to baseline at a certain frequency band. Alpha band hyper-reactivity in Alzheimer's disease as indexed by increased alpha ERD suggests an abnormal increase of the cortical excitation or disinhibition even during simple cognitive demands. Such findings agree with previous functional neuroimaging studies on memory, which demonstrated a stronger allocation of cortical resources in Alzheimer's disease when compared to Nold subjects[66,67]. In addition, they are consonant with other findings of abnormal central rhythms when processing sensory stimuli or performing voluntary movements and with hyper-reactivity of Alzheimer's disease primary motor cortex as revealed by TMS[15,68].

Artificial neural networks (ANNs) are a useful tool in early diagnosing of dementia; they elaborate in an innovative way EEG signals. Starting from a standard EEG recorded with the international 10–20 system, it is a low cost and non-invasive procedure, it is widespread and it does not require highly qualified staff at the moment of recording. It has been shown that a correct automatic classification of MCI and Alzheimer's disease subjects can be obtained extracting spatial information content of the resting EEG voltage by ANNs with an accuracy greater than 92%[69]. Moreover, the classification of the individual Nold and MCI subjects, with this tool, could reach a sensitivity of 95.87% and a specificity of 91.06% (93.46% accuracy)[70,71]. ANNs could be a worthy tool to improve screening of high-risk population one day.

CONCLUSION

Doubtless the only approach to trace a narrow line between physiological and pathological ageing is integrating genetic, biological, structural and functional variables. The latter change early, so measurement of functional variables could be helpful for early diagnosis. Neurophysiological tools that are low cost, non-invasive and widespread could be useful for large-scale screening and follow-up of populations at high risk of developing dementia. One of the most exciting challenges is to improve them.

Potential Regeneration of the Ageing Brain

Stephen B. Dunnett

School of Biosciences, Cardiff University, UK

The brain does not spontaneously regenerate. As long ago as 1928, Cajal recorded that 'once development was ended, the founts of growth and regeneration of axons and dendrites dried up irrevocably. In adult centres ... everything may die, nothing may be regenerated'[1]. Although it remains the case that the damaged mammalian central nervous system (CNS) does not in general generate new nerve cells in response to disease or injury, the intervening 70 years have identified a considerable plasticity of axons to remodel nerve connections and a limited degree of neurogenesis that opens new opportunities for promoting regeneration and repair in the damaged, diseased or ageing nervous system (see Figure 7.1).

ADAPTIVE PLASTICITY

Even if lost cells are not replaced, spared neurons and fibres retain a considerable degree of plasticity to adapt to lost connections by adaptive biochemical compensation both at the presynaptic level – for example by changes in cell firing, transmitter synthesis, release and reuptake – and postsynaptically, by changes in receptor density, receptor sensitivity and post-synaptic signalling (Figure 7.1C)[2,3].

COLLATERAL SPROUTING

The first clear evidence that Cajal's dictum was overly pessimistic in relation to the mammalian CNS came from the demonstration that if a septal cell loses some of its normal axonal inputs then other afferent axons can sprout into the vacated spaces to form new synaptic connections with the target cell[4]. If the new inputs are from a different source they are by and large not functional. However, collateral sprouting of spared fibres of the same systems do appear to be able to sustain functional recovery in a number of model circuits of the brain (Figure 7.1D)[3,5,6].

REGENERATIVE SPROUTING

A major problem for extensive axonal reorganization in the adult brain is that although axons can undergo a degree of local sprouting, they do not typically retain the developmental capacity for long-distance growth through the CNS to distant targets (Figure 7.1E)[3,7]. Long-distance growth of axons can nevertheless be promoted by providing an alternative substrate for growth such as Schwann cells from the peripheral nervous system (PNS) which can be used to bridge a gap caused by a lesion cutting a pathway, or be implanted as a track along which new axons can grow (Figure 7.1H)[8].

NEURAL TRANSPLANTATION

When essential populations of neurones are lost they may be replaced by transplantation. The techniques are now well established for transplantation of embryonic cells derived from the CNS into the brain of adult or aged experimental animals (Figure 7.1G), and such grafts have been demonstrated to survive, repopulate areas of denervation, replace deficient innervations, and restore lost functions in a wide variety of model systems[9,10]. There is now compelling clinical evidence that such grafts can provide a substantial alleviation of symptoms in Parkinson's disease[11], and clinical trials are now underway in Huntington's disease, spinal cord injury and stroke[12–14]. It remains a matter of speculation whether neuronal transplantation can alleviate the more diffuse and widespread degeneration associated with ageing and the dementias.

TROPHIC SUPPORT

Neuronal connections are dependent upon trophic support from their targets, and neurodegenerative diseases of ageing may in part be attributable to a decline in growth factor support[15]. Thus, an alternative approach to prevention of progressive neurodegeneration, and to induction and guidance of regenerative axon growth, is to apply or replace identified trophic factors explicitly. For example, dopaminergic neurones, which decline in several neurodegenerative diseases of ageing, are dependent upon trophic factors (including brain-derived neurotrophic factor (BDNF) and glial cell-derived neurotrophic factor (GDNF)) for trophic support. Chronic infusion of GDNF into the striatum or midbrain can inhibit progressive lesion and age-related atrophy of midbrain dopamine neurones and block the functional decline in motor abilities (Figure 7.1F) both in experimental animals[16] and in man[17]. A similar strategy involving chronic central infusions of nerve growth factor (NGF) has been attempted in a pilot experiment in Alzheimer's disease with only modest success[18]. A major issue to be resolved is how to deliver large trophic factor molecules – which do not cross the blood–brain barrier – to defined targets in the brain; the most powerful experimental techniques to date involve either implantation of cells that are engineered to secrete the particular trophic factor molecule (Figure 7.1G)[19] or direct *in vivo* gene transfer (Figure 7.1F)[20,21].

Normal dopaminergic projections to the striatum arising from dopamine neurons in the ventral mesencephalon. **B**. Toxin 6-OHDA injections into the nigrostriatal pathway deplete striatal dopamine, typically more extensively in the dorsal neostriatum than in the ventral striatum. **C**. Compensatory adaptation of striatal receptors and biochemical turnover from residual spared. **D**. Compensatory collateral sprouting of ventral afferents following complete lesions of dorsal striatum. **E**. Long-distance regenerative axon growth from ventral mesencephalon typically is not a feature of nigrostriatal damage. **F**. Chronic delivery of growth factors such as GDNF by infusion or *in vivo* gene transfer can protect damaged axons and promote axon regeneration within the neostriatum. **G**. Implantation of ventral mesencephalic cells can restore dopaminergic innervation of the denervated striatum. **H**. Implantation of bridge grafts, e.g. of GDNF-secreting glial cells, can provide a substrate for long-distance axon regrowth from the ventral mesencephalon. **I**. Although adult neuron stem cells in the subventricular zone can provide functional cell replacement in dentate gyrus and olfactory bulb, evidence for a similar capacity for cell replacement in the striatum or ventral mesencephalon is weak

ADULT NEUROGENESIS

It was believed until recently that all neurones of the mature nervous system are born in early development so that once lost they are not replaced. It is now clear that there exists in the adult human brain a small population of resting 'neuronal stem cells' with the capacity both to undergo further cell division and to differentiate into both neurones and glia[22]. This opens the hope that such cells may be recruited for repair, either by isolation, expansion and differentiation into defined neuronal cell types *in vitro*, and reimplantation, or by finding the means to induce their spontaneous division, migration to areas of cell loss, and local differentiation into appropriate neuronal phenotype to replace lost target cells *in vivo* (Figure 7.1I). However, claims that endogenous adult stem cells can underlie recovery of function in the adult brain remain largely unsubstantiated, and substantial technical and theoretical problems remain in translating such procedures into applications for repair in human ageing.

CONCLUSION

Although the repair of neuronal damage associated with neurodegenerative disease and normal ageing remains experimental, rapid advances are being made in the techniques for inhibiting degeneration, promoting regenerative growth and replacing lost populations of cells. The pessimism that has for long surrounded the poor prognosis of brain damage in ageing and disease is being transformed to an optimism that these novel experimental approaches may find direct clinical application in the neurodegenerative diseases of ageing. Nevertheless, formidable technical problems still need to be overcome to transform theoretical prospects into practical therapies.

Neuroendocrinology of Ageing

Marcus Simmgen

Thomas Addison Unit, St George's Hospital NHS Trust, Blackshaw Road, Tooting, London, UK

INTRODUCTION

The subject of neuroendocrinology is the interface between the nervous and endocrine systems within the brain. Their structural and functional interaction is bi-directional; that is, neuronal activity modulates endocrine secretion and, in turn, hormones influence brain function. Both neurons and endocrine cells transmit signals to distinct target cells by releasing a chemical mediator that is recognized by specific receptors. There is overlap, as some secreted substances serve as both neurotransmitter and hormone, for example arginine vasopressin (AVP, also called antidiuretic hormone, ADH) or vasoactive intestinal peptide (VIP). Virtually all neurotransmitting systems are involved in the neuroendocrine interaction, and jointly they regulate metabolic homeostasis, growth, development and reproductive function and they influence behaviour, learning, emotional and mental state.

Within the brain, the anatomical sites of closest interaction between the two systems are the hypothalamic-pituitary unit and the pineal gland. Peripherally, endocrine secretion is controlled either by direct innervation through autonomic secretomotor fibres or, indirectly, through the regulation of blood flow.

The endocrine effects on the CNS are widespread: the limbic system structures of hippocampus, amygdala, hypothalamus and cingulate gyrus, as well as the pre-frontal cortex and various other parts of the brain, are responsive to endocrine signals that may alter their morphology or functional behaviour.

The neuroendocrine interface is also linked closely to the body's immunological responses, and the increasingly complex interactions have been described as a neuroendocrine-immune network. Significant immunological changes occur during the ageing process, in part as a consequence of these interactions; however, these aspects are beyond the scope of this chapter.

As in other regions of the brain, the number and function of certain hypothalamic neurons and neuroendocrine cells declines during senescence, while other cell populations remain intact or even hypertrophy[1,2]. Circadian rhythms of secretion undergo a phase shift or become less pronounced and increasingly irregular[3]. Some endocrine axes undergo a significant physiological decline in their activity as a consequence of altered central regulation, loss of peripheral endocrine secretory capacity, tissue responsiveness or post-receptor signalling changes. While the menopause is an established life event for women, the effects of the gradual decline of male sex hormone levels (sometimes termed 'andropause'), of adrenal androgen production ('adrenopause') and of growth hormone ('somatopause') on healthy ageing are still the subjects of ongoing debate and research. In senescence, there are changes in body composition, loss of muscle strength, reduction in endurance and frequently a decline in cognitive, emotional and psychological function. Various hormonal changes contribute to these developments, and the chapter is arranged by endocrine axis and peripheral hormone. A brief overview of its physiology and CNS-related regulation is followed by a description of the changes occurring during senescence, and the implications for the ageing person.

ADENOHYPOPHYSIS

The anterior, glandular lobe of the pituitary gland is derived from pharyngeal ectoderm rather than from neuroectoderm. It achieves a close functional relationship with its regulatory neurons through the capillary portal circulation that exists between the median eminence of the hypothalamus and the adenohypophysis. Releasing and inhibiting hormones thus reach the anterior pituitary gland to exert control over its secretion of hormones with a tropism for the peripheral endocrine glands. All anterior pituitary hormones are released in a pulsatile manner. While they provide feedback inhibition at hypothalamic neurons (short loop), the peripheral hormones exert negative feedback at pituitary and hypothalamic level to ensure stable plasma levels (long loop). The pituitary generally reduces in size during senescence[4].

Somatopause

Growth hormone is synthesized by the somatotroph cell population of the anterior pituitary gland and released in pulsatile bursts with a peak after the onset of sleep. Two hormones are known to stimulate growth hormone synthesis and secretion: growth hormone-releasing hormone (GHRH) and ghrelin, both of which are produced in the hypothalamic arcuate nucleus. The former acts via its cognate GHRH receptor (GHRHR), and the latter via the growth hormone secretagogue receptor (GHSR). In addition, a range of other factors exert control over growth hormone release; such as metabolic substrates, physiological stimuli (sleep, exercise or stress) and certain neurotransmitters. Somatostatin, a hormone produced in the hypothalamic anterior paraventricular nucleus (PVN) inhibits growth hormone release, and the overall output effectively reflects an integration of all these stimuli.

Under the influence of growth hormone, primarily the liver produces insulin-like growth factor 1 (IGF-1), which mediates many of the effects of growth hormone on target tissues. Metabolic effects of growth hormone are: increased muscle mass and strength, reduced fat mass, increased bone density and improved cholesterol levels[5].

Growth hormone levels peak in adolescence and decline by 14% each decade, a process that is further accelerated in postmenopausal women. The amplitude of nocturnal growth hormone pulses falls and may disappear[6]. Since physiological ageing is associated with an increase in body fat and a reduction in muscle mass, as well as with a fall in bone density, there are similarities with adult growth hormone deficiency, and the term 'somatopause' has been used for this. A trial of supplementary growth hormone in a cohort of ageing men showed significant improvement in these parameters[7]. After 12 months of administration, however, side effects of carpal tunnel syndrome, gynaecomastia and hyperglycaemia became evident[8]. A meta-analysis concluded that, while growth hormone replacement was beneficial in growth hormone deficiency, supplementation in an otherwise healthy elderly person showed no evidence for improvements in maximal oxygen consumption, bone mineral density, lipid levels and fasting glucose and insulin levels. There was no suggestion that growth hormone prolonged life. Since there is also a theoretical risk of increased neoplastic disease, there are no grounds to advocate growth hormone supplementation in healthy ageing[5].

As an alternative, small molecules have been developed to act at the GHSR as a long-acting oral ghrelin analogue[9]. One trial was reported after one year to have achieved enhanced growth hormone pulsatility, restored IGF-1 values to juvenile levels, increased fat-free body mass and marginally lowered LDL-cholesterol. Observed side effects were a mild increase in fasted glucose, insulin resistance, cortisol levels and a weight gain of 2.7 kg vs. 0.8 kg in the placebo group[10]. Another compound improved lean body mass and functional strength, balance and coordination. Side effects were deterioration in parameters of insulin resistance, fatigue and insomnia[11]. Neither drug has reached the market.

Prolactin

Prolactin is structurally related to growth hormone, and its secretory regulation is unusual in that the pituitary lactotroph cells are under tonic inhibition by dopamine-producing hypothalamic neurons. Circulating prolactin levels comprise of a combination of basal and pulsatile release[12]. Prolactin levels rise in response to sleep to peak in the early hours[13], and secretion is increased by stress and other stimuli. In men and non-pregnant women, prolactin concentrations gradually decline with advancing age. Frequent nocturnal sampling showed this to be a result of falling basal prolactin secretion that is associated with a reduced lactotroph cell mass or responsiveness, and also to be due to a reduction in hypothalamic stimuli for pulsatile bursts[14]. In ageing rats, the circadian rhythm of prolactin secretion loses the ability to adapt to changes in the light–dark cycle[15].

In a large observational study of a cohort of middle-aged men (52 ± 12.9 years) attending for sexual dysfunction, the lowest quartile of prolactin concentrations was associated with increased risk for metabolic syndrome, atherogenic erectile dysfunction, premature ejaculation and anxiety. There also is evidence for immune-modulating properties of prolactin since, in mice, prolactin deficiency caused impaired lymphocyte function by reducing cytokine-induced macrophage activation[16]. However, the clinical relevance of reduced prolactin levels in senescence is unclear and no trials of replacement therapy in ageing humans have been conducted.

Menopause

The female cycle is under complex regulation by luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which are produced by the gonadotroph cell population of the anterior pituitary gland. Both are released in pulsatile fashion under control by hypothalamic gonadotrophin-releasing hormone (GnRH). In addition to the daily high-frequency pulsatility, their secretion is cyclical over the period of a lunar month. Complex feed-forward and feedback regulation between the hypothalamus, the pituitary gonadotroph cells and the ovary leads to the menstrual cycle during a woman's fertile years. Oestrogen is produced mainly in the granulosa cells of the developing ovarian follicle from an androgenic precursor and is the main female sex steroid hormone.

Follicular depletion, however, is not the sole reason for the menopause. Studies in rats demonstrated that prior to any cycle irregularities there was an early decline in GnRH-neuron response and a consequently reduced LH surge in response to oestrogen around the time of ovulation. Thus the functional loss begins centrally at the level of hypothalamus and pituitary which, together with the changes at ovarian level, leads to the menopause[17].

With the loss of follicular activity, which usually occurs around the mid-sixth decade of life, a rapid fall of oestrogen levels ensues and FSH and LH levels rise due to absence of feedback inhibition. Consequences of a lack of oestrogen are manifold: Atrophy of oestrogen-responsive tissues, rapid loss of bone mass, adverse changes to the lipid profile with increased atherogenic risk, depressive mood swings, lack of concentration, anxiety and loss of libido. Vasomotor symptoms of hot flashes not only impair quality of life, but also represent altered blood vessel physiology that is associated with increased cardiovascular risk[18]. Since the reduction in oestrogen leads to a narrowing of the 'thermoneutral' zone of temperature regulation in the hypothalamus, small changes in core body temperature can trigger symptoms[19].

Oestrogen-containing hormone replacement therapy (HRT) can ameliorate vasogenic menopausal symptoms and delay biochemical changes. To avoid a concomitant excess risk of cardiovascular events, HRT should be taken early[20] and for a limited period only to minimize the additional hazard of thromboembolism and breast cancer[21]. Contrary to expectations, HRT in elderly women did not preserve cognitive ability but was associated with an increased risk of dementia and global cognitive decline that correlated with a reduction in hippocampal, frontal lobe and total brain volumes[22]. It should be noted, however, that some of the noted CNS effects might be (i) specific to the hormone molecule used in the quoted studies, (ii) related to the late timing of HRT, and (iii) due to elevated levels of LH itself, rather than related to oestrogen deficiency[23].

Andropause

Testosterone, the predominant male sex steroid hormone, is produced by testicular Leydig cells under the influence of LH and FSH. As in women, both gonadotrophins are released in pulses from the anterior pituitary gland under GnRH control. Testosterone levels in men follow a diurnal rhythm with peak concentrations occurring in the morning. At puberty, bioavailable testosterone levels begin to rise; they peak around the third decade of life and gradually fall thereafter at an annual rate of 1.3%[24]. Circulating testosterone binds to sex-hormone-binding globulin (SHBG) and, with less avidity, to albumin. Thus the availability of free testosterone reduces as SHBG levels rise

with age by 1.2% per annum. Leydig cell attrition, reduced steroid synthetic activity and a lower responsiveness to LH are the main testicular factors contributing to this decline[25]. The circadian variation in testosterone also declines with age. The term 'andropause' has hence come into use as a male equivalent to the menopause, even though the decline in sex hormone levels is gradual in men compared to the relatively sudden reduction in women.

Reduced testosterone availability exerts major metabolic effects on metabolism and thus lowers muscle mass and strength, raises body fat content and negatively affects bone health, libido and reproductive function, as well as mood and cognition[26]. As in menopausal women, the elevation of LH has been implicated in the pathophysiology of Alzheimer's disease in men, as low testosterone concentrations were correlated with increased amyloid-beta protein levels[27]. While a significant proportion of ageing males over the age of 65 years have reduced levels of testosterone, there was wide variability within a large cohort of community-dwelling men and serum concentrations were a poor indicator of symptoms[28,29]. A recent consensus statement therefore emphasized the need for correlation of clinical symptoms with testosterone levels, the lack of cardiovascular and bone fracture outcome data and the need for surveillance for prostate carcinoma, among others, in case of replacement therapy[30].

Thyroid Axis

The hormones thyroxine (or tetra-iodo-thyronine, T4) and tri-iodo-thyronine (T3) are synthesized and secreted by thyroid follicular cells. Only a small proportion of T4 is converted to T3 prior to its release from the thyroid; almost all of the remainder undergoes monodeiodination in peripheral tissues. T3 has greater biological activity than T4 and a shorter half-life. Plasma levels of both hormones are regulated by thyroid-stimulating hormone (TSH, also called thyrotrophin) that is released by the thyrotroph cells of the anterior pituitary gland, which in turn are under hypothalamic thyrotrophin-releasing hormone (TRH) control.

Virtually all tissues possess receptors for the thyroid hormones, through which the latter regulate the basal metabolic rate, tissue function, protein, fat and carbohydrate metabolism, as well as influence mental function and psychological well-being. The prevalence of thyroid autoantibodies significantly increases with age and, if primary thyroid dysfunction is present (subclinical or overt hypo- or hyperthyroidism), cognitive function is almost invariably affected[31]. Such conditions clearly merit thyroid hormone replacement or suppressive therapy, respectively. In primary hypothyroidism, the pituitary thyrotroph cells appear to lose their responsiveness to low thyroid hormone levels, as the TSH response was significantly reduced at ages over 80 years[32].

In a large, thyroid disease-free population, however, senescence *per se* led only to a minor increase in TSH levels, which remained well within the normal range[33].

Adrenocortical Axis

The hypothalamic–pituitary–adrenal (HPA) axis is central to the adaptive stress response that follows an initial, catecholamine-mediated 'fight-or-flight' reaction. Cortisol is released from the adrenal cortex following stimulation by adrenocorticotropic hormone (ACTH, also called corticotrophin), which is produced by the corticotroph cell population of the anterior pituitary gland. Corticotrophin-releasing hormone (CRH), from hypothalamic neurons residing in the PVN, regulates ACTH secretion in a diurnal pattern.

Cortisol is the main glucocorticoid in humans. It induces insulin resistance and raises blood glucose levels, causes protein and bone catabolism and an elevation in blood pressure. It also dampens the immune response. While a short-term stress response is necessary to deal with the challenges to the body's homeostasis, this reaction must itself be regulated. The hippocampus expresses glucocorticoid receptors and exerts inhibitory control over HPA axis activation, thus limiting the stress response[36]. The physiological day-to-day stress adaptation has been termed 'allostasis'[34], with its regulatory failure leading to an 'allostatic load'[35]. The hippocampus expresses glucocorticoid receptors and exerts inhibitory control over HPA axis activation, thus limiting the stress response[36].

The adrenal capacity for cortisol production is not affected by ageing, although its circadian rhythm is blunted and basal activity increased[37]. However, with advancing age the negative-feedback sensitivity reduces at hippocampal level and the HPA axis activity increases[3]. In both sexes, mean cortisol levels increased by 20–50% between the ages of 20 and 80 years[38]. Magnetic resonance imaging showed that the volumes of hippocampus and anterior cingulated gyrus were inversely correlated with baseline ACTH levels, and that older subjects demonstrated a slower decrease in ACTH in response to an infusion of cortisol than younger volunteers[39]. The stress-induced remodelling of the hippocampus and the resulting rise in glucocorticoid levels thus increases the allostatic load, with negative results for a range of metabolic parameters and the immune system that is associated with ageing[40].

Furthermore, the hippocampus and related limbic structures of the amygdala and pre-frontal cortex are of key importance for learning and memory function, including emotional learning and processing. Persistent elevation of glucocorticoid levels is involved in the emotional memory disturbances found in depression and posttraumatic stress disorder[41].

Adrenopause

Dehydroepiandrosterone (DHEA) and its sulfate ester (DHEAS) are abundant androgenic steroid molecules that serve as precursor molecules for other androgens and oestrogen. DHEA is produced by the adrenal cortex and also serves as a neurosteroid[42]. ACTH regulates its secretion and, in contrast to cortisol and aldosterone, DHEA levels physiologically decline with ageing from the third decade onwards by around 2% annually[43,44]. At the age of 80 years, DHEA concentrations are approximately 20% of those of younger controls[45].

Observational studies have associated low DHEA levels with cardiovascular disease, low bone density, type 2 diabetes, low mood and Alzheimer's disease. However, no causal relationship has been established[46].

DHEA replacement therapy is the focus of research for its potential anti-ageing properties in otherwise healthy older subjects. So far, however, no firm therapeutic indication has emerged[43,47].

NEUROHYPOPHYSIS

The posterior, neural lobe of the pituitary gland contains axonal projections of neurons from the supraoptic (SON) and paraventricular (PVN) hypothalamic nuclei. Axoplasmic flow transports arginine-vasopressin (AVP) and oxytocin to the neurohypophysis for storage.

The nuclei receive cholinergic and noradrenergic innervation and hormone secretion is triggered by a rise in plasma osmolality, reduction in circulating fluid volume, nausea, pain or emotional stress. While the AVP receptor V2 is mainly expressed in the kidney, V1a and V1b receptors are widely distributed within the brain[48].

Arginine-Vasopressin

AVP is central to the maintenance of fluid and osmolality homeostasis throughout life. Basal AVP levels in men were higher in older subjects and showed less responsiveness to fluctuations in osmolality compared to young volunteers. Reduced satiation to water consumption after induction of thirst by infusion of hypertonic saline was demonstrated by altered blood flow in the anterior mid-cingulate cortex on positron emission tomography[49]. The renal tubules become less responsive to AVP in ageing humans and rodents. In the rat, the reduced urine-concentrating ability was found to be due to a down-regulation of the V2 receptor, while AVP levels remained normal[50].

In addition to its function in fluid homeostasis, abnormal plasma AVP levels have been implicated in a range of mental disorders. Elevated concentrations of AVP have been noted in depression, posttraumatic stress disorder, acute schizophrenia and other mental illness[48]. In depressed patients with Alzheimer's disease, however, the content of AVP and oxytocin mRNA in SON and PVN was unchanged compared to controls, and there was no correlation with depression[51]. In rodent models and (confirmed in part) in humans, AVP has also been determined to modify memory and social behaviour such as aggression and affiliation[52].

Oxytocin

Oxytocin plays no significant physiological role in senescence. Basal levels and the response to hypoglycaemia-induced stress remained comparable in older compared to young men[53].

PINEAL GLAND

The pineal gland is situated within the roof of the third ventricle above the Sylvian aqueduct. In fish and amphibians the equivalent structure is light sensitive, whereas in humans the pineal gland receives input from the hypothalamic suprachiasmatic nucleus (SCN) that, in turn, is connected to the retina via non-visual photosensitive pathways. The SCN functions as the master clock for circadian rhythmic activity, which is further entrained by external zeitgebers.

Melatonin

The pineal gland synthesizes and secretes melatonin predominantly during periods of darkness and thus conveys a biological diurnal rhythm as well as an annual seasonal rhythm to the body.

While daytime melatonin production remains virtually unchanged throughout life, nocturnal secretion of melatonin peaks in early childhood and thereafter continuously declines with age. After the age of 60 years, peak peripheral night-time melatonin concentrations fall to 40 pg/ml, compared to 160 pg/ml at the age of 10 years. Background daytime levels are in the order of 30 pg/ml[54].

The SCN and the hypothalamus express a high density of MT1 receptors, allowing for chronobiological feedback to the central clock. In senescence, the circadian rhythm becomes weaker, sleep disturbances more common and there is an associated increasingly irregular diurnal melatonin secretion. The reduced number and density of MT1 receptor-expressing neurons that was found in the SCN of older subjects compared to young controls can, in part, explain this. In the last stages of Alzheimer's disease the prevalence of these neurons was further reduced[55].

Melatonin has non-sedative sleep-inducing properties, and trials of prolonged-release melatonin administration to patients with insomnia aged 55 years and older have shown to improve sleep quality, morning alertness and psychomotor performance. The supplement was administered for three weeks and no withdrawal or rebound symptoms were observed[56,57].

CONCLUSION

Complex neuroendocrinological changes occur during the healthy ageing process at hypothalamic, hypophyseal and target endocrine tissue level. There is increasing evidence that altered neuronal function with irregularities in biological rhythm and decreased secretory responsiveness leads to the significant reduction in availability of several peripheral hormones[3]. Declining levels of sex steroids, growth hormone, adrenal androgens and melatonin secretion contribute to significant adverse changes in body composition and endurance, cardiovascular risk profile, bone strength, sexual physiology, circadian rhythms, cognition and emotional and psychological well-being. Attempts at restoring youthfulness through the replacement of physiologically declining hormones have so far concentrated on time-limited, perimenopausal therapy with low-dose oestrogen. However, promising molecules to improve the growth hormone axis and the melatonin -mediated sleep–wake cycle are being tested. As senescence is a multifactorial process in which other morbidities and drug therapy frequently play a major part, any neuroendocrine changes should naturally not be viewed in isolation. Furthermore, whether a physiological change in life is perceived as being pathological and warranting treatment must be considered within the individual's social, environmental and lifestyle context. An optimistic outlook has the potential to prolong life considerably[58].

Genetic Aspects of Ageing

Ben Pickard[1] and Douglas Blackwood[2]

INTRODUCTION: LIVING LONGER VERSUS CHEATING DEATH

That there may be specific biological processes determining life span is an intriguing concept, and one which has attracted interest from both the academic and commercial sectors. Such interest has often focused on the simple numerical indicator of life span but this can often be at odds with the clinical perspective that centres on quality of life for the elderly. In this chapter we will review the latest findings and current ideas in the fields studying the biological process of ageing, its evolutionary underpinning and the genetic factors intertwined with environmental exposure that determine our life span. There is also a semantic issue of whether a discussion of ageing should include factors contributing to longevity if they merely afford protection against the dominant degenerative disorders or serious illnesses of the elderly or only concentrate on mechanisms that actively delay the ageing process[1]. Plainly, these two aspects of ageing are inextricably linked but from a research point of view, and in the context of genetic models, only the latter offers fundamental insights into the process.

AGEING GENETICS, HERITABILITY AND EVOLUTIONARY INFLUENCES

Danish epidemiological studies have reported that the heritability of human longevity is approximately 25%[2,3]: a figure similar to that for lower organisms. Thus there exists scope for the genetic dissection of the phenotype and a substrate for the processes of evolution to act on[4]. In its purest form, evolution requires that advantageous genetic variation is favoured and increases its frequency in the population through the process of natural selection. This is mediated through its ability to increase a carrier individual organism's 'fitness' and thus its ability to reproduce at a greater than average level. It can be appreciated that this raises fundamental conceptual issues in the context of the genetics of longevity. Female reproductive fitness, in particular, occupies only a proportion of the modern human life span and so it could be hypothesized that gene variants influencing life span in the age range from 55–85 years would be under minimal selection compared to those dictating survival within the 15–45-year age range. It has also been argued that, for some species, individuals living beyond reproductive age are counterproductive to species survival – they are a drain on limited resources and thus compete with actively reproducing individuals. Selection pressure for a biologically programmed 'cap' on life span might avoid this conflict. A second argument against a clear genetic contribution to human longevity would be the vast period of human existence on Earth for which 45 years was 'old age'. In the case of humans, long life spans are a modern phenomenon – average life expectancy dropped in the transition from 'hunter-gatherer' (Mesolithic Stone Age) to agrarian (Neolithic Stone Age) lifestyles[5] and did not significantly exceed the median life span of approximately 30–35 years until recent centuries. The implications are that not only does a long life harm fellow members of one's species, it also has no evolutionary outlet in the form of increased reproductive fitness. The genetics of ageing is left evolutionarily 'rudderless' in these circumstances.

However, two hypotheses offer an alternative view, supporting an evolutionarily 'visible' role for ageing. Firstly, the adoption of agriculture inevitably led to community living and increased social complexity. These social organization developments might be manifest in the altruistic role of the elderly in supporting the community – perhaps through leadership, childcare or other division of labour favourable for group survival. The impact of cultural effects (a form of environment) on ageing can never be entirely separated from genetics in the study of ageing in particular and will be covered in more detail below. Secondly, and perhaps more biologically tractable, is the argument that the genetic variants altering later life survival also play a role in earlier life fitness and are thus relevant to reproductive potential.

Finally, it is also worth considering the corollary of the sudden upturn in life span in recent human history – it has exposed humans to the consequences of genotypes that were never previously expressed for so long. For example, gene variants increasing susceptibility to Alzheimer's disease might be the result of random mutational drift or positive selection for their benefit in the young, but it is only now that they have been exposed to the environment of the ageing brain and consequently deemed pathological.

AGEING BIOLOGY: CLUES FROM HUMAN SYNDROMES

The fact that well-characterized human disorders of premature ageing (progeria) exist suggests that there are real biological processes at work, and ones which are tractable to genetics research. Individuals with progeroid disorders present with a spectrum of phenotypes which closely resemble natural ageing but these occur in young

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

adulthood or even childhood. A multitude of mutations in two particular genes, *WRN* and *LMNA*, account for the majority of these cases. Werner syndrome (WS) is perhaps the best studied of these and is caused by mutations in the *WRN* gene which encodes a helicase/exonuclease protein that functions during the critical processes of active nuclear DNA functioning such as replication, recombination and repair – when potentially pathological errors can be introduced into our DNA. Thus, the consequences to genomic integrity in WS patients are an accelerated version of those hypothesized to occur in normal individuals as a result of a lifetime of environmental exposure and mutation accumulation. The phenotypes are similar too, ranging from osteoporosis, cataracts, type II diabetes, atherosclerosis and cancers (particularly mesenchymal sarcomas) such that WS patients tend to die in their 50s as a result of complications arising from these conditions. Interestingly, the phenotypic spectrum of WS doesn't seem to include the neurodegenerative conditions such as Alzheimer's disease. It is tempting to speculate that these particular disorders are due to the accumulation of protein aggregates (plaques and tangles), i.e., protein attrition rather than genomic DNA attrition.

Mutations in the lamin A gene, *LMNA*, encoding a nuclear intermediate filament protein involved in the packaging of nuclear chromatin, cause 'atypical' WS, or in extreme cases involving a particular *LMNA* splice mutation, the severe and very early-onset Hutchinson–Gilford progeria syndrome (HGPS). A number of other rare progeroid syndromes exist and, of these, Cockayne syndrome type 1 (CS) is the only other one discussed here. This is caused by mutations in the transcription-coupled nucleotide excision repair genes, *CSA* and *CSB*, which also contribute to the cell's battle against genomic damage.

The genes emerging from these human conditions unequivocally point to the maintenance of genomic integrity as a vital process in ageing, involving the concerted action of several different systems to achieve it. Mutations in these systems seem to result in either progerias or cancer syndromes, or occasionally both (e.g. WS). It has been suggested that these alternative outcomes result from the specific responses to DNA damage initiated by the various systems: repair, apoptosis or senescence[6].

AGEING BIOLOGY: CLUES FROM LOWER ORGANISMS

The validity of certain mouse models of ageing has sometimes been questioned for the very reasons discussed previously – distinguishing genuine progeroid features from a numerically shorter life span due to pathological state[7]. Therefore, the presence of features such as kyphosis, as an indicator of an osteoporotic state, stereotypical fat deposition and atrophy of the epidermis are often employed as benchmarks of true ageing models. The progeroid conditions in humans point towards accumulating DNA damage as a mechanism of ageing and the increased life span of mice over-expressing the antioxidizing protein thioredoxin seems to confirm the importance of this process. However, other transgenic mouse models with modulated life spans suggest that additional contributory mechanisms are at play. Historically, it has been suggested that cellular, organ and organismal ageing are affected by the rate of cell proliferation and apoptosis. This has manifest itself in such concepts as the Hayflick limit[8] whereby oxygen levels encountered and cell divisions undergone are recorded by each cell using the gradual shortening of the telomere sequences located at the ends of chromosomes as an internal clock. At a defined telomere threshold length the cell enters a state of protective self-induced senescence, thus reducing the potential for DNA damage to be manifest as oncogenic cellular changes.

Indeed, a number of mouse mutations linked with altered life span involve proteins that can be classified as regulators of mitosis and cellular proliferation (e.g. p53, Brca1 and $p21^{WAF1}$) and these have been reviewed elsewhere[9]. Alternatively, other mouse models centre on the signalling pathways modulating and modulated by growth hormone, insulin and insulin-like growth factor such as the Ames dwarf and Laron mouse strains. Mice deficient for the *Klotho* gene product, encoding a hormone that inhibits the action of the insulin/IGF-1 pathway, show a progeria phenotype whereas *Klotho* over-expressing mice are longer lived. Finally, *SIRT1*, a member of the sirtuin class of genes, downregulates the production of insulin and IGF-1 thus promoting increased life span. These mouse models, particularly the dwarf strains, and other observations point to a correlation between longevity and body size within a species. It has been reported that shorter humans have on average a greater life span – this is even despite the observation that taller individuals are generally protected against atherosclerosis. The speculation is that body size is closely related to 'cellularity', or the number of divisions during the growth process. This in turn is a reflection of the proliferative potential of an individual's cells as discussed above. The correlation is clearly not a simple one as those with progeroid syndromes are often of short stature. Moreover, the role of the growth hormone/insulin pathway in aspects of cell proliferation, growth, DNA repair and caloric intake (discussed below) means that these processes are all interconnected at some level in their contribution to the rate of ageing.

Naturally, many mouse strains deficient in aspects of genomic repair have been generated given the seeming importance of this process in ageing. One intriguing and counterintuitive result comes from the study of *Csb, Xpa* and *Ercc1* mouse mutants and combinations thereof. These mice show definitive progeroid symptoms but also display a downregulation of the insulin/IGF-1 signalling pathway. Normally, such downregulation is protective and life prolonging as discussed in detail below, but in these instances it appears to be an innate compensatory mechanism responding to increased levels of genome instability.

It may be the case that ageing is such a fundamental property of life or the environmental insults so similar that organisms from across all taxa have adopted the same molecular machinery to counter it. In this way there are a growing number of studies which seek to address human ageing through the study of yeast, nematode worm and fruit fly in addition to the mouse. McCarroll *et al*. pursued this approach to the genetics of ageing by employing cross-species profiling of gene expression changes correlated with age[10]. What they observed was a shared set of age-responsive gene expression changes between the nematode *C. elegans* and the fruit fly *D. melanogaster*. Genes involved in oxidative metabolism (such as respiratory chain proteins, ATP synthase and citric acid cycle proteins) and active molecular transport were significantly reduced with age. However, the timing of these changes suggested that this was part of an active programme rather than solely a response to environmental attrition. For instance, in both species, experimentally reducing oxidative stress had the greatest effect on life-span extension during early adulthood. Conversely, modulating the insulin/IGF-1 system had a more pronounced effect on life span in the middle-aged organism. We can interpret these findings to mean that the body has set in place metabolic strategies to pre-empt and minimize the damage associated with ageing. As the authors suggest, a greater appreciation of human health-affecting behaviour in early adulthood might yield benefits in later life.

The same laboratory pursued the role of the *insulin/IGF-1* and *daf-2* (insulin/IGF-1 receptor) pathway that was already known to affect life span in *C. elegans*[11]. Using mutant strains and RNAi methodologies, they showed through microarray screens that the FOXO transcription factor *daf-16* is required to mediate this signalling pathway: *daf-2* deficiency releases *daf-16* from repression and allows it to activate its downstream target genes. Interestingly, the insulin/IGF-1 signalling system has close parallels in mammals – a mammalian orthologue of *daf-16* exists, *FOXO3A*, that is regulated by the IGF-1 pathway effector and ageing gene, $p66^{SHC}$. In the *C. elegans* experiment, sets of *daf-16* upregulated and downregulated genes were identified in longer living mutant strains. In the former group, the genes encoding for stress response and antioxidant genes such as *superoxide dismutase 3* and a *metallothionein* gene were identified together with lipid hormone metabolism and antimicrobial genes. In mammals, *FOXO3A* seems to additionally upregulate components of the genome maintenance pathway. In the latter, downregulated, group of genes were examples of metabolic genes, ubiquitination genes and genes of the vitellogenin structural egg yolk protein group. In the light of the earlier discussion regarding whether longevity is the result of active life extension or avoidance of death, it is interesting to see examples of both mechanisms (antioxidant/metabolic inhibition vs. antimicrobial) represented in the gene lists.

REACTIVE OXYGEN SPECIES, CELLULAR DAMAGE AND GENETICS

The damage to DNA and other cell macromolecules is caused by the reactive oxygen species (ROS) produced as a result of the energy-generating oxidative phosphorylation occurring within the mitochondria in each of our cells[12] – a small proportion of the oxygen consumed in this process is released as reactive superoxide species. Because mitochondria themselves possess a genome (encoding some of the components of the oxidative phosphorylation machinery) located near the source of the ROS, it has been suggested that it is very likely to be subject to high levels of damage (mutation accumulation) as the organism ages. Mitochondrial mutations would potentially cause feed-forward degeneration: a reduction in oxidative phosphorylation efficiency causing an increase in ROS production and, therefore, further propensity for cellular damage. Ageing not only results in the accumulation of mutations in the mitochondrial genome but it also permits the mutated genomes to accumulate within each cell (each cell has anywhere between 10s and 100s of mitochondrial genomes). At some point, a threshold will be crossed where the accumulating mitochondrial deficits impinge on cell function – and it can be appreciated that if such cells are part of the proliferating stem cell niche then either the dissemination of the deficit could be accelerated within a tissue or the proliferation process inhibited by the reduction in oxidative phosphorylation leading to a decrease in tissue regeneration[13]. It is now well documented that multiple organ systems are compromised by mitochondrial failure[14]. Perhaps due to their high energy demands, the central and peripheral nervous systems appear particularly susceptible to mitochondrial dysfunction which manifests itself in the form of neuropathies and dementia. Nevertheless, pathologies of the heart, lungs, musculature, pancreas and thymus have also been linked to mitochondrial failure in humans. Two studies have shown particularly clear age-dependent accumulation of definitively pathological mitochondrial mutations in the substantia nigra – a region of the brain implicated in the aetiology of Parkinson's disease in the elderly. The causal link with illness is not straightforward, however, as the mutation prevalence appears to be equal in aged individuals with or without Parkinson's disease[15,16]. Mitochondria, like nuclei, have dedicated mechanisms for repairing damaged DNA and thus mouse models have been generated that lack one of the repair proteins encoded by the *Polg1* gene. These mice have greatly increased levels of mitochondrial mutations and show a decreased life span associated with typical ageing phenotypes such as osteoporosis and weight loss[17,18].

A GENE–ENVIRONMENT INTERACTION BETWEEN CALORIC INTAKE RESTRICTION AND LONGEVITY

A longstanding direction for ageing research is based on the observation that a reduction in caloric intake results in not only an increase in life span but also an increase in general health including a reduction in illnesses of old age[19]. These studies seem to hold true across a wide range of species from yeast, *C. elegans* and *D. melanogaster* through to mouse and monkey. In terms of reproductive fitness, however, dietary restriction actually reduces fecundity. This suggests that variants leading to reduction in food uptake or slowed metabolism are unlikely to be favoured by genetic selection processes as they will be outcompeted by variants promoting an 'eat fast–die young' strategy that produces greater numbers of offspring.

Dietary restriction seems to exert its effect on life span through a number of mechanisms. These can be essentially divided into two classes: those that alter intracellular pathways governing metabolism and survival and those that counteract the production of the harmful reactive oxygen species that are a byproduct of the oxidative phosphorylation pathway[20].

As detailed earlier, metabolic control through the insulin and insulin-like growth factor pathway is implicated in ageing and this is highlighted by its role in the response to dietary restriction. In times of freely available nutrition, insulin signalling results in the phosphorylation and subsequent degradation of Forkhead transcription factors (*daf-16* in *C. elegans* and *FOXO3A* in mammals). However, when food is limited, these transcription factors are able to enter the nucleus where they activate a set of genes which are thought to mediate a change in organismal strategy geared towards survival or even hibernation-like states. New insights from *C. elegans* are rapidly filling in the gaps at the 'top' part of the pathway translating caloric restriction into longevity. The *eat-2* gene encodes a nicotinic acetylcholine receptor subunit which is involved in the innervation of musculature required for eating. Mutants for this gene mimic the dietary restriction phenotype of increased longevity because of mechanical difficulties in eating. This reduced ageing phenotype is absent, however, in the presence of a second mutation in *wwp-1*, which breaks the link between dietary restriction, altered metabolism and life extension. The *wwp-1* and *ubc-18* genes encode interacting E3 and E2 subunits, respectively, of a ubiquitin ligase complex that targets other proteins for destruction. Current research suggests that components of the TOR pathway (a sensor of amino acid nutrition) and PHA-4 protein (FOXA, a transcription factor that overlaps functionality with daf-16/FOXO) may be such targets, ultimately leading to the activation of the life-prolonging metabolic state[21]. TOR signalling has received considerable interest recently because a large-scale study of dietary supplements affecting ageing in mice showed that a TOR inhibitor, rapamycin, significantly extended life span[22] even when administered to aged mice. Rapamycin, already used as a cancer treatment, has immunosuppressant activity meaning that it is unlikely to be used as the first anti-ageing therapy.

However, direct suppression of the pathways targeted by TOR (translation of mRNAs into protein and the breakdown and recycling of cellular components through the process of autophagy) might provide more specific and less harmful therapeutic options.

Two principal conclusions can be made by the reader of longevity research literature. Firstly, the various pathways described above exhibit significant cross-talk at several levels. This cooperation is required to ensure detection and integration of all relevant nutritional/environmental signals and to coordinate responses across metabolic, cell cycle and genomic repair systems. Secondly, this is perhaps the clearest example of gene–environment interaction. It will be interesting to see how quickly this research moves from 'bench to bedside', either in the form of proactive and preventative health education policies or in the search for drug therapies mimicking the beneficial effects of dietary restriction.

Finally, we may speculate on the efficiencies of evolution such that the biological processes used by unicellular organisms to withstand primordial boom-and-bust conditions have been molecularly conserved but now reworked as homeostatic mechanisms impacting on cellular proliferation, fecundity and, ultimately, life span.

The Clinical Pharmacology of Ageing

Brian Clarke and S. H. D. Jackson

Department of Clinical Gerontology, Kings College Hospital, London, UK

INTRODUCTION

The proportion of the world's population over the age of 60 years doubled in the last century and will increase two- to threefold in the first century of this millennium[1]. This population has a higher prevalence of chronic illnesses including cardiovascular diseases, cancers, osteoporosis, diabetes, Parkinson's disease, dementia and many other conditions. An increasing body of research is adding further prescribing indications for diseases that occur in the elderly population. This, along with the increasing size of the population, means that the numbers of prescriptions for elderly patients are increasing. Depending on the age group between 60% and 80% of elderly people are taking medication and between 20% and 30% of these patients are taking at least three drugs[2]. It is also estimated that although those over 75 years account for 14% of the population, they receive 33% of medication prescribed[3].

An appreciation of the physiology of the ageing process and how it affects an individual's response to, and handling of, drugs (and drug combinations) is essential to ensure safe prescribing for this vulnerable population[4]. The ageing process can be described as the consequences of the sum of local effects at the cellular and molecular level. A feature of cellular ageing is the disruption of regulatory processes between cells and organs with consequent failure to maintain homeostasis. There is also time-related loss of functional units (the smallest structures still capable of performing the specific physiological activity characteristic to the organ involved) such as nephrons and neurons[5]. These age-related physiological changes affect all organ systems in the body, they significantly affect how the ageing body handles and responds to pharmacological agents and hence need to be considered when prescribing. Chronic illness in older age and related organ dysfunction can compound these ageing-associated changes.

In this chapter we describe the age-associated changes in physiology and consequent changes in pharmacokinetics and pharmacodynamics and their implications for prescribing in elderly patients.

PHARMACOKINETICS AND THE AGEING PROCESS

Pharmacokinetics is the description of how the body handles drugs after administration. It incorporates the liberation, absorption, distribution, metabolism and excretion of drugs and their metabolites. These processes may be affected by the physiological changes associated with ageing resulting in changes in the pharmacokinetics of drugs.

Absorption

Following administration, a number of factors affect a drug's entry into the circulation. These include properties such as particle size, molecular weight, charge, solubility and pK_a (the pH at which 50% remains in an un-ionized, lipid-soluble state). Most drugs are weak acids or bases and are present in solution as both ionized and non-ionized species. Non-ionized drugs are lipid soluble and diffuse easily across the cell membrane. Following liberation some absorption may take place in the stomach, depending on the pK_a of the drug and the pH of the stomach. Gastric acid secretion decreases with normal ageing, confounded by the widespread use of proton pump inhibitors and, to a lesser extent, H2 receptor antagonists, as well as eradication of *Helicobacter pylori*[5]. Drugs requiring an acidic environment to become ionized will be affected most (e.g. iron compounds). However, for most drugs the large surface area of the small bowel makes it the main site of drug absorption. With ageing, although many drugs show no change in absorption, there is slightly reduced small bowel absorption of some substances (including iron, calcium and sugar). There is slower colonic transit time with age, and an associated decrease in peristalsis, largely due a loss of neurons involved in control of the gastrointestinal tract[1]. Passive intestinal permeability is probably unchanged in old age for most substances. However, active transport of other agents such as vitamin B12 is impaired. The effects of these age-related changes would influence primarily those drugs with low permeability and low solubility, e.g. cephalexin. Agents such as benzodiazepines and lithium are readily absorbed. Some agents such as neuroleptics can be esterified with long-chain fatty acids to yield depot formulations that are only slowly absorbed from the site of peripheral injection, e.g. flupentixol where the elimination half-life ($t_{1/2}z$) can be prolonged from 6 hours to 36 hours by use of an intramuscular depot preparation.

Distribution

The volume of distribution (V), also known as apparent volume of distribution, is a pharmacological term used to quantify the distribution of a medication between plasma and the rest of the body after oral or parenteral dosing. It is defined as the volume in which the amount of drug would need to be uniformly distributed to produce a given plasma concentration. Put another way it refers to the fluid volume that would be required to contain all of the drug in the body at the same concentration as that in the blood or plasma. A drug

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

with a high V (e.g. morphine −300 litres) implies extensive distribution outside the blood or plasma to other tissues such as fat or muscle. The V is dependent on lipophilicity and the ability of the drug to bind to plasma proteins such as albumin (acidic drugs) and α1-acid glycoprotein (basic drugs) thus holding drug in the blood compartment and reducing V[6,7].

An initial phase of distribution reflects cardiac output and regional blood flow, to well-perfused organs (heart, liver, kidney and brain). A second phase, involving a larger fraction of the body mass, to muscle, skin, viscera and fat can take several minutes to hours to reach steady state. Drugs accumulating in a given tissue, such as fat, may serve as a reservoir that prolongs drug action in that same tissue or at a distant site[7].

With ageing there is a decrease in lean body weight, muscle mass and body water and an increase in body fat per kg of body weight. As a result, lipid-soluble drugs such as benzodiazepines, morphine, neuroleptics and amitriptyline have an increased V due to the higher proportion of body fat. With ageing the higher V for such lipid-soluble drugs, (along with reduced clearance) will result in prolonged elimination half-life and hence drug effects. For water-soluble drugs, V will fall hence higher concentrations will be reached after initial administration. Loading doses of water-soluble drugs should, therefore, be reduced in elderly patients unless the drug also binds to muscle such as digoxin when the muscle mass would be a relevant consideration.

Protein Binding

Many drugs are protein bound to a varying degree. Bound drugs are inactive. An unbound drug is free to mediate its effect. The binding is usually reversible. Most acidic drugs (diazepam, phenytoin, warfarin) bind to albumin. Basic drugs such as lidocaine and tricyclic antidepressants bind to α1-acid glycoprotein. With healthy ageing there is no substantial change in plasma proteins, however, intercurrent illness can result in a drop in albumin and an increase in α1-acid glycoprotein (an acute phase protein)[5]. Chronic disease tends to accelerate the age-related decline in serum albumin. This can produce clinically significant increases in the free fraction of very heavily protein-bound drugs such as ibuprofen (99.5% bound)[5]. Other highly protein-bound drugs include benzodiazepines (>90%) and many antipsychotics (>90%). Lithium, however, is not protein bound and is excreted unchanged rather than being metabolized.

Clearance – Hepatic

Hepatic metabolism of drugs is dependent on the ability of the liver to extract drugs from the blood passing through the organ. Lipophilic drugs are metabolized into more hydrophilic compounds to facilitate elimination, particularly through the urine. However, in some cases metabolites are biologically active or even toxic. Thus risperidone is metabolized to an active metabolite (9-OH risperidone) which has a $t_{1/2}z$ of 22 hours versus the parent drug $t_{1/2}z$ of 4 hours. Similarly, diazepam is metabolized to an active metabolite (desmethyl diazepam) and amitriptyline is metabolized to nortriptyline. Both active metabolites have a longer $t_{1/2}z$ than the respective parent drugs. In the liver, phase I metabolism introduces a functional group onto the parent compound, generally resulting in loss of pharmacological activity. Phase I reactions are located primarily on the endoplasmic reticulum and are performed largely through the cytochrome P450 system of enzymes. This family of enzymes oxidize, hydroxylate or hydrolyse the drug substrate[6,7]. Several studies have shown an age-related decline in the clearance of drugs by phase I metabolism, probably reflecting a reduced hepatic mass (and, for high clearance drugs, blood flow), as enzyme activity is preserved[5]. Induction or increased synthesis of the cytochrome P450 enzymes induced by drugs, such as phenytoin, isoniazid, glucocorticoids and alcohol, may decrease the bioavailability of parent drug compounds.

Inhibition of drug biotransformation enzymes, commonly by depletion of necessary co-factors, results in elevated levels of parent drugs. This can lead to increased pharmacological effects and an increased incidence of drug-induced toxicity. Inhibition of different isoforms of cytochrome P450 enzymes can be seen with erythromycin and ketoconazole (CYP450 3A4); SSRIs (CYP450 2D6). For two of these enzymes, CYP4502D6 and CYP4502C19, genetic polymorphisms exist that lead to poorly functioning enzymes causing individuals to be poor metabolizers. Thus when prescribing drugs metabolized by these enzymes where the therapeutic window is narrow, prescribing should be on the basis the patient is a poor metabolizer. For example when prescribing haloperidol starting doses should be those appropriate to poor CYP2D6 metabolizers.

Many pharmacokinetic drug interactions occur at the level of hepatic metabolism. For example the inhibition of clozapine and chlorpromazine metabolism by cimetidine.

Phase II reactions are conjugations. They are performed in the cytosolic compartment. Glucuronidation is the most important of the conjugation reactions. The increased water solubility of the glucuronide conjugates promotes their elimination in the urine or bile. Examples of drugs metabolized this way are benzodiazepines and morphine. The two main metabolites of morphine are morphine-3-glucuronide and the active metabolite morphine-6-glucuronide. Although they are formed in the liver they are excreted renally and hence accumulate in chronic kidney disease. Much less effort has been directed at the investigation of the effects of ageing on the conjugative mechanisms. In general, however, studies have not reported a major effect of ageing on the pathways of conjugation.

Clearance – Renal

Excretion of drugs and metabolites in the urine involves three processes: glomerular filtration; active tubular secretion; and passive tubular reabsorption. With ageing, renal mass decreases, as does glomerular filtration rate (GFR). There is also a reduced ability to concentrate urine and a reduced thirst during water deprivation.

GFR decreases at an average rate of 1 ml/min/year after middle age, and is often considered the most important pharmacokinetic change in older age. A normal GFR in a young adult is 120 ml/min depending on body size. Reduction in GFR with age affects the clearance of many drugs such as water-soluble antibiotics, diuretics and lithium and some non-steroidal anti-inflammatory drugs. Declining renal function cannot be quantified by measuring serum creatinine alone as creatinine production is a reflection of muscle mass, which declines with age. Clinically significant reduced renal function may be present with a serum creatinine still within the normal range. GFR can be calculated using several equations. The Cockroft–Gault (CG) equation uses age, weight, gender and serum creatinine[8]:

$$\mathrm{GFR(ml/min)} = 1.23 \times \frac{(140 - \mathrm{age})(\mathrm{years}) \times \mathrm{weight(kg)} \times (0.85 \text{ if female})}{\mathrm{Creatinine\ (\mu mol/L)}}$$

The Renal National Service Framework recommends that all laboratories report a formula-based estimation of GFR when serum creatinine is requested in adults[8]. The Modification of Diet in Renal Disease (MDRD) study equation (based on serum creatinine, age, gender and ethnic group) is widely used. The MDRD formula has the advantage of not requiring a weight, and can therefore be issued by the laboratory at the same time as a creatinine result is reported, however, it takes no account of muscle mass other than via age. Cockroft and Gault estimates tend to be lower than MDRD estimates. The adjustment of drug dosing in becomes particularly relevant where drugs are substantially or entirely excreted by the kidney. Routine pre-prescribing estimation of GFR is an essential adjunct to good prescribing in this vulnerable group. Given that the MDRD estimated GFR is now routinely provided this is the method of choice.

Where there is a narrow therapeutic index, significant toxicity can occur if doses are not adjusted downwards to account for renal impairment and subsequent reduced excretion. Examples include lithium, aminoglycosides and digoxin. Lithium toxicity is manifest as neuromuscular excitability, coarse tremors, fasicular twitching, motor agitation, delirium, nausea and even seizures if severely toxic. It is the most dialysable toxin known due to its low molecular weight. Indications to dialyse include high lithium concentrations (>4 mEq/L), or a concentration >2.5 mEq/L in a markedly symptomatic patient.

The presence of causes of chronic kidney disease such as hypertension and diabetes will potentiate the age-associated decline in renal function. It is especially important to review regularly drug therapy in frail older patients who may have, along with other known cardiovascular morbidities, undetected significant renal dysfunction.

Elimination Half-Life

The elimination half-life ($t_{1/2}z$) is the time it takes for the plasma concentration to be reduced by 50% during the elimination phase. This is distinct from the absorption half-life ($t_{1/2abs}$) or distribution half-life ($t_{1/2\ 1}$). It is a function of both volume of distribution and clearance, where clearance is the nominal volume of blood that is cleared of drug per unit time:

$$t_{1/2}z = V/Cl$$

where $t_{1/2}z$ = elimination half-life; V = volume of distribution; Cl = clearance

The $t_{1/2}z$ provides a good indication of the time required to achieve steady state after a drug is started, and also an estimate of the time required to remove a drug from the body, and of appropriate dosing intervals. It takes approximately five half-lives to reach steady state during chronic dosing and a similar time to remove the drug when dosing is stopped. Thus for amiodarone with a $t_{1/2}z$ in excess of two months in elderly patients, it would take at least 10 months to reach steady state or to remove the drug from the body. For lipid-soluble drugs, the elimination half-life increases with age, due to both reduced clearance and increased V[6,7]. For water-soluble drugs such as lithium the reduced volume of distribution partially offsets the effect of reduced clearance on $t_{1/2}z$.

Renal tubular interactions are a common cause of pharmacokinetic drug interactions. For example renal tubular reabsorption of lithium is increased by thiazide and loop diuretics. This leads to reduced clearance of lithium and hence rising concentrations. Thus therapeutic drug monitoring can help manage such interactions unlike pharmacodynamic interactions (see below).

Bioavailability and First-Pass Metabolism

Bioavailability is a term used to describe the fractional extent to which an unchanged drug reaches the systemic circulation from its original site of administration. This takes into account the absorption, hepatic metabolism and biliary excretion of a drug that may occur before an oral drug reaches the systemic circulation.

Drugs that undergo substantial first-pass metabolism in the liver are avidly extracted from the blood during passage through the presystemic circulation (gut wall and liver), reducing their bioavailability. Ageing is associated with a reduction in first-pass metabolism, probably due to a 20–30% reduction in liver volume with age and a concomitant reduction in liver blood flow. As a result the bioavailability of drugs that undergo extensive first–pass metabolism, such as chlormethiazole, propranolol and labetalol can be significantly increased[5].

Pharmacodynamics

Pharmacodynamics can be defined as the study of the biochemical and physiological effects of drugs and their mechanisms of action. This includes therapeutic effects and unwanted effects. The effect of ageing may result in increased or decreased effect of a given drug concentration, when compared to the effect of the same concentration in a younger patient. These changes in sensitivity occur independently of any changes in pharmacokinetics that may also exist. Drugs exert their effect by binding selectively to target molecules within the body, these are usually proteins, but are also other macromolecules. The main drug targets are receptors, enzymes, ion channels, transporters (carriers) and DNA. An agonist drug uses a receptor site to activate or enhance a cellular response to that specific receptor. Benzodiazepines, for example, act as agonists at GABAa receptors. A drug that binds to a receptor target but is unable to elicit a maximal tissue response, in effect demonstrating less intrinsic activity or efficacy, is termed a partial agonist. Buspirone is an example of a partial agonist at 5-HT_{1A} receptors, providing anxioselective effects without inducing extra-pyramidal side effects. The antipsychotic aripiprazole acts as a partial agonist at dopamine D2 receptors.

An antagonist binds to a target site and inhibits the action of an endogenous agonist at that site. Mirtazapine is an antagonist at presynaptic α_1-adrenergic, 5-HT_2 and 5-HT_3 receptors. Most antagonists are competitive, in that they bind reversibly to a site and the effect of the antagonist may be overcome by raising the concentration of the agonist, as an example, many antipsychotics competitively antagonize dopamine receptors.

Other mechanisms of antagonism include irreversible competitive antagonism, whereby raising the concentration of endogenous agonists does not overcome the antagonist's effect: selegiline, for example, irreversibly inhibits monoamine oxidase-B. Noncompetitive antagonist drugs do not block receptors, but block the signal transduction process initiated by receptor activation. Pharmacokinetic antagonism reduces free concentration of a drug by reducing its absorption or by accelerating its elimination. A chemical antagonist combines with the drug to neutralize its effect, e.g. protamine sulphate neutralizes the action of heparin[6,7].

Receptor activity and expression changes with ageing and the effect of age on drug sensitivities will vary depending on the drug studied. This makes generalizations difficult. However, there is evidence of reduced β-adrenoreceptor function in advancing age, reducing the elderly patients response to propanolol (β-adrenoceptor antagonist)

and salbutamol ($\beta 2$-adrenoceptor agonist). The responsiveness of α-adrenoceptors on the other hand is preserved with advancing age.

The ageing cardiovascular system also has reduced aortic and large artery elasticity and compliance, leading to higher systolic blood pressure, increased impedance to left ventricular ejection, with resultant tendency towards left ventricular hypertrophy. There is also a reduction in intrinsic heart rate and a reduction in baroreceptor sensitivity.

Orthostatic intolerance increases, as the response to posture change is blunted, leading to increased postural sway and propensity to falls[5,9]. This can of course be exacerbated by the concomitant use of anti-hypertensives and vasodilating drugs, and by drugs that may cause this as a side effect such as the α-blocker, tamsulosin.

In the brain, cholinergic function decreases with age, thermoregulation is also impaired, especially in frail individuals. There is also reduced shivering and vasoconstriction responses to hypothermia. Frail elderly patients are particularly prone to the adverse effects of neuroleptics, including delirium (anticholinergic effect), extrapyramidal symptoms (D_2 blockade), arrhythmias (prolongation of QT) and postural hypotension (α_1 blockade).

Of significant concern to elderly patients is the increased risk of death and cerebral ischaemia or stroke among those receiving treatment for psychosis or behavioural manifestations of dementia[10]. On the basis of 17 placebo-controlled trials of new neuroleptics, involving 5106 patients with dementia-related psychosis, the US FDA reported a 1.6- to 1.7-fold increase in the risk of death associated with all atypical antipsychotics[11]. The relative risk of stroke or transient ischaemic attack with risperidone is reported as high as 3.3 in this group versus controls[13]. It is, however, the only neuroleptic to have a marketing authorization for short-term use in the management of persistent aggression in patients with moderate to severe Alzheimer's disease.

There is increased sensitivity to the central nervous system effects of benzodiazepines, sedation being induced at much lower concentrations with advancing age. In addition these drugs are associated with an increase in postural sway and consequently falls. Table 10.1 lists some of the more common drug-specific pharmacodynamic changes that are seen with ageing along with some examples where ageing has no effect[5].

Pharmacodynamic drug interactions are those where drug A changes the effect of drug B without affecting its pharmacokinetics. Examples include the potentiation of the effects of lithium by calcium channel blockers, the lowering of seizure threshold by tricyclics and lithium reducing the effect of anticonvulsants.

ADVERSE DRUG REACTIONS

Approximately 5–10% of hospital admissions are related to managing drug-toxicity effects. Adverse drug reactions (ADRs) are common in elderly patients – it has been estimated that ADRs are the fourth to sixth leading cause of death. When adverse reactions occur in elderly patients, they are more likely to be severe and are less likely to be reported or recognized[1]. ADRs can be described as dose related, in that they are predictable based on the drug's pharmacological properties. Alternatively they may be idiosyncratic and not predictable on the basis of the pharmacological properties of the drug. These are often of an unknown mechanism and more likely to be more serious than dose-related ADRs (e.g. anaphylaxis)[1,13]. Recent data suggest that half of all disability or premature deaths from medication-related problems are preventable through prescribing vigilance and monitoring[3].

The presence of multiple drug treatments has been identified as an important factor associated with ADRs – the more medication the greater the chance of an ADR. However, ageing can be associated with an increased risk of adverse effects due to changes in pharmacodynamics independent of pharmacokinetics and multiple drug prescriptions. Non-steroidal anti-inflammatory drug (NSAID)-induced adverse events such as gastrointestinal haemorrhage and perforation increase with age, as does NSAID antagonism of antihypertensive therapy.

POLYPHARMACY VERSUS APPROPRIATE PRESCRIBING

The art of prescribing for the elderly patient is a balance between the conflicting demands of research evidence, practical considerations and patients' wishes. Polypharmacy can be defined as the concurrent use of multiple drugs (variously defined as the use of five or more drugs). It is no longer a useful term as it fails to encompass the omission of treatments for which there are clinical indications. Appropriate prescribing has been used to describe various aspects of medicines such as formulation and packaging, but should also be used to cover overuse, underuse and misuse of treatments. This term therefore describes not only the omission of medicines not indicated but also the use those that are indicated[14]. The National Service

Table 10.1 Selected pharmacodynamic changes with ageing

Drug	*Pharmacodynamic effect*	*Age-related change in sensitivity*
Adenosine	Heart-rate response	⇔
Diazepam	Sedation, postural sway	⇑
Diltiazem	Acute and chronic anti-hypertensive effect	⇑
Diphenhydramine	Postural sway	⇔
Enalapril	ACE inhibition	⇔
Furosemide	Peak diuretic response	⇓
Heparin	Anticoagulant effect	⇔
Morphine	Analgesic effect, respiratory depression	⇑
Temazepam	Postural sway	⇑
Warfarin	Anticoagulant effect	⇑

⇔= no significant change; ⇑= increase; ⇓= decrease

Table 10.2 Causes of suboptimal drug prescribing

Clinical skills
• Inadequate clinical assessment leading to incorrect diagnosis
• Failure to obtain history of or document previous adverse drug reactions
• Failure to record current medication including over-the-counter medication
• Failure to monitor response to treatment
• Failure to recognize potentially serious drug interactions
• Failure to recognize subtle adverse drug reactions
• Failure to review repeat medication
• Failure to take account of altered pharmacokinetics and pharmacodynamics
• Simple error

Source: Modified from the Royal College of Physicians[16]

Table 10.3 Prescription checklist

• What are the patient's views?
• What is the diagnosis (or diagnoses) you are treating?
• What is the main aim of treatment?
• What are the treatment possibilities in this patient? (non-pharmacological potential?)
• How are your preferred drug and its metabolites (if active) cleared?
• Will other disease states affect your choice?
• Will physiological states (e.g. ageing) affect your choice?
• Could one drug treat more than one problem?
• What is the best route and dosage?
• When will you dose titrate?
• What will its duration be?
• What are the potential adverse effects?
• What potential drug interactions are relevant?
• Would discontinuing another drug help?
• What information should you discuss with the patient?

Framework for Older People highlights the need for appropriate prescribing[15]. Optimizing prescribing includes developing an awareness of the causes of suboptimal prescribing (Table 10.2) and the use of a prescription checklist to aid decisions (Table 10.3). Certain drugs should be actively avoided in elderly patients including: long-acting oral hypoglycemics as they present a high risk of hypoglycemia; long-acting benzodiazepines due to an increased risk of falls and disorientation; and non-selective anticholinergics as they can impair cognition and have significant peripheral anticholinergic side effects.

CONCLUSIONS

The ageing process is characterized by functional changes in all organ systems and results in reduced homeostatic capacity. These changes affect the pharmacokinetics and pharmacodynamics of many drugs commonly used in this age group. The high prevalence of co-morbidities and consequent high number of concomitant prescribed drugs are major factors in the development of ADRs. The reduced functional reserve associated with ageing is also responsible for an increased vulnerability to the effects of prescribed drugs and ADRs. A knowledge and appreciation of these processes, and their consequences, is necessary to ensure appropriate and safe prescribing in this age group.

Cognitive Gerontology

Patrick Rabbitt

Neurocognitive Development Unit, School of Psychology, University of Western Australia, Australia

'Cognitive gerontology' is the study of changes in mental abilities and behaviour in old age and so also of changes in the brain and central nervous system that cause them. It developed alongside the rapid growth in academic psychology during the 1950s, promoted by the respect, and the access to funding that investigators, who then termed themselves 'human experimental psychologists', had gained by work on military applications during World War II. Leading figures of that decade were James Birren in the USA and Alan Welford in the UK. Welford was trained in applied experimental psychology and in ergonomics by Sir Frederick Bartlett. His book, *Ageing and Human Skill* (1958), summarizes his research with gifted colleagues in the Cambridge UK Nuffield Unit[1]. This was funded to discover how the contributions of older workers to the post-war economy might be optimized by appropriate training, systems and equipment. Present sensitivity to the imminent demands of ageing populations makes these key aims of current cognitive gerontology. Birren, was convinced by his work with the distinguished psychophysicist, 'Smitty' Stevens that the study of perceptual systems and response times must be the most direct way to use behavioural evidence to deduce changes in the central nervous system. He greatly broadened this view when he became director of the Section on Aging in the National Institutes of Health in Bethesda, MD, where his congenial personality facilitated collaborations that confronted him with medical, biological, epidemiological, demographical and social concomitants of old age. His friend Nathan Shock had begun at Baltimore the first, longest and most thorough longitudinal study of physiological, medical social and psychological changes in a large sample of older people[2]. From Shock's experience Birren learned to appreciate the separate and interacting effects of these factors in contributing to the enormous variability between individual trajectories of ageing – points missed by colleagues with backgrounds solely in 'mainstream' psychology who, because neurophysiological data was then unobtainable, typically borrowed from 'mainstream cognitive psychology' experimental paradigms originally designed to test functional models of mental abilities in young adults. The study of age changes in mental abilities potentially offered a timely challenge to the models then current in mainstream cognitive psychology which, at that time, represented unrealistic 'steady-state' systems that described neither individual differences nor processes of change within them. This challenge was not met until the late 1990s, when unanticipated results from brain imaging and electrophysiology began to bring into question models that had been derived solely from behavioural evidence. These new opportunities now allow us more sensibly to address some of the basic questions for cognitive gerontology: Why do cognitive changes occur? Are they inexorable or can we delay them? What, precisely, are the changes that occur in the brain and central nervous system and how do these affect mental abilities and behaviour? When do changes first begin and how fast do they proceed? Do all individuals age at the same rate or do some age earlier and faster than others? Do all cognitive abilities change at the same or at different rates? Do individuals experience similar or different patterns of changes in their abilities? How does ageing affect our everyday cognitive competence and what can we do to mitigate its effects?

Physiologists had long recognized that because changes in the brain, body and central nervous system occur at markedly different rates in different species and individuals it is not useful to index ageing only by calendar time. They tried to derive algorithms to quantify progress of 'biological ageing' from a variety of different markers of the progress of physiological change[3]. These algorithms are interesting in actuarial and epidemiological contexts, but have proved less fruitful than study of associations between changes in specific biological subsystems, such as are involved in vision, hearing, touch and motor control and concomitant changes in mental abilities. Sensory changes evidently affect cognitive abilities because losses of visual acuity contrast sensitivity and colour vision[4], hearing, especially in higher frequencies, tactile sensitivity, smell and taste all degrade the information that we need to perceive and interpret objects and events[5] and losses of fine motor control impair our ability to respond rapidly and appropriately to our environments[6]. However in addition to these direct effects of information degradation, sensory changes also have other 'knock-on' entrained effects because the additional effort necessary to resolve degraded sense data draws on the limited pool of information-processing resources necessary to interpret and remember what we have seen or heard[7,8]. Because the time courses of sensory changes correlate robustly with those of declines in mental abilities such as intelligence, decision speed and memory, amounts of sensory losses are very effective biological markers for the extents of cognitive changes[9,10]. A logical problem in interpreting such associations between changes is key to many issues in ageing studies: because all physiological, neurophysiological and cognitive changes occur over the same periods of time between their progress are inevitable but may be as functionally uninformative as between independent clocks running at different rates. Imaging of brains *in vivo* now resolves this issue, showing that most of the shared variance between sensory and

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

cognitive changes is accounted for by concomitant gross changes in brain volume and blood flow[11] and prevalence of white matter lesions[12].

A further question is what are the basic functional causes of these interdependent changes in general physiology and neurophysiology? Whether, for example, they are the burden of damage from pathologies and accidents that accumulates throughout the lifespan or whether some other processes, distinct from the effects of the sum of all pathologies and acquired physiological damage, that acts on all biological systems, though possibly at different rates, that is possibly genetically programmed, and so can be loosely described as 'biological ageing'. Like most apparent dichotomies in the 'nature/nurture' debate, this is misleading because both endogenous and exogenous factors operate jointly and strongly interact. There is good evidence for a 'medical model' of ageing based on the premise that, even after differences in their calendar ages have been taken into account, the pathologies and 'negative biological life events' that individuals have experienced account for a large proportion of the variance in mental abilities between them. Exceptionally healthy older men retain greater ability than those with poorer health[13]. Mental changes accelerate as death approaches[14] and some terminal pathologies, such as diabetes and infections, are associated with faster 'terminal decline' in cognitive abilities than others[15]. Thus, even apart from the incidence of particular neuropathologies such as dementias and cerebrovascular accidents that directly affect brain integrity, a substantial proportion of age-related decline in mental abilities is driven by a variety of pathologies that affect cerebrovasuclar sufficiency and brain metabolism. It would be useful to have quantitative estimates of exactly how much of that proportion of variance in mental abilities between older individuals, that is associated with differences in their calendar ages, can be accounted for by experience of particular pathologies. Though exact quantitative data are not yet available it seems no longer useful to argue whether cognitive changes are brought about 'mainly' by inexorable processes of endogenous 'normal ageing' or 'mainly' by pathologies and accidents. New technologies such as brain imaging, transient magnetic stimulation and cortical evoked potentials will soon tell us to what extent the amounts and patterns of central nervous system changes differ between individuals, what pathologies, genetic factors or life events may produce faster changes or different patterns and precisely how brain changes affect different mental abilities.

'Cognitive gerontology' is now a science in transition between a legacy of models to interpret a rich archive of behavioural observations and to gain an increasingly better understanding of the relationships of changes in abilities to the ageing brain and central nervous system that reveals these models to be inadequate – as indeed their proposers knew that they would as better neurophysiological evidence accumulated.

Discussion of the behavioural legacy may begin with Jim Birren's conviction that measurements of response times are an exceptionally good tool to investigate age-related cognitive change[16,17]. This idea had been reinforced by Joseph Brinley's discovery that exact estimates of average decision times for groups of older adults can be closely estimated by multiplying those of young adults by a simple constant[18]. John Cerella verified this for reported data from 108 different tasks on which older and younger groups had been compared[19]. Tim Salthouse greatly extended the implications of these findings by a further discovery that age-related variance in response times can also account for most of the age-related variance in errors on tests of verbal memory in which decision times are not constrained[20,21]. He argued from this that 'general slowing' of the cognitive system not only reflects, but also is the main functional driver of losses in all or most other mental abilities, so that behaviourally measured changes in performance on all, or most, cognitive tasks can be related to changes in a single, very simply measured, index of task performance. This idea became central to discussions for the next 20 years. This was a very powerful theory, but also became uncomfortable because it seemed to leave nothing further to investigate.

Investigators attempted various escapes. Some argued that 'general slowing theory' confused levels of description because behaviourally measured performance indices, such as response times, are distinct logical entities from psychometric statistical constructs such as 'general fluid intelligence' or 'information processing speed' that are computed on the basis of shared variance between performances on different tasks, and that both these entities are distinct from 'neurophysiological system characteristics': the many and various properties of neurones and their mutual interactions that determine their efficiency. Others re-evaluated the implications of the simple linear scaling suggested by 'Brinley plots'[22].

Other investigators beyond discussions of simple relationships between task complexity and averages of decision times to propose sophisticated models to account differences between distributions of response times produced by older and younger adults[23,24]. A third escape from the constraints on discussion imposed by 'general slowing theory' derived from observations that neuronal changes occur earlier and are greater in the frontal and prefrontal and temporal cortex than in other parts of the brain[25]. This makes it plausible that tasks derived from diagnostic tests for frontal damage, such as inhibition of irrelevant information in perception, planning, 'working' memory or task alternatives, may be especially sensitive to increasing age. Considered across all published studies in which no neurophysiological information is available, have been unclear. This is probably because while it is increasingly apparent that the range and variety of patterns of brain ageing differ widely between individuals behavioural comparisons have been made on small samples often of 20 persons or fewer who have not been selected on imaging data. Nevertheless more sophisticated mathematical analyses do suggest that some differences in distributions of reaction times and errors consistent with the frontal ageing hypothesis can be found, even on relatively small and unselected samples.

The frequency of elderly individuals' complaints of memory inefficiency is second only to that of their complaints about arthritis[26]. Nevertheless subjective reports of memory problems seem to be associated more with current levels of depression than with objective performance. Models for age-related declines in memory efficiency have been influenced by evidence of 'general slowing'. Craik and Lockhart showed that because the longer people are allowed to inspect and process words the better they can subsequently recall and recognize them, consequently age impairments can, at least partly, be attributed to reduced 'depth of processing' caused by slowing of information processing[27]. There is also support for the idea that impairment may be specific to some aspects of memory tasks rather than general to all. Craik and Byrd report that age impairs the ability to select critical information to be remembered[28]. However, discussions of age-related memory losses have been less constrained by the 'general slowing' hypothesis because most investigators have been more concerned with the nature of our memory representations of events and information than with the speed with which these can be established and retrieved. Consequently, a large literature discusses whether old age makes it more difficult to encode and recall some kinds of information rather than others. Differences are reported between verbal and

spatial information, for faces, for proper names, for hymn tunes, and for the sources and context of correctly recalled material. There are also 'natural history' experiments comparing age-differences reports of vividness, detail and accuracy of so-called 'flashbulb memories' of striking public or private events (e.g. see[29]). Another critical distinction is between memory for information that has been acquired, used and so rehearsed over many years and memory for more recently learned material (e.g. see[30]). Conceptually related to this distinction between memory for recall of recent and distant information, for more and less frequently rehearsed material and for more and less emotionally charged and striking information are investigations of the numbers of memories that elderly people can retrieve of events from different periods of their lives[31]. Most studies find a scarcity of quantity, but not necessarily of the vividness of memories from childhood. This contrasts with a 'reminiscence bump' of memories relating to adolescence and young adulthood, with a marked decline in memories for the very recent past[31]. One explanation is that the greater efficiency of the central nervous system in youth makes memories of earlier experiences more detailed and durable. Another is that events experienced in youth are, at least when they are experienced, novel, possibly also more exciting and are likely to have been more frequently recalled in subsequent years than the probably more often repeated, and possibly more banal, experiences of late middle age and senescence. Consistent with this idea are findings that, irrespective of the ages of individuals when they experienced them, particularly eventful historical periods such as World War II are especially numerous and vivid, and of course also more often provide material for reminiscence.

This distinction between the ability to recall and to use information and skills acquired over a long lifetime and continually updated by practice and the ability to remember new information and events and to learn new lessons from them is a key issue that differentiates between the study of abilities in old age and in youth. It is best defined in the work of John Horn who distinguished between what he termed 'fluid abilities' that are early impaired by age and 'crystallized' abilities' that show relatively little decline[32]. Fluid abilities are indexed by scores on tests of general intelligence and of the ability to acquire and recall new information and 'crystallized' abilities are indexed by tests of acquired, and subsequently continuously practised, material such as vocabulary and social skills.

Memory studies have also been influenced by the hypothesis that because ageing affects the frontal and temporal lobes of the brain earlier and more severely than other areas, so the selection of relevant from irrelevant information held in memory must be more sensitive to age than other abilities (e.g. see[33]). Also associated with the frontal and temporal lobes are the abilities, collectively termed 'prospective memory', to use past information to anticipate what is likely to happen next, to plan how to cope with anticipated events and to retain these plans until they can be appropriately implemented[34]. A key insight has been that, in old age, the efficiency of prospective memory, as indeed other kinds of memory, depends on the availability of environmental information to support recall.

Studies of cognitive ageing use two methodologies: cross-sectional comparisons between groups of different ages and longitudinal studies in which the same groups are repeatedly assessed. These can very profitably be combined by analyses including both kinds of comparisons[35] (see Baltes, 1968). A pervasive difficulty for both is inadvertent selection of participants. Elderly individuals who volunteer for demanding studies are atypically able and well members of their generations and are usually also better educated, more likely to have practised intellectually demanding professions and are usually also not socioeconomically disadvantaged. Representation of ethnic minorities is also questionable. In more arduous longitudinal studies self-selection of volunteers not only biases initial recruitment but also brings about selective attrition because less healthy and so least able participants withdraw or die leaving a progressively elite group of survivors. So, in longitudinal studies, true rates of cognitive change will be miscomputed unless the incidence of these deaths and dropouts is taken into consideration[14]. Another difficulty for longitudinal studies of mental abilities is that if participants are repeatedly given the same, or similar, tests even at intervals of many years, they show significant practice effects. This also leads to potential miscomputations of trajectories of change, more particularly because older and less able individuals, and those who approach dropout or death, experience less improvement from practice than the younger, more intelligent and more healthy. Anstey, Hofer and Luszcz illustrate how some of these issues can be dealt with in an exploration of both cross-sectional and longitudinal examinations of the ways in which correlations between sensory and cognitive variables change over time[9].

It is becoming questionable whether very large and prolonged longitudinal studies that collect only behavioural data on cognitive change, with additional data on health and demographics, are the most resource-effective way of learning how and why age affects mental abilities. The rapid development of non-invasive brain imaging means that we can now detect changes in the brain and central nervous system over periods measured in months rather than decades that can be related to cotemporaneous patterns of cognitive changes within individuals. Thus, even with small samples we can study variability in idiosyncratic patterns of brain changes and correspondingly patterned changes in cognition[36]. Raz *et al*. provide excellent general discussions of how such studies can be carried out and what they can tell us[37]. An explosion of studies of relationships between changes in specific brain locations and in particular aspects of cognitive performance includes age differences in the functional neuroanatomy of verbal recognition memory[38], the functional neuroanatomy of age related changes in visual attention[39], changes in entorhinal cortex and losses of memory function, age-related differences in working memory using real-time fMRI, differences in brain activity associated with age-related changes in memory function and brain changes associated with changes in motor performance.

These relationships between changes in specific brain locations and in specific abilities proceed against a background of global changes affecting all parts of the brain such as increasing prevalence and distribution of white-matter lesions, losses in brain volume and declines in cerebral blood flow that all appear to be associated with declines in information processing rate[11,12]. This complicates interpretation of cognitive effects of localized brain changes that may be masked or blurred by these global changes that affect all systems, but to different degrees. This may partially explain apparent contradictions between the results of the many studies using behavioural evidence alone to test the sensible hypothesis that earlier and faster 'ageing' of the prefrontal cortex must result in correspondingly more marked age decrements in abilities such as working memory, planning, attention and executive functions. For example most of the adapted behavioural clinical diagnostic tests for frontal damage tests used to test this hypothesis are scored in terms of the relative speed with which decisions can be made. Since we know that gross brain changes such as white-matter lesion incidence specifically impair processing speed, scores on so-called 'frontal' tasks must evidently reflect some complex combination of local and global effects. It is therefore unsurprising that comparisons between small groups of 30 or fewer individuals

for whom information on brain status is not available should only sometimes find evidence for the 'frontal ageing' hypothesis.

With these cautions, 'cognitive gerontology' is now becoming an exciting science in which a rich body of behavioural data and growing sophistication in understanding brain changes is rapidly transforming our understanding of how and why our mental abilities change, why all of us do not change at the same speed or in the same ways and, hopefully, suggest what we may do about this.

Chronological and Functional Ageing

David Melzer and Iain Lang

Peninsula Medical School, University of Exeter, UK

INTRODUCTION

Ageing is a surprisingly difficult process to define or measure. In a superficial sense it is everything that happens to an individual over time but, for geriatricians and gerontologists, notions of ageing are tied to physiological deterioration and increasing vulnerability to diseases absent in the young. This notion of ageing is synonymous with 'senescence' and is defined[1] as progressive deterioration during adult life that underlies an increasing vulnerability to challenges and a decreased chance of survival.

The relationship between chronological and functional age has implications for ageing research and public policy. In this chapter we describe more meaningful ways of thinking about human ageing than through the proxy of elapsed time, or chronological ageing.

THE PLASTICITY OF AGEING

Ageing is widely seen as the result of lifelong accumulation of random molecular damage[2]. Damage results in declining function at many levels[3], including in mitochondrial function, DNA transcription (through unrepaired somatic DNA mutations) and in the ability of cells to divide and repair tissues. The balance between damage and repair mechanisms determines the amount of unrepaired damage, which manifests as ageing at the cellular and organism level. Secondary responses to damage can then occur, including chronic inflammation, hypothesized as a major element in human ageing[4].

Ageing processes are surprisingly plastic and variable. This is evident at all levels from the molecular to the societal and global population levels. The most dramatic demonstration of the plasticity of ageing is the finding that hundreds of mutant genes (mainly knockouts) can produce radical life extensions in model organisms[5]. In addition to affecting stress responses and telomeres, endocrine signalling has also emerged as particularly important in these models. In general, the impact of 'longevity' gene manipulation on lifespan becomes progressively smaller on moving up the evolutionary ladder[6] and relevance to human ageing is speculative.

In addition to genetic manipulation, caloric restriction in laboratory settings also increases lifespan when compared to unlimited feeding[7,8]. In humans, obesity is a risk for mortality and functioning in older people[9] but whether there are benefits in radically reducing caloric intakes below those required for maintaining a healthy weight is unclear.

The variability of ageing in humans is apparent both in single organs and in the longevity and functioning of individuals. Analyses of the Baltimore Longitudinal Study of Ageing have shown marked heterogeneity in the rates of decline in function of different organ systems: for example, mean maximum work rate and renal blood flow generally decline far faster than measures of nerve conduction[10]. More surprising, individuals show great heterogeneity in patterns of impairment of individual systems, with little indication of typical patterns. In human population studies, it is usual to find people functioning at a higher level than others aged 20 or 30 years younger.

One potential means of identifying an individual's 'true' age is through identifying biomarkers of ageing. The concept of biomarkers of ageing is appealing because it implies biological measures can reflect the rate of ageing and that successful interventions on the ageing process may affect these markers. The American Federation for Aging Research proposed that a biomarker of ageing must[11]:

- predict the rate of ageing – i.e. it should be a better predictor of lifespan than chronological age;
- monitor a basic process that underlies the ageing process, not the effects of disease;
- be testable repeatedly without harming the person;
- be valid in humans and in laboratory animals.

Markers showing potential include telomere length[12]and $p16^{INK4a}$ expression[13].

The search for biomarkers of ageing assumes there is an underlying biological state of ageing that can be summed up as a single number but counterarguments regard ageing as a complex, uncoordinated phenomenon that cannot be encapsulated so simply[14]. Despite much research effort, most gerontologists accept that no biomarkers of ageing have yet been validated[11,15].

FUNCTIONAL HEALTH STATUS

A key aspect of functional ageing or functional health status assesses functioning at the level of the whole older person. Functional health status is related to chronological age, disease and need for care, and understanding the functional aspects of ageing is an important part of geriatric medicine. In the medical model of disease, the clinician gathers symptoms and signs, makes a diagnosis and bases the therapeutic approach on this diagnosis. Complementing this

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

disease-orientated approach, functional assessment provides an understanding of the impact and consequences of the older person's disease or diseases, giving information on level of independence and prognosis, as well as health care, rehabilitation and social needs.

Since a major impact on functional health comes from disease, a framework that represents the relationship between disease and disability is valuable in developing the concept of functional ageing. The World Health Organization (WHO) originally proposed a theoretical pathway progressing from disease to impairment to disability to handicap[16]. An alternative pathway, proposed by Nagi[17] and utilized by the US Institute of Medicine[18], progresses from diseases and conditions to impairment to functional limitation to disability. An effort to operationalize this latter pathway defines 'impairment' as dysfunction and structural abnormalities in specific body systems, 'functional limitation' as restriction in basic physical and mental actions such as ambulating, grasping, and stepping up, and 'disability' as difficulty in doing activities in daily life such as personal care, household management, job and hobbies[19]. The importance of identifying external factors that needlessly cause disablement outside the individual is a major theme in the more recent WHO classification systems[20].

Means of assessing and reporting functional health status include the following.

Self-Reported Functioning

Physical functioning shows a downwards trend with age and is often assessed through self-report of the ability to perform specific tasks, including self-care activities such as bathing and dressing (activities of daily living), and activities necessary to maintain independence in the community, such as shopping and food preparation (instrumental activities of daily living)[21–24]. A concern with self-reported functioning is that different individuals and groups may have different thresholds for reporting difficulty or inability to carry out activities[25].

Performance Measures

Performance measures of functioning, in which the individual is asked to carry out standardized tasks, offer a way of benchmarking function and comparing over time or across populations[26]. Self-reported functional status may differ from measured function for a variety of reasons, including differences in the domains measured. Assessing both allows us to combine an objective measure of poor performance with an indication of how much everyday function is affected[27]. Tests of physical function are used in clinical assessments of older people[28,29] and can help identify individuals with pre-clinical limitations who are at increased risk of developing disabilities[30,31]. One established measure is the short physical performance battery, including measures of gait speed, chair stands and tandem balance tests: this score has been widely used in clinical settings for the assessment of mobility limitations[32]. Other approaches include these measures plus muscle strength and respiratory function[33].

Frailty

Frailty, generally taken to mean multisystem impairment and a high level of vulnerability, has been defined in two ways: as a phenotype; and as a score of age-related deficits or 'frailty index'. The phenotypic approach defines frailty as a clinical syndrome in relation to five criteria: unintentional weight loss (10 lbs or more in the preceding year); self-reported exhaustion; weakness (grip strength); slow walking speed; and low physical activity[34]. Using these criteria, individuals are defined as either frail (three or more criteria present) or not frail (fewer than three criteria). The frailty index approach sums the number of age-associated deficits experienced by an individual, including symptoms, signs, diseases and disabilities[35] (Rockwood 2007). The resulting score provides an indication of the likelihood that frailty is present, and the index demonstrates characteristic changes with age. Each of these operationalizations of frailty has been validated in multiple populations. Although the two approaches overlap there are substantial differences between them[36] and it has been suggested each represents a different form of frailty and a different trajectory of age-related loss of function[37].

Cognitive Function

Age-related functional decline has cognitive as well as physical aspects. These often occur together, and they share some risk[38] as well as protective[39] factors. The care burden associated with dementia, on both a societal[40] and a household level[41] level, is large. There are major public health concerns about the impact on health and social care services of growing numbers of older people with declining cognitive function and dementia[42]. Among the challenges of dealing with this growing problem is the shortage of effective treatments for dementia, and attention has been drawn to identifying individuals with mild cognitive impairment – that is, those who are not demented but have a memory impairment beyond that expected for age and education[43]. Cognitive function and dementia are covered in more details in Part IV of this book.

Factors Affecting Functional Health Status

The prevalence of disability in activities of daily living (ADL) in the non-institutionalized population rises steeply with increasing age and is higher in women than men at the older ages[44] – see Figure 12.1.

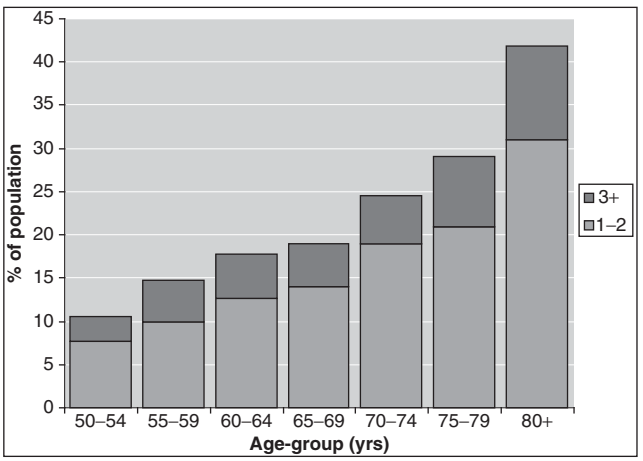

Figure 12.1 Percentage of community-living respondents reporting one to two, and three or more disabilities in activities of daily living. Activities include dressing, walking across a room, getting in and out of bed, eating and using the toilet
Source: Data from the English Longitudinal Study of Ageing (Steel *et al*., 2004)

The prevalence of ADL disabilities in institutional settings is generally very high. It is important to keep in mind that, although chronological age is strongly related to disability prevalence, many other factors, particularly socioeconomic status, have large impacts on disability that are independent of age[45,46]. Large differences in functional health status exist between groups, with those in less privileged social positions having higher rates of incidence and prevalence of disability, in both developed[47] and emerging countries[48].

Cognitive impairment is a major contributor to functional disability[49,50], as are depressive symptoms[51,52]. A number of potentially modifiable behaviours are associated with physical function or functional decline in later life. These include obesity[53], smoking[54] and low levels of physical activity[55]. The onset of functional disability often occurs relatively early in life: recent studies have identified that up to one in five adults aged 50–64 experiences some problems with walking a quarter of a mile[56,57].

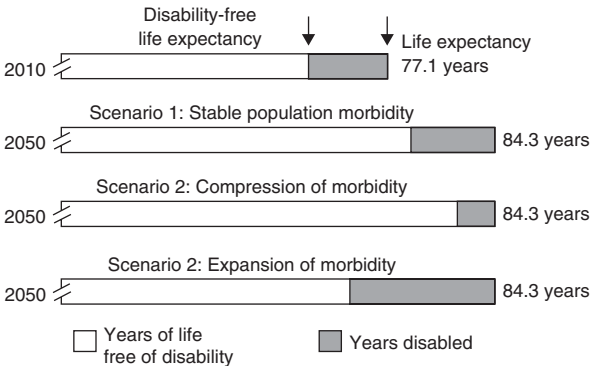

Figure 12.2 Scenarios for change in average burden of population disability level: compression of morbidity and alternatives

LONG-TERM TRENDS IN FUNCTIONAL HEALTH STATUS AND POLICY IMPLICATIONS

An important issue connected to functional ageing is the relationship between length of life and time spent in a disabled state. Life expectancy increased substantially through the 20th century. One consequence of reduced early-life mortality may be that more people survive to ages where they suffer from chronic diseases, leading to increased prevalence of long-term disability and loss of independence. Increases in life expectancy which bring longer periods of life with impaired function are undesirable both for individuals and for societies and a major goal of gerontology is increasing longevity without increasing the number of years spent in the disabled or dependent state.

An important concept in relation to evaluating the consequences of worldwide population ageing is 'active life expectancy' or 'disability-free life expectancy'[58]. Active life expectancy is defined as the average number of years an individual at a given age will survive and remain in the active, or non-disabled, state. Most analyses of active life expectancy define disability in relation to activities of daily living, with active life expectancy calculated using life-table techniques that consider transitions from the active, non-disabled state to a disabled state or death. The original analysis of active life expectancy considered the transitions to both death and disability as irreversible[58] but recent studies have shown a substantial proportion of disabled persons returns, at least temporarily, to the non-disabled state[59].

Compression of Morbidity

A related theory is 'compression of morbidity'[60], the idea that the burden of lifetime illness may be compressed into a shorter period prior to death. Fries argued that in all species the maximum lifespan is fixed, human beings are quickly approaching this limit, and with a stable life expectancy any postponement of disease and disability would result in a compression of morbidity. He stated the compression of morbidity was inevitable and predicted a decrease in the period people could expect to spend with severe disease and disability. The relationship over time between life expectancy and active life expectancy can be used to assess the occurrence of a compression of morbidity. Three possible scenarios for population morbidity in women are illustrated schematically in Figure 12.2. The total length of the bars in this figure represents life expectancy for Non-Hispanic black U.S. females projected by the Census Bureau for 2050. The length of the unshaded segments of the bars represents active or disability-free life expectancy, and the shaded areas of the bars represent the average number of years in the disabled state. In scenario 1, the onset of disability has been postponed the same number of years as life expectancy has increased, and the number of years spent in the disabled state is unchanged from 2010. In scenario 2, there has been a compression of morbidity. Finally, in scenario 3, although disability-free life expectancy in 2050 has increased compared with 2010, it has not kept pace with increases in life expectancy and there is an expansion of population morbidity.

Active life expectancy is not always easy to assess and debates persist about whether compression of morbidity is taking place. However, trends in disability can be estimated in other ways. It is possible to estimate disability prevalence, which is not equivalent to disabled life expectancy but reflects a cross-sectional picture of the proportion of the population that is disabled. Much attention has been focused on examining longitudinal trends in disability by analysing annual estimates of disability prevalence. In the US, it appeared that in the 1970s the prevalence of age-related disability was rising but in the 1980s rates declined[61–63] and this trend seems to have continued. A number of studies have reported ongoing year-on-year improvements in the health of the older population[61,64–66] and reports from other countries, including New Zealand[67] and England[68] suggest similar patterns of decline in age-related disability may also be occurring there.

Possible causes of these declines in disability prevalence include environmental changes making daily tasks easier[19], more intensive use of assistive devices[69] and other social changes, including attitudes to being active in old age. In addition, the proportion of older people who have little education (a potent risk factor for disability) has declined[63,70]. There is evidence of declining prevalence of some medical conditions in old age, especially cardiovascular disease, and health risk avoidance and improved diagnostic and therapeutic techniques will also have contributed[71].

The future burden of morbidity and disability in the older population is of great concern to those involved in planning, financing and delivering health care and social services. If current rates of disabling diseases such as Alzheimer's disease and hip fracture remain unchanged, the numbers of older people with these diseases will increase substantially during this century[72]. Understanding the factors that affect functional ageing is critical to reducing the burden of disability and compressing morbidity. Effective interventions are needed to prevent the onset and mitigate the consequences of diseases and conditions that lead to much disability in later life.

Department of Primary Care and Population Health, University College London, UK

BACKGROUND

Population ageing and increases in life expectancy in the developed world have led to international interest in how to age 'successfully'. But there is no interdisciplinary agreement on what successful ageing is. The literature reveals that conceptual definitions and measurement of successful ageing vary both within and between disciplines; there is little interdisciplinary cross-referencing. Biomedical models emphasize physical and mental functioning as successful ageing, while sociopsychological models focus on social functioning, life satisfaction and psychological resources. Older people themselves adopt multifaceted definitions of successful ageing[1,2]. Moreover, research shows that older people consider themselves to have aged successfully, but classifications based on traditional, narrower domain models do not[1–3]. This suggests that a model of successful ageing needs to be multidimensional, cut across disciplines, and incorporate a lay perspective for social significance. Moreover, there is overlap, and lack of clarity, in the literature between concepts of successful ageing, active ageing and quality of life. Analysis of overlap between lay perceptions of these concepts in surveys using comparable methods showed that lay perceptions of active ageing emphasized striving to *maintain* health, functioning, and wider well-being (e.g. exercising the body and/or mind in order to maintain health and functioning), while lay definitions of successful ageing and quality of life focused on the existence of a state, rather than the striving for its achievement (e.g. the having health and ability *per se*[4]). This distinction is consistent with the literature on active ageing, which portrays quality of life, and also having 'successfully *aged*', as the end points, although 'successful *ageing*' can also be viewed as a dynamic process.

An earlier interdisciplinary systematic review of the literature by this author[1,3] found that the most common definitions of successful ageing were based on theories of social functioning, life satisfaction, psychological resources and biomedical approaches. A small body of literature focused on lay views. The distinction between concepts as either predictor or constituent variables was not always clear. The survey with the highest citations for successful ageing was the MacArthur Foundation studies of successful ageing[5–7], which are based on a biomedical model, broadened to include active engagement with life.

SOCIAL FUNCTIONING

Social functioning has been conceptualized and measured in many different ways, including social engagement, social roles, participation and activity, social contacts and exchanges, and/or positive social relationships. The main theoretical approaches relating to successful ageing and social functioning are disengagement, activity and continuity theories, although each suffers from limitations, and all are now outdated (see Bearon for critique[8]).

LIFE SATISFACTION

A smaller number of authors included life satisfaction, well-being or their elements in their conceptual and empirical definitions of successful ageing. Components of life satisfaction include zest, resolution, fortitude, relationships between desired and achieved goals, self-concept and mood, including happiness[9–11]. Havighurst[11] (p. 305) stated, 'a person is aging successfully if he feels satisfied with his past and present life', thus arguing that life satisfaction is an attribute of successful ageing, although others have argued that it is a condition for its achievement. Feelings of well-being were an outcome indicator of successful ageing in the Berlin Aging Study[12]. There is lack of consistency about the status of life satisfaction, in particular, as an indicator or constituent variable.

PSYCHOLOGICAL RESOURCES

Few investigators have included psychological resources as their study definition of successful ageing, and again it was not always clear whether the concepts used were predictor or constituent variables. Psychological models include possession of the resources of personal growth, creativity, self-efficacy, autonomy, independence, effective coping strategies, sense of purpose, self-acceptance and self-worth. These models have been criticized for their emphasis on autonomy, thus marginalizing frail older people[13].

Baltes and colleagues[14] developed a strong theoretical model based on the need to employ compensatory strategies when facing the dynamic between challenges and depleting reserves: selective

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

optimization with compensation (SOC). With this model, it is proposed that individuals can contribute to their own successful ageing: when *selected* activities can no longer be performed, strategies are needed to find new ones, and to maximize reserves. There is some supportive evidence from the Berlin Aging Study that people who use these strategies have better well-being than others[12].

Ryff's theoretical model of successful ageing emphasizes a life course approach, and holds that a developmental focus is required[15,16]. She argues that successful ageing includes 'positive or ideal functioning' and is related to development over the life course. Fisher[17] also emphasized adaptability and coping, and defined successful ageing as an ability to continue to grow and learn by using past experiences to cope with present circumstances and set goals for development.

BIOMEDICAL THEORIES

Biomedical or decline theories generally define successful ageing as the optimization of life expectancy, while minimizing physical and mental deterioration. The MacArthur Foundation in the USA commissioned a major study of successful ageing led by Rowe, which comprised a three-site longitudinal study of adults living in the community aged 70–79 in 1988. It was rooted in Rowe and Kahn's[5–7] model of successful ageing as absence, or avoidance of, disease and risk factors; maintenance of physical and cognitive functioning; and active engagement with life (with others and in productive activities). They made the distinction between 'usual ageing', which describes normal decline in physical, social and cognitive functioning with age, and 'successful ageing', in which physiological and cognitive functional loss is minimized, there is active engagement with life, and capabilities even enhanced. This only partly recognizes heterogeneity among older people, and criticisms of Rowe and Kahn's model include its narrowness, neglect of life course dynamics, failure to address adaptation to disease, and neglect of those who are incapacitated who cannot age successfully by the criteria used. A small number of studies have used elements of both biomedical and psychosocial approaches.

LAY VIEWS OF SUCCESSFUL AGEING

Lay views are important to investigate in order to ensure that models of successful ageing have social significance, and to minimize the danger that definitions reflect mainstream cultural expectations and norms for the behaviour of older people. Without social significance, policy initiatives to enhance successful ageing are likely to fail.

The systematic review of the literature, and empirical research by this author, illustrated that lay people view this concept multidimensionally, and included the following elements in their definitions: physical health and functioning; mental and cognitive health; psychological well-being and life satisfaction, including happiness; social functioning – relationships, support, activities and productivity; psychological resources, including personality, personal growth, accomplishments, sense of purpose, physical appearance, self-acceptance, coping, positive outlook, sense of humour; spirituality; lifestyles; neighbourhood; financial circumstances and security. It is also perceived as a dynamic concept. Von Faber *et al*.[18] reported, from the Leiden longitudinal study of people aged 85+, that older people defined successful ageing as a process of adaptation rather than as a state of being, supporting psychological rather than biomedical models. Thus, investigations of older people's views of successful ageing have indicated that they are far more multifaceted than existing models, crossing the boundaries between the physical, psychological and social self. Moreover, research shows that, overall, many older people consider themselves to have aged successfully while biomedical classifications do not categorize them so. Strawbridge *et al*.[19] compared self-ratings of successful ageing among their sample members aged 65–69 from the longitudinal Alameda County Study with Rowe and Kahn's three-factor model. They reported that, while half the sample could be categorized as having aged successfully with their own self-ratings, only 19% could be so categorized with Rowe and Kahn's model. Bowling's further national survey of people aged 50+ living at home in Britain, asked people what they understood by the term successful ageing, then to rate the extent to which they had aged successfully[2]. Two-thirds of respondents defined successful ageing in terms of having good health and functioning; almost half defined it psychologically. Others defined it mainly in relation to social roles and activities, social relationships, neighbourhood and local community. About four in ten (39%) respondents rated themselves as ageing successfully 'Very well', and a further 37% as 'Well', as opposed to 'All right', 'Not well' or 'Not very well' (see Figure 13.1).

There were positive correlations between self-rated ageing successfully and good self-rated health, no reported longstanding illness, and good quality of life. There were no statistically significant associations with age. The main reasons people gave for their self-ratings of successful ageing included their physical and mental functioning, followed by psychological well-being, social relationships and financial circumstances[1,2]. Also, while over a quarter indicated that they felt defiant about ageing when asked how they thought ageing would affect them, about 40% mentioned worse health and/or functioning, about a fifth thought they would be limited in their lives, and about 10% each mentioned worsening mental health and dependency (see Figure 13.2).

In a further study, Bowling and Iliffe[20] constructed and tested alternate biomedical, social, psychological and multifaceted lay-based models of successful ageing in a national population survey of people

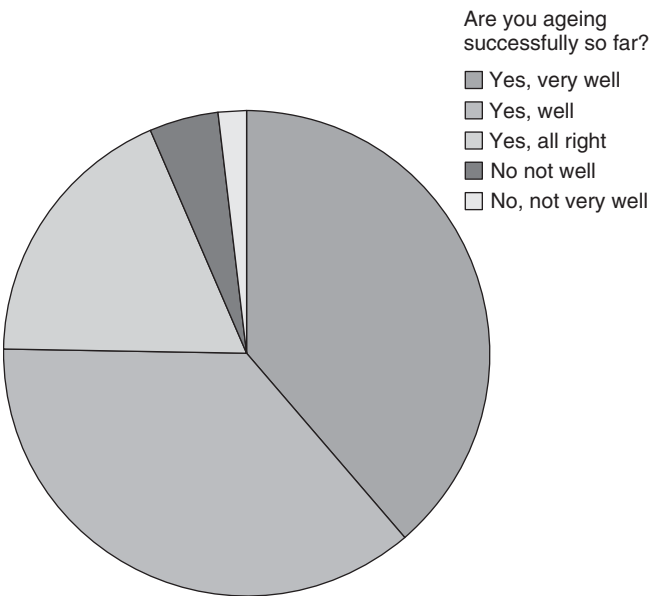

Figure 13.1 Self-rated successful ageing: national population sample aged 50+ in Britain. Data from the *English Longitudinal Study of Ageing* (Steel *et al*., 2004)

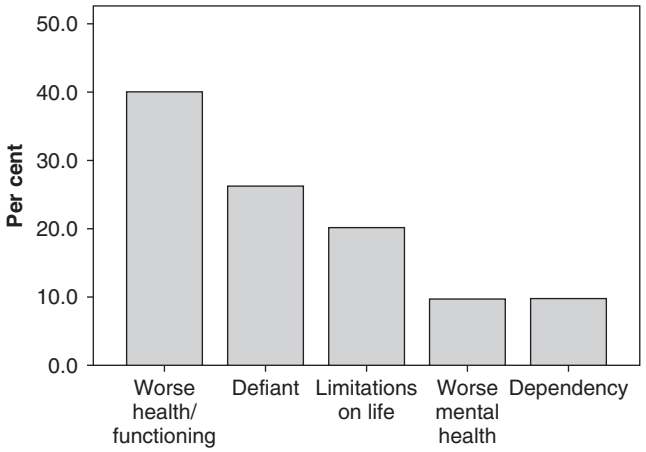

Figure 13.2 How do you think getting older will affect you? (Most common responses shown)

aged 65+ living at home in Britain. Respondents classified as successfully aged with the multifaceted lay model, compared to those classified as not successfully aged, had over five times the odds of rating their quality of life as good rather than not good. The comparable odds ratios from the other, single domain models, while significant, were considerably lower.

Table 13.1 shows the associations between pairs of successful ageing themes mentioned by respondents. While the table shows several instances where mention of one definition was associated with reduced odds of mentioning another, it also indicates the multidimensionality of lay definitions. Respondents who defined successful ageing in terms of health had almost twice the odds, compared to those who did not, of also defining it in terms of finances. Respondents who mentioned social activity had almost twice the odds of mentioning social relationships (and vice versa), possibly reflecting the perceived need for companionship to undertake social activities (e.g. to accompany one on outings). Those mentioning social relations also had over twice the odds of mentioning finances, compared to those who did not. Similarly, respondents who mentioned finances had almost twice the odds of mentioning health and twice the odds of mentioning social relationships (and vice versa). And respondents who defined successful ageing in terms of neighbourhood factors had almost twice the odds of also mentioning financial circumstances. The importance of these results is the demonstration that successful ageing is not perceived narrowly by lay people, in contrast to most theoretical models. It also illustrates the interaction between domains of life, e.g. social relationships may be needed for people to participate in social activities (to accompany people), and people see having both health and money as important for successful ageing.

CONCLUSION

In conclusion, most authors in this field have made unwarranted conceptual leaps and assumed, often, that they have addressed 'successful' ageing with their chosen outcome indicators, with relatively few attempts at theoretical or conceptual justification. Rowe and Kahn's three-factor biomedical model (including social elements) of successful ageing is the most popular and widely used in biomedical research, even outside the MacArthur studies of successful ageing[5–7]. In contrast, lay models of successful ageing are more multidimensional, and, in particular, include more psychosocial elements. Also, to be realistic, the concept needs to be broadened, and to be seen on a continuum, rather than categorized dichotomously in terms of successful or unsuccessful. Also, given the inconsistency with which variables are used as either predictor or constituent variables in the study of successful ageing, advances could be made by grounding the term in older people's definitions, and building on multidimensional theoretical approaches.

Thus a definition of successful ageing would include longevity, physical, cognitive, psychological and social health and functioning, including effective coping, living circumstances (finances, neighbourhood) and overall life satisfaction. Precursors of effective coping strategies are likely to be possession of resources such as SOC, as hypothesized by Freund and Baltes (1998)[12]. Using this approach, the different models are complementary to each other, and successful ageing is not only about maintaining good health and functioning, but it is also about coping and remaining in control of one's life over the life-course, with the aim of achieving dynamically a status

of having successfully aged. Then the question of whether, and the extent to which, successful ageing is achievable can be addressed. Also, clinicians involved in the care of older people need to balance a *dis-ease* with a health and psychosocial perspective of older age, in order to enhance mutual understandings about desired treatment goals.

Sexuality, Non-Traditional Relationships and Mental Health in Older People

Ian Peate

School of Nursing and Midwifery, Thames Valley University, London, UK

INTRODUCTION

Despite an ageing population, little is known or understood about the sexual behaviours and sexual function of older people in society. Individuals (including the older person) manage their sexuality and sexual identity in a number of ways. Assumptions concerning ageing and intimacy in later life are now being challenged. Specific issues concerning sexuality and ageing will be discussed. In a minority of cases clinicians will be working more and more with older people who are involved in non-traditional relationships – a non-heterosexual context. Issues may arise for clinicians and older people concerning sexual identity. Many of those working with the older person will have had little training or education regarding non-heterosexual relationships and the older person. This chapter will emphasize the need to respect the fact that the expression of sexuality in older age is an important aspect of an individual's being, as well as remembering that for some older people coming to terms with their sexuality may bring with it psychological distress. The chapter addresses the mental health of the older lesbian, gay and bisexual (LGB) person; issues concerning transgender and gender dysphoria will not be addressed here. A brief discussion concerning HIV and the older population has been included.

SEXUALITY AND AGEING

Sexuality according to Ginsberg *et al.*[1] is an activity of daily living that is important for a number of older people. Despite this, Edwards[2] notes that within health care systems the sexual needs of the older person are often unrecognized and unmet, often as a result of negative attitudes and beliefs towards sexuality, sex and sexual desires. Many believe that these complex concepts can only be likened to youthfulness. Other factors can impinge on the individual's ability to express freely their sexuality, for example, environmental (structure) constraints in long term care facilities may hinder an older person being able to express their sexual needs[3]. Some common barriers to enjoying sex as a person ages are health problems or lack of a partner as opposed to lack of desire. Little research has been carried out with respect to stereotypical ideas about sex and ageing.

Healthy people are often sexually active people and this has an impact on the quality of an individual's life, therefore to deny an elderly person the option of being sexually active may result in dysfunction and distress. Among older adults there is an internal drive or need for sexual fulfilment[4].

As people age the frequency in which they engage in sexual activity declines. Nevertheless, a substantial number of men and women engage in vaginal intercourse, fellatio, cunnilingus and masturbation, and some people remain sexually active in their eighties and nineties. The limited data that has been analysed demonstrates that there are some men and women who maintain sexual and intimate relationships and desires throughout their lives[4].

Illness can seriously impede sexual activity but there is a dearth of literature regarding how illness impacts on the sexual activity of the older person. Altered pathophysiological changes often associated with the ageing process impact on sexual response in men and women, and most of the changes have a negative bearing on the person, both physically and psychologically.

The loss of a partner as a person ages is common (particularly in older women). Problems associated with the sex act may be a precursor to problems related to an underlying illness such as diabetes mellitus, a genitourinary tract infection or cancer[5]. There are a number of age-related changes in the vasculature and smooth muscle tissues involved in the erectile process as well as increased sensitivity to inhibitory signals in the smooth muscle[6,7]. There are physiological changes that are associated with the menopause (these are complex); for example, a reduction in vaginal lubrication in response to a decrease in oestrogen levels. Attitudinal responses by society to postmenopausal women and their sexuality may also lead to an increase in vulnerability to depression.

Sexual problems for men can include difficulty in achieving or maintaining an erection, lack of interest in sex, climaxing too quickly, anxiety about performance and an inability to climax. For elderly women bothersome problems include lack of interest in sex, difficulty with lubrication, an inability to climax, disliking sex and pain – often felt at the vagina during entry[4].

If problems associated with sexual activity are not treated or are left undiagnosed this may lead to depression or social withdrawal. There are also a number of medications that can result in sexual dysfunction that patients need to take for an ongoing physical or psychiatric illness. The result of sexual problems arising from the taking of prescribed medications may induce the person to stop taking them in an attempt to reduce the negative side effects related to them.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Bancroft *et al*.[8] emphasize the effect of relationship factors and mental health (particularly with regard to women) as being more important predictors of sexual well-being than the physiological factors of sexual arousal and response. For a number of women (tentatively, this could also be said for some men) being in a relationship, the quality of that relationship and a partner's sexual problems are more important than their sexual responsiveness. Bancroft *et al*.[8] considered only heterosexual women in his study; further research is needed to consider the impact of relationships versus sexual responsiveness in the LGB population. Kellett[9] suggests that counselling may allow a couple who are experiencing sexual problems to express their fears and inhibitions, with the therapist educating the couple about the normal changes that accompany ageing.

ISSUES OF CONSENT AND COGNITIVE IMPAIRMENT

The law demands that both parties engaging in sexual relations must consent; this is equally true for the older person, who may have issues associated with cognitive impairment such as dementia. Sexual abuse is a criminal offence. Free will and capacity are germane to informed consent. It may be difficult to ascertain if a person who is cognitively impaired has the capacity to consent to sexual relationships and as such this renders that person vulnerable. There are several potential ethical and legal issues that may arise as a result of this (Mental Capacity Act, 2005). Assuming that a person with dementia cannot make decisions and consent to intimate relationships or that they are unable to comprehend the consequences of decisions associated with consent, sex is unacceptable.

Dementia leads to a variety of changes in people's lives and one area that receives little attention is in respect to sexual relationships. Dementia in the older person is common, as is drug-induced confusional state; these issues are discussed elsewhere in this text. In drug-induced confusional state, a review of current medication is needed. A feature of dementia is the development of several cognitive deficits that include memory impairment. These cognitive deficits can be so severe that they can cause impairment in social functioning, including the ability to consent freely to engage in sexual activity with another person. The deficits may also predispose the person to inappropriate sexual behaviour.

Dementia can impact on the individual's feelings, desires and needs; sexual behaviour and their ability to express intimacy can change. The clinician should explain to the person and others that these changes are not a reflection on any individual and that it is possible to express intimacy in other ways if their chosen way has changed. People with dementia can experience sudden changes associated with their ability to express their sexuality. A range of behaviours can occur depending on what aspect of the brain is affected; sexual interest may diminish or conversely it may increase; there may also be a change in the level of inhibition.

Usually, sex for many people is a private affair; dementia has the potential to bring many private activities out into the open, revealing many private intimate thoughts, feelings and sexually charged actions; for example, inappropriate touching of self and others, undressing and using sexually loaded language. While these actions may be embarrassing for others, they can also be confusing and distressing for the older person with dementia.

What may appear to be inappropriate sexual behaviour may have a number of diverse causes. The causes can be identified by analysis of antecedents, behaviours and consequences, thus providing the clinician with information that will inform the most appropriate intervention if needed. Staff may need training in respect to the management of inappropriate sexual behaviours and the most appropriate ways to help the individual, families and other staff.

MENTAL HEALTH OF LESBIAN, GAY AND BISEXUAL PEOPLE

Older LGB people may experience mental health distress for a number of reasons unconnected with their sexuality, as is the case with older heterosexual people. There are, however, a variety of social factors that may have an impact on the lives of the older LGB person and hence their mental health. There are some personal and social characteristics that may further exacerbate mental distress, for example, ethnicity and disability.

Little is known about the mental health of the LGB population in the UK and even less is known about the LGB older population. Evidence that has been collected suggests that anxiety, depression, self-harm and suicidal feelings are more common among the LGB population when compared with the heterosexual population[10]. There are also higher rates of drug and alcohol misuse among LGB people. The LGB population has been found to have the highest levels of mental distress. The data cited here refers to the LGB population as a whole in the UK and not specifically the older LGB population; nevertheless, as with all populations, LGB people will age and become older LGB people and some of these findings may well reflect those of the older LGBs. The reasons underpinning these findings are complex and as yet not fully understood. Warner *et al*.[10] note that poor mental health in the LGB population has often been linked to experiences of homophobia, discrimination and bullying. Older people are not immune to the effects of homophobic discrimination and bullying by society generally and by those who provide and plan health care.

HOMOPHOBIA AND HETEROSEXISM

Homophobia could be defined as the unreasonable hatred, prejudice and fear of LGB people. Extreme forms of homophobic behaviour can manifest as bullying and physical attacks. Heterosexism – where a society or community is conditioned to expect everyone to live and behave as heterosexual people do – can have a subtle impact on a person's self-esteem and self-image. There are a number of instances where homophobic and heterosexist behaviours exist in the provision of health care with the outcome being detrimental to the health and well-being of the older LGB person.

Institutional homophobia relies on the promotion of heterosexuality as the norm and when health services are provided where policy provision has neglected to take account of the needs of LGB people. In these instances an individual's sexuality has been seen as inferior to the dominant hegemony – the heterosexual. The health service, legal system and police force all have histories of institutionalized homophobia. There are a number of organizations that work with older LGB people who neglect to take into account the reality that not all service users are heterosexual. Some residential care homes and sheltered housing are often mixed sex and are usually set up in such a way that service provision is directed towards heterosexuals, neglecting or refusing to accept that some of their clientele may be lesbian, gay or bisexual.

Homophobia can have an impact in a number of ways. Being lesbian, gay or bisexual is not in itself a mental health problem; however, coping with the consequences of homophobia can have damaging effects on the health and well-being of an LGB person.

Warner *et al*.[10] have demonstrated a possible correlation between levels of homophobia and mental ill health among LGB people. Levels of anxiety, self-harm and depression among participants in this study were higher than average among the LGB participants. Homophobic experiences include damage to property, physical attack and bullying.

OLDER LESBIAN, GAY AND BISEXUAL PEOPLE

There is often little value in using rigid categories when describing who is old or older as these terms can include a number of different generations. There is the potential when using such descriptions that the person (or people) being described may be disempowered and as such the term should be used with caution and tact.

For the majority of older LGB people, living their life predominantly in the twentieth century may have meant that being open about their sexuality would have resulted in oppression and abuse within the mental health services[11] as well as from society. There may be a number of reasons why this occurred; for example, mental health services then reflected the homophobia of the wider society. The Local Government Act (1998) made it illegal for teachers to sanction homosexuality in schools and described gay family relationships as false; this Act was repealed in 2003. Homophobia was also given legitimacy within psychiatry and psychology; theories of mental health pathologised homosexuality. Homosexuality was seen as the cause and effect of a mental illness or even as a mental illness itself. Damaging aversion therapies were often used regularly during the 1960s and 1970s to try to 'cure' homosexuality. Homosexuality was not officially struck off the UK government's list of psychiatric disorders until 1993.

Change is on the horizon and a number of legislative modifications have occurred to combat institutional homophobia in the UK. LGBs are now legally protected from discrimination associated with their sexual orientation from providers of goods and services; this also includes those who provide mental health services. There are some problems that remain. Some people who use mental health services and counselling or psychotherapy services are still being discriminated against with regards to their sexuality, and in some cases this is further exacerbated because of their age. The key factor for such discrimination is associated with lack of awareness among clinicians and due in part to ignorance as opposed to malevolence. A systematic review has been undertaken by the British Association for Counselling and Psychotherapy into the experiences of LGB people who have received counselling or psychotherapy services[12]. Gaps in knowledge have been identified as well as revealing negative attitudes among some therapists. The review recommends that these gaps should be addressed in the training and education of therapists.

Caution must always be taken with reviews of mental health services and the needs of the LGB population, as the results may under-represent the actual number of LGB people taking part in or being included in studies or reviews. There are some people who may be reluctant to disclose their sexuality and there may also be some discomfort and embarrassment on the part of the researcher in asking questions concerning sexuality and the older LGB person.

As well as being lesbian, gay or bisexual, other characteristics such as age, ethnicity or disability can complicate or exacerbate an LGB person's experience of mental illness. Attempts in the past to cure some older LGB people may have left these people with feelings of guilt accompanied with emotional damage. There may be a number of older people who have never acknowledged to themselves or others that they are lesbian, gay or bisexual.

Negative societal attitudes towards sexuality in older age can also have detrimental effects on a person's health and well-being. Older people are often seen as unattractive and socially uninteresting. The 'gay scene' is generally geared towards meeting the needs of the younger LGB population. Lack of social opportunities can deny older LGB people the chance to meet other older LGB people; social isolation may ensue. Harmful societal attitudes can impact on communication between the physician and the patient. The outcome may be an unwillingness of patients and physicians to initiate discussion concerning sex.

HIV INFECTION IN OLDER POPULATION

HIV infection in the older population has until recently in the main been ignored. Much of the published data regarding immunologic and clinical responses to highly active antiretroviral treatment (HAART) are associated with younger cohorts. The reasons why older people have for the most part been ignored are varied, and could include the risk of age related co-morbidity associated with clinical trials.

With increased life expectancy and the success of HAART accompanied by an enhanced length of survival as a result of the improvement of the immunodeficiency caused by HIV infection, the number of older people with HIV is likely to continue to increase. As a result of this, clinical trials (research) that are age specific, taking into account the needs of the older person (i.e. considering co-morbidity and potential drug interactions) are required in relation to the impact of HIV on this population, including therapeutic and clinical outcomes.

CONCLUSION

There are a number of older people who are sexually active although little is known about their sexual activities, behaviours and attitudes. Sexual problems are widespread among the older sexually active population; these problems are rarely discussed with clinicians. A number of older people may become sexually inactive because of a variety of sexual problems – these may be physiological in origin or as a result of their sexuality and societal reactions.

For some older people heterosexual and LGB sex may play an important part in their relationships and well-being; there are also some who do not see this aspect of their lives as crucial. There may be some older people who would benefit from the input of clinicians who are willing to broach what is sometimes seen as the embarrassing and taboo subject of sexuality and the older person.

Evidence suggests that being able to express one's sexuality is positively correlated with good physical and mental health. Allowing the older person to express their sexuality will enhance their health and well-being in a number of ways. For this to happen clinicians must encourage the older person to discuss the issues that concern them. However, for this to take place the clinician must first feel comfortable with their sexuality and challenge any stereotypes they may have that concern the older person's sexuality.

The Care Home Experience

Alisoun Milne

School of Social Policy, Sociology and Social Research, University of Kent, Canterbury, UK

INTRODUCTION

This chapter aims to highlight the key dimensions of the evidence base exploring the experience of living in a care home, with a particular focus on dementia. Despite the extent of recent policy and practice attention paid to care homes in both the UK and the US, surprisingly little is known about residents' lived experience. Research is only now beginning to take account of the perspective of users with dementia and is embarking on the not inconsiderable task of developing tools and methodologies that can meaningfully capture their voices[1]. By way of introduction, the broader context within which the care home experience is located is provided before moving onto the chapter's core focus. Although much of the evidence presented is drawn from UK research, key messages are equally applicable to the US and mainland Europe.

Background

In the United Kingdom about 5% of the total population aged over 65 lives in care homes. This is comparable with other European countries, the figure being slightly higher in Scandinavia[2]. In the United States 4.2% of the 65 and over population live in nursing homes[3]. In terms of absolute numbers, in 2007 420 000 people lived in care homes in the UK while in the US over 1.8 million people lived in nursing homes. It is important to note that US figures do not include 'assisted living facilities' whereas UK figures incorporate care homes that do *not* provide nursing care[i] as well as those that do.

Care homes' residents tend to be very elderly and frail; multiple physical problems and/or co-morbidity with mental disorders are common[4]. Typically, UK residents are aged over 80 years, are female, have previously lived alone, are on a low income and have multiple disabilities. In a recent UK study of 16 000 residents, over half had dementia, stroke or other neurodegenerative disease, 78% had at least one form of mental impairment, 71% were incontinent and 76% needed help with mobility or were immobile[5]; 27% were immobile, confused *and* incontinent. It is estimated that over two thirds of people living in *all* UK care homes have dementia, most often in the advanced stage, and about a third of all care home places are registered to provide specialist dementia care[6]. In the US it is estimated that 23–42% of residential community/assisted living residents have moderate or severe dementia. Many residents with dementia experience behavioural problems such as activity disturbances (agitation), aggression and psychosis; reported prevalence of these so-called 'challenging behaviours' can be as high as 90%[7].

In addition, an estimated 50% of all care home residents have depressive disorders that would warrant intervention[8]. Depression in care home populations is associated with functional impairment (e.g. sensory loss, incontinence, loss of mobility), physical health problems (notably pain, dysphasia and heart disease), and social problems such as loneliness[9]. Due to the complexity of assessing the extent of depression among people with dementia and the limited evidence base, it has been suggested that depression in care home residents is often either under- or misdiagnosed[10]. Anxiety symptoms are also relatively common; they are particularly associated with depression and stroke[11].

Living with Dementia in a Care Home

Despite the predominance of older people with dementia in care homes, research that draws on the experience of this group of residents has only recently emerged. In part, this reflects the liminal status of people with dementia inside, and outside, the 'care system', as well as the genuine complexity of collecting data from people whose cognitive capacity and communication skills may be limited[12]. It is notable that an accumulating body of evidence offers valuable insights into the subjective experience of living with early stage dementia. It is also increasingly accepted that people in the middle to late stages of dementia retain the capacity for emotional expression and many can reliably express preferences[13]. As improving long term care for people with dementia is now a key policy priority in both the UK and US, the continuing marginalization of this pivotal perspective in both the practice and research arenas can no longer be justified[14].

Currently, there are two main sources of evidence about 'the care home experience'. One draws on practice-based work whose core aim is that of improving care. 'Dementia care mapping' (DCM) is the most prominent example of this type of work; its influence also extends into the realms of research and inspection (see below)[1]. The second source is drawn from research that has attempted to capture the nature and dimensions of care home life 'from the inside' and/or through the eyes of carers[15]. Predominantly this material is

[i]The term 'care home' covers any establishment providing accommodation with personal or nursing care. There are broadly two types of care home: homes that provide nursing care (nursing homes) and homes that provide personal care and support (residential homes).

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

gathered from observational or questionnaire-based studies, which provide valuable insights and include evidence about the experience of the person with dementia; work that focuses specifically on the subjective experience of users is a new addition to the research portfolio[16].

These two areas of activity combine around the concepts of quality of life and quality of care, both pivotal to the experience of living with dementia in a care home. As quality indicators used by the Commission for Social Care Inspection[ii,iii] (CSCI) move to focus more on 'outcomes of care', taking account of the perspective of the person with dementia becomes increasingly important[17]. A brief review of research findings about quality of life in care homes for people with dementia and 'what is important' to residents will be offered before turning to evidence about their lived experiences.

Quality of Life and Quality of Care

Assessing quality of life among care home residents is a difficult task; it is a complex construct, which is variously measured and evaluated. A number of scales do exist, several of which have been specifically developed for people with dementia; these include the Quality of Life in Alzheimer's Disease (QoL-AD)[18] scale, the DEMQOL[19] and the DQol[20]. A persistent challenge in evaluating quality of life is that there are often differences between the ratings of staff, carers and residents. This appears to be a consequence of a difference in emphasis: a recent study found that residents' quality of life scores were most affected by the presence of depression and anxiety, whereas staff ratings were associated with dependency and behaviour problems[21]. A full picture of quality of life may thus require a combination of measures, incorporating the observations of all three groups[22].

Despite the difficulties associated with measurement, evidence to date suggests that quality of life in care homes is largely determined by the existence of mental health problems and subjective well-being[11]. Systematic assessment of residents' needs, and consideration of whether or not they have been met, has been suggested as a means of improving quality of life. The Camberwell Assessment of Need for the Elderly has been used towards this end[23].

Limited consensus also exists in relation to the linked concept of quality of care. First – as with quality of life – there are multiple perspectives to be accommodated. Second, the components of 'care' include those elements that are provided within the home as well as those offered by external sources, such as medical care. Third, good quality care depends on a range of micro level (satisfied staff) and macro level (financial stability of the provider) factors and their interaction; this make its assessment complex and multifaceted. An important contribution to this field has been the development of DCM, an observational approach where items recording residents' activity can be combined to calculate a care index score[24] (see Chapter 30 for details on DCM). Given the limitations of all approaches to gathering information about quality of life and quality of care, an approach that accommodates multiple methods is recommended, rather than relying on a single source of evidence[25].

As might be expected, evidence about the quality of care in homes is mixed. Some of the variation between studies results from methodological differences. For example, studies adopting a 'checklist' approach tend to reach more positive conclusions than those using direct observations[26]. There is more robust evidence in relationship to those issues that impact negatively on user quality of life. These include prescribing patterns and covert administration of medication, physical restraint, electronic tagging and abuse[27].

In terms of therapeutic care practice, a recent survey undertaken by the Alzheimer's Society[28] of 4 084 family carers, and care home workers and managers found that people with dementia are not always afforded dignity and respect. 'Dementia' had become a label that subsumes all other needs and submerges the person's characteristics; this tendency undermines the delivery of individualized care and encourages a task-oriented approach. Lack of activity and stimulation were also highlighted, particularly for people with severe dementia. As the availability of activities and opportunities for occupation is a major determinant of quality of life affecting depression, physical function and behavioural symptoms, this is a primary concern.

A 2007 CSCI[17] inspection of care homes for people with dementia echoes a number of these themes. Although the inspectors found some excellent examples of one-to-one attention and care offered with warmth, understanding and tolerance, impersonal assistance was widely in evidence. The report noted that quality of staff communication with residents – both verbal and non-verbal – had a significant impact on well-being. Positive communication that is warm and friendly results in the person with dementia feeling happy and relaxed. Conversely, negative or neutral communication – interactions that are impersonal or task focused – leave residents feeling distressed and withdrawn. It is thus evident from this and other CSCI inspections that residents with dementia do not always receive person-centred care – care which is delivered in ways that promote independence and which draw on the individual's life course and experiences. It is to the role of experience in extending understanding of the person with dementia's life in a care home that we now turn.

Evaluating the Experiences of the Person with Dementia

Structured observational methods developed specifically for evidencing quality in long term care settings have a sustained history. They provide an opportunity to include the perspective of the person with dementia by collecting data on their experiences in communal areas, how they spend their time, and how they are treated. The most widely used dementia-specific observational tool is DCM. Kitwood, who developed the early prototype of DCM, described it as 'a serious attempt to take the standpoint of the person with dementia, using a combination of empathy and observational skill' (p. 4)[29]. DCM requires training to employ but even with a standardized training programme the inter-rater reliability of practitioners is not high; those who use DCM for research purposes can achieve good reliability[22]. A linked example of an observational tool is the Short Observation Framework for Inspection (SOFI). This draws heavily on DCM and involves structured observation of a sample of five residents in a communal area and over an extended lunch period[17]. As part of an overall inspection, SOFI adds observational depth and detail.

More recently video and digital recordings have also been used in care settings[30]. They can provide fine-grained analysis enabling in-depth observation to occur. Video evidence can be particularly valuable when working with people with very advanced dementia whose speech on first listening seems meaningless, but on repeated replay shows clear attempts at communication[31].

[ii]The CSCI has responsibility for monitoring standards in care homes. In April 2009, the CSCI was replaced by the Care Quality Commission.

[iii]Regulatory bodies are established in each UK country to apply and monitor care standards: in England, it is the Care Quality Commission; in Wales, the Care Standards Inspectorate; and in Scotland, the Care Commission.

The extent to which selfhood or identity is preserved in people with dementia has been a key focus of observational studies[32]. Results suggest that although the self is affected by dementia, manifestations of selfhood persist even in late stages of the illness along with the capacity to develop positive relationships[33]. Questionnaire-based studies have also begun to address this issue, concluding that aspects of identity, as with selfhood, are retained by people with advanced dementia[34]. Research also identifies recurrent issues of loss, communication difficulties, frustration and sadness among residents along with lack of meaningful occupation. Minimal levels of well-being are widely noted in many studies of care homes; these are particularly pronounced for people with the greatest dependency needs[35].

Very recently attempts to explore the subjective experiences of people with advanced dementia in long term care have been made. A seminal study by Clare *et al*.[16] provides an interpretive phenomenological account of the subjective, psychological experience of living with moderate to severe dementia in a care home. The thematic account highlights four interrelated experiences (see Table 15.1). Daily experience was shaped by the losses resulting from dementia for most residents and was characterized, to a considerable degree, by distressing thoughts and feelings. The psychological impact of 'being in the home' was associated with a sense of uncertainty, lack of control and limited self-determination. These feelings were compounded by multiple experiences of loss – lost abilities, lost memories, and lost identity – which resulted, for some, in feelings of worthlessness. Fear of 'being alone' or 'being lost' was also a dominant experience. However, through their accounts the residents emerged as 'agents actively seeking to cope with their situation' (p. 718). Many found ways to contribute and focused on the positive aspects of home life, including being part of supportive relationships. Such relationships appeared to be pivotal to maintaining a sense of well-being; their absence contributed to feelings of distress and alienation[36]. Although participants displayed many constructive ways to cope, the effects of changes resulting from dementia, coupled with the context of institutional care, placed severe limitations on their expression of personal agency. Consequently, some residents experienced frustration, anger and boredom, especially around minimal activity and daily occupation[37]. Lack of freedom and independence was experienced by some residents as 'restrictive' and communal living could give rise to considerable confusion. If we are serious about addressing current deficits in care home provision, understanding the subjective experience of people with dementia is a fundamental dimension of enhancing practice and thereby improving both quality of life for users and quality of care. The implications of this shift in emphasis are the focus of the final section.

Table 15.1 Key themes from the study of Clare *et al*.[16]

Nothing's right: isolation, alienation, lack of choice, lack of control, fear, worthlessness
I'll manage: making the best of things, valuing contacts and friendships, finding ways of continuing to be useful, being accepted as you are, having a friend in the home, having links with relatives/family, acknowledgement of getting older
I still am somebody: part of coping, affirming one's sense of identity, managing well despite limitations
It drives me mad: frustration and anger at the situation, confined, wanting more independence, boredom, lack of activity, annoying behaviour of other residents, uncertainty, fear, irritation

IMPLICATIONS FOR PRACTICE: ENHANCING QUALITY OF LIFE IN CARE HOMES

Much of the evidence reviewed above identifies an overarching need to embed person-centred values into care planning and delivery in care home settings. The pivotal role of developing meaningful relationships and an emphasis on effective communication appear to be the twin routes to enhancing well-being in residents with dementia[38]. There is a related need to address a number of practical and therapeutic deficits. Extending levels of engagement for people with dementia by offering meaningful activities is a prominent example; supporting the continued expression of personal agency and autonomy is a secondary challenge[39]. Managing the difficult and often negative emotions that many residents experience is also important; this depends on the establishment of genuine staff–resident relationships and the capacity of staff to respond sensitively and on an individual basis to need. Supporting role identity is another element of good care; this depends on staff engaging with residents' life course and promoting opportunities for residents to have a continued social role. Being aware of the challenges of living a semi-public life in an institutional setting is an additional facet; this includes working with residents to deal with difficult relationships and providing opportunities for privacy[16].

As noted above, evidence suggests that preservation of self and identity is possible even in those with advanced dementia. The maintenance of previous relationships with friends and relatives is key to providing biographical continuity. Moving into a care home tends to disrupt existing relationships, which may impact negatively on users' sense of self, a process compounded by loss of independence[40]. In this context the relevance of care that is truly person centred becomes clear and understanding what matters to an individual, including his or her wishes, is critical. Story-telling and biographical work can help to develop relationships between staff and residents; this not only increases the likelihood of the resident being seen and valued as an individual[41] but also helps to maintain their cultural and ethnic identity.

Recognition of residents' emotional and social needs – in addition to their physical needs – is crucial to achieving person-centred care. Spending time engaging people with dementia 'in conversation' can also provide a powerful counterweight to the often task-oriented exchanges between residents and staff. It has been suggested that relationships are the key to maintaining well-being in people with dementia and that effective communication – the by-product of a good relationship – undergirds good quality dementia care[42]. Some commentators even argue that caring for a person with advanced dementia is *essentially* about finding ways to communicate even when these may be unfamiliar. Meaningful interactions require the development of a set of core skills among staff: attentiveness, active listening, observation of non-verbal signs, and the use of personal objects to support communication[43]. Staff can also enhance effective communication by ensuring that they face a resident when speaking, have light upon them rather than behind them, using gestures that are consistent with what they are saying, and presenting information simply and slowly[44]. A part of this process is also supporting the 'coping strategies' the user has developed to manage the difficulties he or she encounters in the home.

For many care staff, being able to effect meaningful communication with residents is a crucial component of job satisfaction; lack

of opportunity to build personal attachments is a strong predictor of staff burnout[45]. This evidence suggests that enhancing communication skills – a widely noted practice deficit – needs to be a distinctive focus of dementia care training and that care homes need to find ways to ensure staff have the time and expertise to build up and sustain interactions with residents. It is important to recognize that providing care that takes residents' emotional experiences and wishes seriously, facilitates choice and provides a sense of security and reassurance is both time consuming and intensive[46].

A number of key characteristics mark out those care homes that successfully promote and sustain good quality care: clear leadership, a positive ethos, and staff training and support to enhance communication skills and promote retention[47]. A recent project – the 'Enriched Opportunities Programme' – offered a multilevel approach to enhancing the quality of care in three care homes for people with dementia: it included a strong emphasis on leadership and dementia expertise, a trained care team with empathy for residents, and a programme of care and activity developed to meet the needs of individuals. It evidenced that by adopting a coherent focused approach that takes full account of the experiences of residents, care practice and the overall culture of care can be significantly improved[48].

CONCLUSION

People with dementia living in care homes face enormous challenges. In addition to declining cognitive powers, users have to cope with a new and often unpredictable environment. They may also be cared for by people who know very little about them and who are, encouraged by an over-reliance on 'procedures', to focus on their physical safety rather than their emotional well-being. Additionally, frailty, communication difficulties and dependency on others often means that their needs are overlooked and their voices marginalized. Understanding more about the experience of living with dementia in a care home is a critical contribution to improving both quality of life and quality of care. Prioritizing relationships and communication, the establishment of genuine staff–resident attachment, managing distressing emotions, and ensuring that care is individually planned and delivered are key dimensions of practice that place the user experience at its core. Intimate biographical knowledge about the user and their life history, and bolstering the user's abilities, sense of self and identity are key aspects of providing person-centred care. The provision of tailored day activities and recognition of the stresses communal life can cause are also important issues highlighted by research. Excellence in dementia care begins with an understanding of what it is like to live with the illness *throughout* its trajectory[49]. As there is no doubt that residential care is, and will continue to be, one of the dominant types of provision for people with advanced dementia in the developed world, increased emphasis on research that explores the user experience and practice that foregrounds it, is a central component of effective and positive practice in care home settings.

INTRODUCTION

The term 'ageing' is a generalized complex terminology that can address a number of concepts, including aspects such as the demography of the whole population or trends within specific age groups (such as births or the older population). But the term 'ageing' is also a generic term for the older population and factors associated with it. Within this chapter we aim to investigate some of these factors and show how the population of the world has changed, how historical changes will affect health in the next decades, how our estimates of population change are challenged by diseases and treatments and what can we currently say about the health of the older population.

TRENDS IN POPULATION SIZE

The historic, current and future population demography demonstrates historic and interesting changes. Over the course of the last 50 years and in the next 50 years there has been and will be a fundamental shift in the distribution of the human population. Different areas of the world display different demographic shift patterns; for example the shifts in the United Kingdom and United States show patterns that are different from those seen in China and India[1]. Nevertheless, all countries are experiencing population ageing.

Figure 16.1 shows the demographic changes across different regions of the world. China and India have not only had a large change in the distribution of the population, they have also increased dramatically in size. The shift in this distribution means that the proportion of the population that is already considered 'older' varies greatly by country. Current estimates of the proportion of the population aged 60 years and over are shown in Figure 16.2. Although the relative distribution shifts from Europe and North America in 1950 towards Asia by 2050 (Table 16.1) there are large numbers in the older population throughout the whole world.

Despite these differing demographic patterns already 64% of the older population (aged 60 and over) live in developing countries and by 2050 nearly 80% of those aged 60 and above will live in developing countries[2]. This definition, however, includes only Europe, North America, Japan, Australia and New Zealand within the developed countries – a pattern that may not reflect true differences[3].

Table 16.1 Percentage distributions of those aged 65 and older by region, 1950–2050

Region	1950	1975	2000	2025	2050
World	100	100	100	100	100
More developed regions	49.0	48.7	40.7	31.5	21.7
Less developed regions	51.0	51.3	59.3	68.5	78.3
Africa	5.5	5.4	6.2	6.8	9.4
Europe	34.4	33.5	25.6	17.8	12.1
Asia	43.9	43.6	51.6	57.9	62.1
North America	10.8	10.8	9.3	8.7	6.4
Latin America and the Caribbean	4.7	6.0	6.7	8.1	9.4
Oceania	0.7	0.7	0.7	0.7	0.6

TRENDS IN FERTILITY

Trends in fertility affect the composition of the older population many years later. While this ensures that surprises are not often encountered in the description of the older population it also means that demographic influences are less immediate at solving the challenges predicted. The decisions made on childbirth both between the two World Wars and after the Second World War are now shaping the composition of the older population. The generation of children to the 'baby boomers' in the 1960s are now reaching middle age and the size of this demographic bubble can be clearly seen in the population pyramids (Figure 16.1). Many European countries have for a number of years been below the reproductive factor (2.1 births per woman[2]). This rate of replacement of the younger population will again shift the relative balance of the population in terms of young and old. In this case there is a double impact, as the baby boomers reach old age with a lack of grandchildren to replace the status quo of the pyramid. This will create, at least for the next 50 years, an ageing society. The current fertility decisions of the early adults are not suggesting that this imbalance will refocus. In fact the decisions to delay or reduce childbirth across the whole of the developed population (and wider in many cases) mean that the majority of countries are now below the 2.1 factor.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

In the less developed regions where infant mortality is still high, despite advances resulting from the Millennium Development Goals (UN Millennium Goal 4), the fertility rate is still relatively high but is reducing dramatically. The developing countries are still experiencing an ageing population, but in a more historically understood way, although many unknowns remain[4]. A recent UN report states that fertility levels are unlikely to rise again to the historic highs and therefore the expression of population ageing is irreversible[5]. However future population size is sensitive to small but sustained deviations from the replacement level[5].

The patterns of fertility affect not only the absolute level of the future middle-aged and older population but they also have a direct impact on the life of the older population at the individual level. The number of available carers within a population is almost universally linked to the extended family support. As this family structure shifts so will the life of the older person[6]. An international comparative survey on the older population undertaken in 1996 showed that the proportion of the older population aged 60 and over living in three-generation households was 29–43% in Asian countries compared with 2% for European and North American countries[7]. If this structure is mimicked with the changing demographic then it will impact enormously on policy.

TRENDS IN LIFE EXPECTANCY AND HEALTHY LIFE EXPECTANCY ACROSS THE AGE RANGE

There has been a steady and consistent increase in life expectancy at birth across all continents and in both males and females (Figure 16.3). However, the major issue in the statistical trends in healthy life expectancy is whether with the extension of longer life there is also an extension of healthy life (i.e. the total remaining life that can be expected to be free of disability). Three patterns of

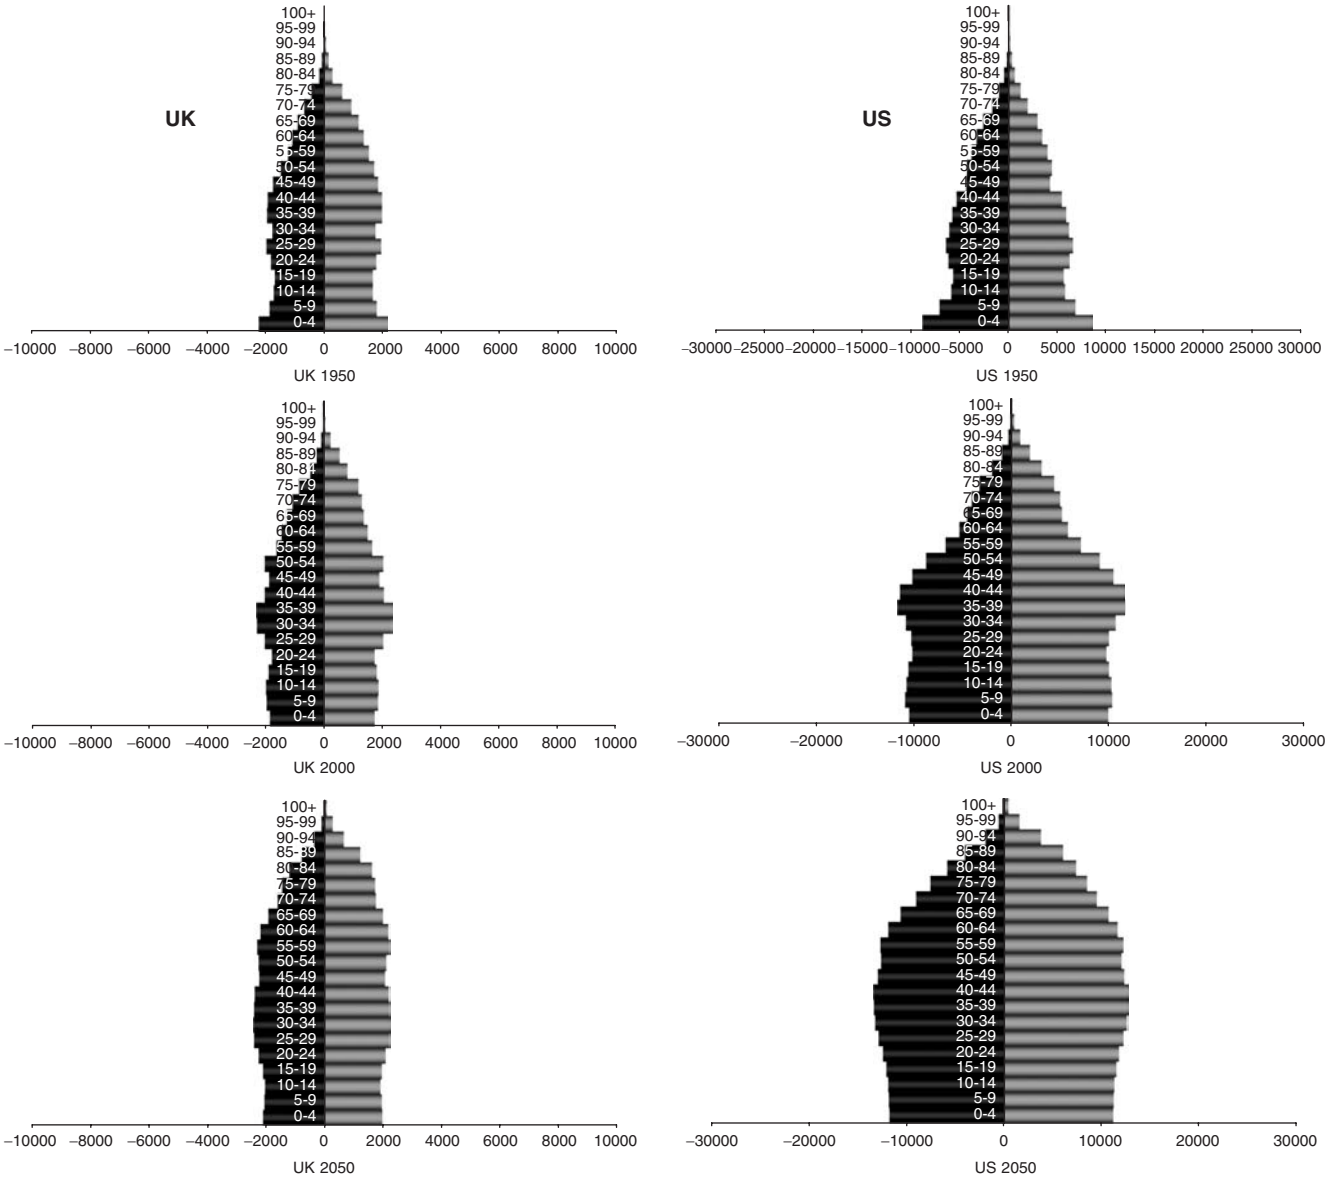

Figure 16.1 Population pyramids and changing distribution. Bars refer to the size of the population (in thousands) of men (left) and women (right) in each age group

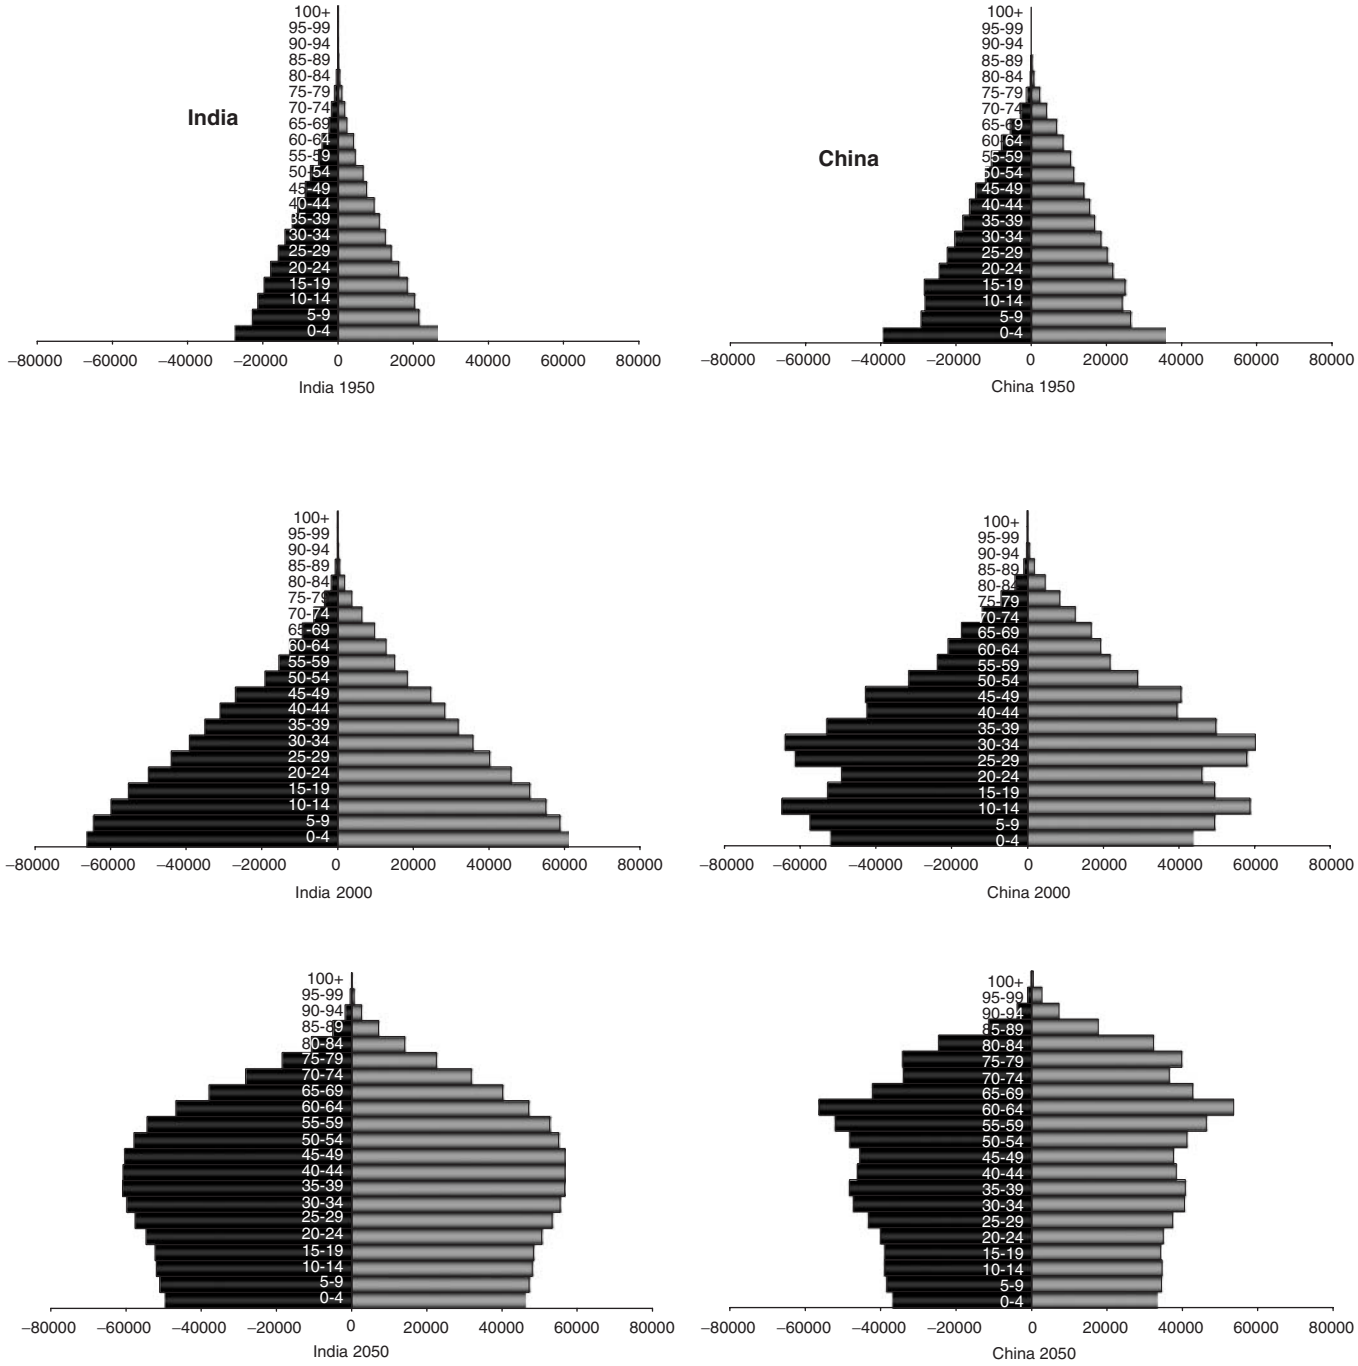

Figure 16.1 (*continued*)

population change in healthy life expectancy have been proposed, an expansion of morbidity[8], a compression of morbidity[9] or dynamic equilibrium[10]. Expansion of morbidity would imply longer life expectancy but at the same time longer life expectancy in ill-health, compression of morbidity would imply that the life extension is predominantly from the healthy life and dynamic equilibrium implies that severity may change, but the burden remains constant. Evidence to date suggests that all three scenarios can occur in different populations at different times.

MEASURING THE CHANGING HEALTH STATUS OF THE OLDER POPULATION

Assessing the compression or expansion of morbidity relies on being able to measure the health status of the older population. Complementary insights regarding the changing health of the older population can be gained from several major sources, each with their own merits and drawbacks. In developed countries routinely gathered statistics such as census data and birth and death certification may be used and these provide reliable information on demographic changes. Routine

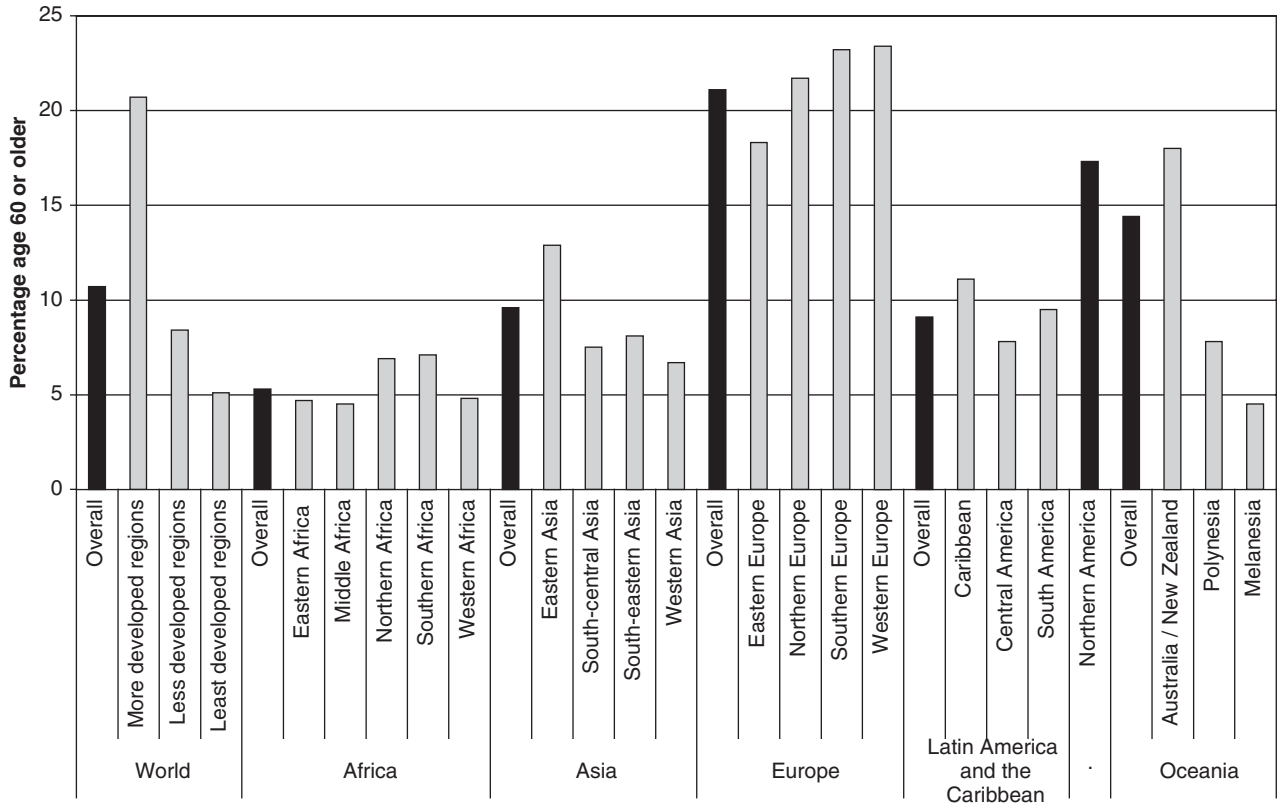

Figure 16.2 Proportion of the older population by country

medical databases, such as hospital admissions data, prescription records or disease registers provide another source. However the reporting of medical conditions to these registers may be biased by various processes. Both the mechanisms by which older people come to the attention of health care providers and reporting practices change with time, particularly in the older population, as a result of changing awareness, attitude and perception of health both by older people and their health care providers. Reporting practices can also vary geographically. Psychiatric conditions in the older population are particularly likely to be under-reported, and death certificates often do not mention major diseases such as dementia despite it being present or a major contributing factor to the death of an older person. Using routine data to record the health and in particular the psychiatric health of the older population is therefore unreliable. Furthermore in many areas of the world such statistics are not collected routinely.

To overcome some of these methodological difficulties, epidemiological studies are conducted. These typically involve recruitment of a cohort who are chosen to be as representative of the population as possible, and these are then subjected to a standardized assessment of their health. Repeating standardized assessments in the same cohort over time leads to a longitudinal study in which changes in the health of the population can be examined. Longitudinal epidemiological studies of health are not without their difficulties. Biases in selection and drop-out are possible and must be examined carefully. Epidemiological studies often have limited applicability outside the populations in which they are conducted, and compared with routine statistics they are limited by their size in terms of detecting small changes. Studies that rely on self-report may still be influenced by changing understanding or perceptions of health[11], or by cross-cultural differences in the interpretation of questions, and so questionnaires must be designed to be as objective as possible.

Projections about the future burden of disease in the older population are generated by combining demographic data on the likely future numbers of older people with epidemiological data regarding disease prevalence and the impact of disease.

TRENDS IN GLOBAL HEALTHY LIFE EXPECTANCY

The international patterns of disability and healthy life expectancy are not consistent with different patterns seen within different populations. Countries have reported both an increase in the prevalence of disability (Sweden[12]), rates stagnating (Australia[13]), or decreasing (United States[14], France[15], Finland[16], Japan[17]) and different evolutions reported for subgroups (men and women in Spain[18] and Denmark[19]) or for mild rather than severe disability (Netherlands[20]). Trends in disability rates are not sufficient, however, as changes in the age distribution of the population need to be combined with the changes in the disability rates to see the full population, and hence conflicting results with another study from Australia found evidence of a compression of morbidity[21]. A recent European comparison has shown that there are still large variations across Europe, and that these inequalities may be becoming larger, particularly between Eastern and Western Europe, and that healthy life expectancy may show more variations than life expectancy[22].

In the developing world there is currently little evidence to investigate whether there is a compression of morbidity or an

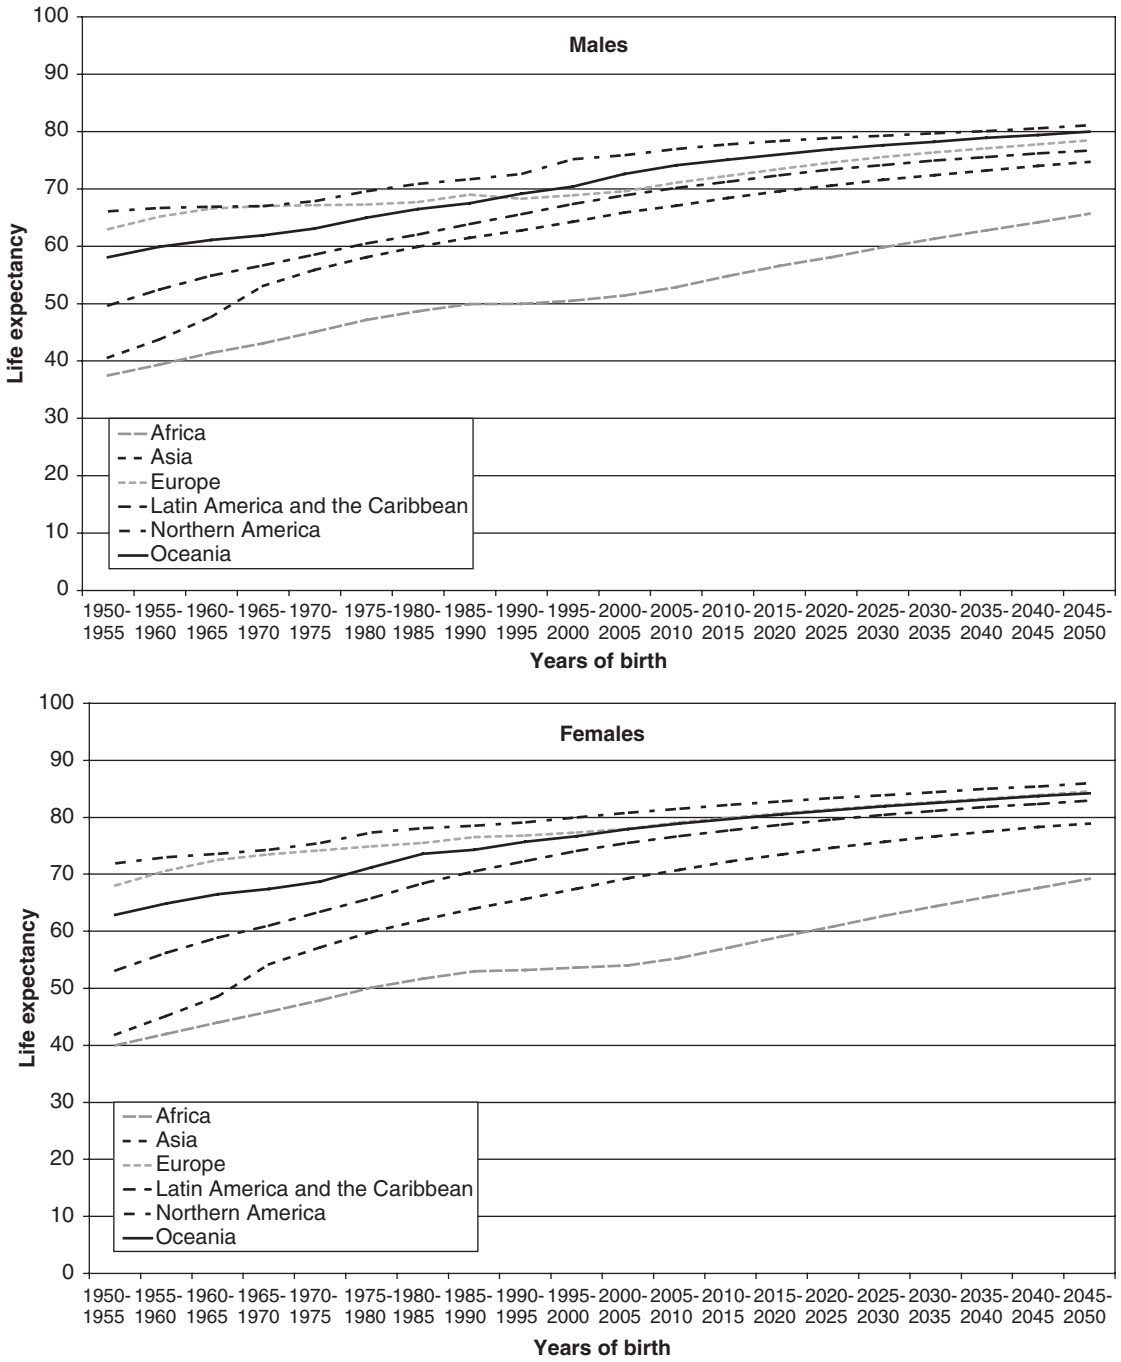

Figure 16.3 Life expectancy at birth across world regions. From Population Division of the Department of Economic and Social Affairs of the United Nations Secretariat[1].

expansion[23]. These countries are at the early stages of the chronic disease growth, though it is becoming an increasing problem. The challenge for a healthy older population across the entire world is one of a focus on lifelong health, not just health in mid to late life[24]. This sort of focus is long term and often overlooked within a resource scarce environment.

It is also possible that these different balances will fluctuate in different populations at different times and may well be modified by intervention strategies and changes to national care policies.

CHANGES IN MARKERS OF HEALTH

As well as varying across cultures, whether the health of the older population is improving or worsening also depends on which measures of health are considered[25,26]. Most studies of changes of health in the older population focus on changes in the levels of disabilities, since this is one of the major determinants of poor quality of life, the inability to live independently and the need for long-term care. Many such studies have shown improvements between cohorts with time. However, the level of disability of an

individual is determined both by their underlying health conditions leading to functional impairment and by their environment. Changes in levels of disability may therefore be caused by changes in lifelong exposure to risk factors affecting the prevalence of diseases, the changes in the impairments caused by diseases when they occur, and by changes in technology and the environment. Changes in the prevalence of health conditions may reflect both changes in incidence and in survival with that condition.

The evidence regarding age-specific trends in disability in the older population is mixed. Some evidence of an improvement has been seen in the prevalence of mild disability, while the level of more severe disabilities has remained constant or has worsened slightly. In contrast, most comparisons of health conditions in the older population have shown an increase in major disease prevalence and co-morbidity as well as in objective measures of specific functional limitations[12,27,28]. Consistent improvements in survival with diseases such as heart disease and stroke have not been offset by reductions in their incidence, leading to an increase in prevalence. On the other hand, disability among stroke survivors and those with heart disease has decreased.

Although much of the increase in human life expectancy in the past century has been caused by a reduction in infant mortality, life expectancy of the older population is also increasing. This will lead to changes of the population structure within the older population, particularly in an increase in the numbers of the oldest old compared with the younger old[29]. The oldest old are an emerging population group in terms of research and information on changes in their health and demographic characteristics are only beginning to become available. The oldest old have high rates of physical and cognitive impairment and are likely to live in institutions[30]. A recent report highlighted changes in the demographic and socioeconomic characteristics of the oldest old population in England and Wales[31], revealing an increase in the numbers of the oldest old living alone and as well as an increase in health care resource utilization. More research is needed on the oldest old.

CHANGES IN MENTAL HEALTH

Mental health is increasingly recognized as a significant independent contributor to the burden of disease and as a mediator of aetiological factors for other diseases[32], and maintaining healthy brains in later life is now a research priority[33]. Mental health issues such as schizophrenia and depression affect the whole population, and in the older population dementia and cognitive decline are of specific importance. Mental health in early and midlife is a strong predictor of mental health in old age.

Little reliable evidence is available regarding trends in the prevalence of psychiatric conditions in the older population. A comparison of two studies with similar methodology carried out 10 years apart showed a significant increase in major depression diagnoses in all sociodemographic groups[34].

The effect of changes in age structure of the global population on the number of people with dementia was estimated by a Delphi consensus study, which combined all the available evidence regarding dementia prevalence and future population trends[35]. The number of people aged over 60 with dementia in Europe and North America is likely to have increased by 50% from 2001 numbers by 2020 and will have doubled or trebled by 2040. The numbers with dementia in East Asia and Africa are expected to increase by four times in this time period. There are projected to be 81.1 million people worldwide with dementia in 2040 compared with 24.3 million in 2001, with 70% living in the developing world. However these estimates are based on limited information; while reliable estimates for dementia prevalence are available in the developed world, direct estimates are not available in many areas, although cross-cultural studies that have been undertaken suggest that patterns may be different and further information on global dementia epidemiology is urgently being sought.

Changing incidence and survival with dementia and changes to the disability associated with dementia will affects its impact in the ageing population, and these trends will depend on changing prevalence of risk factors as well as interventions and management. The age-specific incidence of dementia and cognitive impairment has been suggested to have decreased slightly, possibly due to the effects of improved health-related lifestyle and education[36], while the increase in survival from stroke, might suggest an increasing prevalence[37]. Social networks and intellectual stimulation are increasingly recognized as being important determinants of health and mental health in the older population. Models estimating the impact that changes in dementia trends and treatments will have on the future disability burden illustrate the uncertainty in predictions and highlight the need for treatments that will alleviate that burden[38].

FUTURE PROSPECTS AND DIRECTIONS

International trends in ageing are difficult to predict, though recent publications have attempted to investigate not only the population shift[5], but also the trends in disability and health[38]. However it is not just the population shift that requires careful consideration, other factors including changes in food, water, housing, education, early and midlife health and behaviour and the physical and biological environment will all affect our future health prospects[39]. Trends seen across the world raise a number of concerns for the future of the ageing population, foremost of which are the increase in the burden of disease and dependency. Interdisciplinary research across the whole world and in all populations is required in both the ageing process of an individual and the effects of an ageing population, in order to understand and meet the challenges now and in the years ahead[40].

Economics of Ageing and Mental Health

Anders Wimo

KI Alzheimer's Disease Research Center, Department of Neurobiology, Care Sciences and Society, Karolinska institutet, Stockholm, Sweden

INTRODUCTION

The greying of the world and the high prevalence of mental disorders have highlighted the vulnerability of the social and health-care systems. Based on demographic forecasts, almost apocalyptic scenarios have been presented. The number of people 65 years and older will increase from about 500 million people in 2010 to about 1 billion in 2030. The diseases of the elderly and mental disorders are in general chronic, resource demanding, more or less incurable and long lasting (decades). These disorders also involve many sectors of the society; not only the health-care sector but also to a greater extent social services and informal carers, and they cause a substantial loss of well-being and life-years worldwide[1]. If we also add a financial crisis in the many public care systems we must consider fundamental issues such as economic burden, cost effectiveness of treatments, priority settings, equity, how to organize, finance and distribute care in any health economics analysis.

Health economics is the application of economic theory to health care[2]. There are, however, several methodological issues in this field, which also link to fundamental health economics questions. Some basics in health economics must also be considered. The main focus in this chapter is on dementia and similar disorders, but the principles are applicable to any mental or chronic disorder and so we have also included examples from other mental conditions.

PERSPECTIVE

A health economics analysis can be seen from different viewpoints such as a societal perspective or specific cost-bearers (e.g. county councils, municipalities, insurance companies)[3]. A societal perspective is preferable and should include all relevant costs (that is both direct costs within the health sector and indirect costs due to production losses and costs of informal care) and outcomes. Depending on the selected viewpoint, the outcome of the analysis may vary.

RESOURCE UTILIZATION AND COSTING

A key issue in all economics is the cost concept. The opportunity cost, which most economists recommend using in descriptive studies and economical evaluations, is the value of a resource in its best alternative use[2]. Care resources are more or less always scarce and the use of a resource in one specific way will result in some lost benefit because resources were not allocated to another option[4].

Ideally, opportunity costs should be based on market prices, which in health care are not always easy to identify. For example, for an informal caregiver, who because of the care-cost demands is not working, the opportunity cost is the value of the forgone work that could have been done.

Costs can be divided into direct medical costs, direct non-medical costs and indirect costs. In a simplified approach, direct costs refer to the value of resources used and indirect costs to resources lost. Direct medical costs refer to resources used in the medical care system, such as costs of hospital care, drugs and visits to clinics. Direct non-medical costs are those outside the medical care system, such as costs for formal community care and transports. Depending on how care is organized, costs of long-term care and home care can be regarded as a medical or non-medical direct cost.

Indirect costs are costs due to production losses (such as sick leave, early pension, impaired productivity) or mortality. Costs of informal care (see below) is a complicated issue in itself[5,6], and are often classified as indirect costs, but this is not always obvious.

The costing process usually consists of two phases: first the use of resources is measured in terms of physical units (e.g. days in hospital, hours of home support) during a specified period of time; secondly, this resource utilization is calculated into costs. For economic studies of dementia, we have developed a process called resource utilization in dementia (RUD) (Table 17.1)[11]. Because the organization of dementia care varies between countries, the process must be adapted to the particular national situation. This process also includes linguistic adaption, because the meaning and the costs of care concepts (such as 'institutional care') may vary between countries even if the basic language is similar, e.g. if English is spoken in the UK and South Africa, it does not necessarily mean that the interpretation of care concepts is the same. In multinational trials, it is recommended that the aggregation of results from different countries is in physical units and not in costs.

TYPES OF STUDIES

Several approaches can be used in health economics analyses (see Table 17.2)[7]. With the cost description (CD) approach, the costs of a single treatment are described without outcomes/effect measures

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

Table 17.2 Different types of health economics studies

CD	Cost description
CA	Cost analysis
CMA	Cost minimization analysis
CEA	Cost effectiveness analysis
CBA	Cost benefit analysis
CUA	Cost utility analysis
CCA	Cost consequence analysis
COI	Cost of illness

and without making any comparisons with alternative treatments. In a cost analysis (CA), the costs of different treatments/therapies are compared, but there are no outcomes/effects included in the analysis. A complete health economics analysis should include both measurements of costs and outcomes and comparisons between different treatment alternatives. This is often expressed as a ratio: the the incremental cost-effectiveness ratio (ICER)

$$\Delta C/\Delta E = (C_A - C_B)/((E_{AT1} - E_{AT0}) - (E_{BT1} - E_{BT0}))$$

where C = costs, E = outcomes/effects, A,B = treatments, T0,T1 = time for assessments.

There are, however, other approaches such as net benefit analyses (net monetary benefits and net health benefits)[7]. Irrespective of approach, a willingness-to-pay level (for a specific outcome) is crucial.

In a cost minimization analysis (CMA) there is evidence that the effects/outcomes are similar between the treatment options and thus the analysis is focused on identifying the therapy with the lowest cost. The difference between CA and CMA is that in a CA there is no data about effects/outcomes.

In a cost-effectiveness analysis (CEA), the effect is expressed as a non-monetary quantified unit such as the cost per death or nursing home admission averted. Other outcomes may be functional measures such as activities in daily living (ADL) capacity, severity states of disease and cognition (e.g. scoring on different scales). In a cost benefit analysis (CBA), costs and outcomes are described in the same unit (usually monetary). Early CBA analyses had a simple human capital approach, while the modern theory of CBA is complex and includes willingness-to-pay approaches such as contingent valuation[8,9]. In a cost utility analysis (CUA), the effect is expressed in terms of utilities, such as quality of life. In CUA, the concept of quality adjusted life years (QALY) is frequently used (as well as other similar measures such as disability adjusted life years (DALY) and healthy years equivalents (HYE)).

In a cost consequence analysis (CCA), cost and outcomes are analysed and presented separately and there is no direct mathematical connection between these two measures.

Cost of illness (COI) studies are descriptive (such as the costs of illness of dementia in Sweden in SEK 50 billion/year). Two approaches can be used: the prevalence method and the incidence method. With the prevalence approach the costs include for all cases for a specified time period, most often one year, including those already suffering from dementia and for new cases occurring during the period in question[10,11]. With the incidence approach the costs for new cases during e.g. one year are estimated, here both the annual costs and future (discounted) costs are included. The choice of approach depends on the purpose of the study: if the aim is to illustrate the economic consequences of interventions, the incidence approach is preferable. If the idea is to estimate the economic burden during a defined year the prevalence approach is the best option.

Another issue in COI studies is whether to use a top-down or a bottom-up approach. In top-down analysis, the total costs for a specific resource (e.g. health-care costs) are distributed over different diseases. Such studies often rely on data from national registers or similar. The bottom-up method starts from a defined sub-population (often from a local area) with for example dementia and registers all cost of illness related to the disease, followed by an extrapolation to the total dementia population. The problem here is compensating for co-morbidity and net costs may be difficult to estimate. It is also important to specify the included cost categories (e.g. cost of informal care). COI studies can be expressed as costs per case and year or as total costs in a specific country/region. Examples of COI studies of mental disorders are seen in Table 17.3. The cost figures highlight the great variation in cost estimates and the importance of identifying the included cost categories.

INFORMAL CARE

Family members and friends or others close to people with mental disorders are heavily involved in their care. Their situation is of great interest from two aspects. First, mental disorders have consequences for the carers themselves. In this sense, their situation is often very stressing (it can be described in terms of burden, coping, but also in terms of morbidity and mortality).

Secondly, in their role as informal carers they are producers of unpaid care. This production of care is a very important part of the costs of mental disorders from a societal perspective. Costing of informal care is complicated and controversial. There are two frequently used methods: the replacement cost approach and the opportunity cost approach, both of which have drawbacks when applied to mental disorders. The replacement cost approach means that if informal care has not been provided, professional staff must be hired on a 1:1 ratio (e.g. one hour of informal care corresponds to one hour of professional care).

In our opinion, informal care should be valued by its opportunity cost, which for a person of working age, is a production loss, but regarding leisure time and contributions by retired persons or persons with no position on the labour market, it is more complicated and there is no given answer.

In most cases, the replacement cost approach results in higher costs of informal care than the opportunity cost approach.

Table 17.3 Examples of COI studies of mental disorders

Country/ Region	*Disorder*	*Costs (billion US$ 2006)*	*Annual costs per patient (US$ 2006)*	*Cost categories included*	*Source*
World	Dementia	326.8	11 138	D, IC	(42)
EU27	Dementia	195.6	26 761	D, IC	(43)

Table 17.4 Randomized controlled trials with empirical economic data on pharmacological interventions in Alzheimer's disease

Drug	*Disorder*	*Country*	*Duration*	*Results (US$ 2006)*	*Reference*
Donepezil	Alzheimer's disease	Nordic	1 year	1 228 (ns)	(50)
Donepezil	Alzheimer's disease	Canada France, Australia	6 months	320 (ns)	(51)
Donepezil	Alzheimer's disease	UK	60 weeks	−907 (ns)	(52)
Memantine	Alzheimer's disease	USA	6 months	7 946 ($p < 0.05$)	(53)
Risperidone (r), olanzapine (o) and quetiapine (q)	Alzheimer's disease	USA	9 months	(per month)2002, ITT 193(r),−9(o), −199 (q) Overall $p = 0.02$ (placebo lower)	(54)

BOOTSTRAPPING

Cost data are often skewed (large variation in resource utilization and costs and lots of zero values), making traditional statistical analyses questionable. To compensate for these problems, bootstrapping is frequently used. By resampling from the original database, a new database is created. After each drawing from the original database to the new database, the drawn case is returned to the original database. There are many ways of bootstrapping but in general the new database has the same number of cases as the original sample. After repeating the resampling process several times (e.g. 100–10 000 times, using statistical software), statistical analyses, such as calculating confidence intervals, can be performed, assuming a better representativeness compared to the original reference population[12]. Confidence intervals are often more narrow with bootstrapping than without.

OUTCOME MEASURES

A health economics analysis is incomplete if there is no outcome/effectiveness measure related to the costs (mostly as a cost-effectiveness ratio). In mental disorders or diseases of the elderly, the choice of effectiveness measure is not obvious. The priority discussions may be between different treatments of a particular disease, but also between treatments of different diseases (e.g. schizophrenia and stroke). In the first situation, diagnosis-specific outcomes may be used (e.g. depression scales in depression, cognition in dementia), but in the latter case, generic outcomes are necessary. Also when diagnosis-specific outcomes are used, there may be interpretation problems – what is the societal value of an incremental cost of X US$ for a one-point reduction in a depression scale?

Health-related quality of life (HRQoL) is often suggested as the most relevant outcome measure in chronic disorders (such as mental diseases). HRQoL instruments consist of several dimensions (e.g. ADL, social interaction, cognition, perception, pain, anxiety, economic status) and they can be diagnosis-specific or generic[13]. A specific problem in dementia and other mental disorders is that the subjective dimension may be difficult to measure. Thus, proxies (mostly caregivers) are often used[14]. Indirect measurement per se, with proxies is, however, not necessarily a problem – the US Panel for cost effectiveness recommended that the general public should value health states[15]. However, if the proxy is a family member, the answers may more or less reflect the situation and interests of the proxy and not the patient's viewpoint.

Examples of instruments used in dementia are the dementia quality of life instrument (DQoL)[16] and quality of life – Alzheimer's disease (QoLAD)[17,18]. The quality of life assessment schedule (QoLAS) is an instrument that has been used in neuropsychiatric disorders[19–21]. Since these instruments are not preference based[15,22], they are less appropriate for cost utility analysis.

Generic HRQoL scales provide opportunities to make comparisons with other diseases. There are also two types of generic scales.

Table 17.5 Economic evaluations with bootstrapping approaches

Intervention	*Disorder*	*Country*	*Design*	*Study length*	*Outcome*	*Cost difference (US$ 2006*)*	*ICER in base option (US$ 2006)*	*Sensitivity analysis or similar*	*References*
Case management	Dementia	Netherlands	RCT + bootstrapping	6 months	Successful treatment	$246*	4 315/unit	95% vs. WTP of 34 000€	(55)
Case management	Dementia	Netherlands	RCT + bootstrapping	3 months	Successful treatment	$2 247*	Dominance (94% probability)	99% vs. WTP of €2000 per 'successful treatment'	(56)
Psychotherapy of 55+	Depression	Netherlands	RCT + bootstrapping	12 months	Recovery, QALYs	$798	ICER 366 921/ recovery Intervention not cost effective	Bootstrapping: 17% more effective, less expensive. 35% more effective, more expensive, 37% less effective, more expensive. 11% less effective, less expensive	(57)

Table 17.6 Examples of economic evaluations with modelling approaches

Intervention	*Disorder*	*Country*	*Design*	*Model length*	*Outcome*	*Cost difference (US$ 2006)*	*ICER in base option*	*Sensitivity analysis or similar*	*Reference*
Donepezil	Alzheimer's disease	USA	Markov model	2 years	QALYs	92	Dominance	<0 to 529 566 (all scenarios)	(58)
Rivastigmine	Alzheimer's disease	Canada	Survival model	2 years	QALYs	438	Dominance	NA	(59)
Galantamine	Alzheimer's disease	UK	AHEAD model	10 years	QALYs	−817	14 755	9 861–29 585	(60)
Memantine	Alzheimer's disease	Sweden	Markov model	5 years	QALYs	13 454	Dominance	<0 in all scenarios	(61)

Examples of indexes or profiles are the sickness impact profile[23], the short form 36 (SF-36)[24] and shorter versions; SF-20 and SF-12.

Regarding caregivers, burden scales, such as the burden interview[25], can in some sense be used as indicators of QoL, but the interplay between patient characteristics, caregiver QoL and burden is complex[26].

Other types of generic scales are used to calculate quality adjusted life years (QALY)[27]. These include the health utilities index (HUI)[22,28], the EuroQoL/EQ-5D[29] and the index of well-being/quality of well-being scale (QWBS)[30].

The QALY concept reflects both quantity of life and quality of life[22,31] and is expressed as figures between 0 (death) and 1 (perfect health); it is widely used in CUA. The use of QALYs is under debate, particularly regarding the elderly[32]. Chronic, incurable, progressive disorders may be disfavoured when compared with e.g. surgical treatment such as cataract or hip replacement surgery.

Postponing institutional (long-term) care has sometimes been defined as an advantageous effect of interventions, making itself a potential outcome. However, this approach can be questioned for several reasons. The concept of institution is not homogeneous[33]. There are also situations where institutional care is a better alternative that insufficient care 'at home'. If postponing nursing home care is successful, there will also probably be a shift from formal care in an institution to formal home care but, which is more notable, also to an increased period of informal care. The latter shift may cause consequences on the caregiver's private situation, and also from a societal cost perspective.

MODELLING

Dementia and other mental disorders most often last for many years. The economic literature in this field with empirical data from interventions is often based on short periods of time. Such studies are shown in Tables 17.4 and 17.5 (Table 17.5 with bootstrapping approaches). The longest study period in these studies is 60 weeks. Since for practical reasons is difficult to perform interventions studies lasting for several years, there is a great interest in using different approaches of modelling to catch the long-term effects[34]. In an economic model, results from a short empirical core period are extrapolated to a longer period. Inputs from several sources, e.g. efficacy, costing and progression, are used. Various applications of Markov models[35] are frequently used, but several other approaches are at hand. In a review, Cohen and Neumann identified 13 types of models regarding Alzheimer's disease[36].

Discounting of costs (and perhaps outcomes) with rates between 3–5% is recommended[15]. Examples of different modelling approaches are given in Table 17.6. Notable is that most models tend to indicate cost effectiveness. One reason is that the models are based on a positive efficacy effect of the active treatment and a relation between disease progression and costs. Factors that neutralize are the costs of the treatment itself (e.g. not only the drug but also diagnostics and laboratory tests that follow treatment), effects on mortality and costs of side effects.

Models are controversial: the results are highly dependent on the assumptions. Long-term effects, such as exhaustion of carers and staff, which do not occur in the early stages of a disease, and symptoms which do have not a linear progressive course, such as behavioural and psychological symptoms in dementia (BPSDs)[37], are difficult to model. A model is also linked, implicitly or explicitly, to a specific organization of care. Although we regard modelling as an essential part of health economics, many drug authorities and clinical researchers are often sceptical about models; they regard such studies as not being 'empirical'.

PHARMACOECONOMICS AND PROGRAMMES

Even if the literature on health economics is sparse, there is a great deal concerning health economic evaluations of drug treatment. Other clinical interventions (here referred to as 'programmes') such as day care, caregiver support, psychotherapy, case management, housing programmes are common in the clinical reality, but sparse in the health economics literature of dementia and other mental disorders. There are several reasons for this. A drug intervention is rather easy to define and operationalize, while concepts such as 'day care' are more vague. Furthermore, it is difficult to include a sufficient number of study objects in an evaluation of a programme, resulting in poor statistical power. The basic field conditions (e.g. care structure, staff situation) at one study centre may differ considerably from another, making the intervention itself (e.g. day care) difficult to differentiate between different sites. In this sense a pill is much easier to define. The costs of a programme may also be very high if a lot of staff is involved and the economical strength of the sponsors is often weaker than the resources of drug companies.

CONCLUSION

Due to the enormous socioeconomic impact of chronic disorders of the elderly (such as dementia and other mental disorders), it is

obvious that there is a great need to obtain information about 'value for money'. Many clinicians take a position that it is unethical to discuss cost effectiveness of diseases that affect weak patient groups. Our position is the opposite: it is unethical NOT to discuss cost effectiveness of the treatment and management of these disorders. Care for these patients demands great investment and if we have no idea of what we get for the money, there is a great risk for a waste of money and resources. This is indeed unethical.

The Influence of Social Factors on Mental Health

Donna D. McAlpine[1] and David Mechanic[2]

[1]*School of Public Health, University of Minnesota, Minneapolis, USA*
[2]*Institute for Health, Health Care Policy and Aging Research, Rutgers University, New Brunswick, USA*

Social factors have an enormous influence on the life course, affecting development and socialization; the relative influence of family and peers; opportunities for education, work, recreation, social participation and patterns of social integration; and independence as one reaches the later years of life. They also influence the availability of various health providers and health care settings if one seeks medical care. It is not surprising, therefore, that almost every aspect of mental health and well-being is influenced by social factors[1].

Understanding the social context of mental illness requires appreciating how social factors may be causally related to either the first-onset or re-occurrence of mental illness, and, in turn, how individuals' social circumstances are shaped by having a mental health problem early in life. Moreover, at all stages of the life course, social context and social policies help explain variation in response to symptoms, treatment patterns and outcomes.

A life course perspective acknowledges that individuals carry into their later years all their prior experiences that influence health status as they age. Such a perspective also directs attention to cohort and historical differences in life circumstances and the experience of health and illness. With the rapidity of social change, persons living a normal life span are required to modify their expectations and behaviour on many occasions if they are to adapt successfully to shifting social conditions. Transformations in technology, sexuality, fertility, family and work life, household structure and many other aspects of life also make it inevitable that different age cohorts will have diverse life experiences and thus, different experiences of health and illness.

Epidemiological studies indicate that ageing is not associated with greater risk of experiencing a mental disorder. Moreover, among community residents, the lifetime prevalence of disorders such as depression appears to be lower among older persons compared to their younger counterparts[2]. This finding may be due to methodological difficulties inherent in asking persons to recall their first onset of disorder, the omission of elders living in institutional settings from these studies, age differences in willingness to acknowledge feelings, or the fact that persons with mental disorder die earlier than those without such disorders. Given recall and selective reporting problems, the reliability and validity of lifetime estimates of mental illness can be seriously questioned. But the finding may also in part be suggestive of an important cohort difference; younger cohorts may be at greater risk of some mental disorders such as depression[2]. If these findings are supported by further evidence, and these conditions are not self-limited, we might expect that as younger cohorts age, the prevalence and societal burden of mental illness among older persons may increase.

The discussion that follows focuses more on severe mental illness than on levels of psychological distress or emotional well-being. The distinction between major mental illness and emotional distress is not always clear. The boundaries between what constitutes elevated symptoms of distress and what constitutes clinical disorder are porous and do not always reflect clinical reality. While the risk of experiencing a clinical disorder may not increase with ageing, there is evidence that depressive symptoms or psychological distress do increase in older age[3]. Mirowsky and Ross suggest the approximation of a U-shaped pattern with high depressed mood in late adolescence and young adulthood, lower levels in the middle years, and highest levels at old age[4]. Many studies deal with symptoms that do not reach the threshold of disorder but such symptoms can still have devastating effects on functioning and quality of life, and are a major source of disability, surpassing in impact many serious chronic diseases[5].

Overwhelmingly, research indicates that mental illnesses are neither randomly distributed nor solely the result of one's genetic heritage. But, investigating the social causes of mental illness is not inconsistent with the potential causal role of biology or genetics. Severe mental illnesses such as major depression, bipolar conditions and schizophrenia result from complex, but poorly understood, interactions between biological vulnerabilities and psychological and social influences. Adverse social and developmental factors may increase susceptibility to serious mental illness, or may trigger illness among vulnerable persons. There is increasing interest in gene–environment interactions and the role of early abuse and stress interacting with genetic vulnerabilities[6].

There is a large body of research documenting that social characteristics and position are associated with the prevalence and incidence of mental disorder. Generally, the research indicates being female, unmarried or from a disadvantaged social class increases risk for experiencing mental health problems. Much debate continues on the relative role of social selection and social causation in influencing these patterns. While the impact of these factors among the elderly has been less well studied, it appears that similar patterns characterize later life[7].

Explanations for the social patterning of mental disorder have explored both social causation and social selection. The search for the

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

social causes or contributors to these disorders has been dominated by the stress paradigm that largely focuses on depressive symptoms. Childhood abuse, stressful events and chronic strains, poor coping resources, lack of intimate and instrumental relations and low self-efficacy have all been found to be associated with the occurrence of depressive symptoms and to a lesser extent major depression. Experiences very early in life such as death of a parent, and physical or sexual abuse during childhood may be related to onset of depressive disorders well into adulthood[8]. Prenatal and nutritional deficiencies may play a role in neurodevelopmental processes and possibly conditions such as schizophrenia[9,10]. Research among the elderly supports the significance of the stress process for understanding the occurrence of depressive disorders in later life[7].

Research has also emphasized the importance of social support, both as a buffer to life stress and its absence directly contributing to the onset of depressive symptoms or disorder. However, social support remains a vague concept, having varying operational definitions ranging from marital status, network size and instrumental support, to the subjective qualities of relationships such as intimacy[11]. While not conclusive, the research suggests that lack of emotional support is most strongly associated with risk of major depression and most strongly buffers the potential deleterious effects of life stress[12]. Contrary to popular impressions, research indicates that individuals are able to maintain supportive relationships as they age; emotional support appears relatively stable across old age, while instrumental support appears to increase[13]. However, as people reach old age, lifetime networks become depleted as friends and intimates die. Support when significantly diminished may increase vulnerability to mental distress.

There is growing attention to the role of religion or spirituality as causally related to health outcomes, including mental disorder[14,15]. Results from many studies indicate that persons who are more involved in religious activities such as going to church report less psychological distress and lower rates of depressive disorder than those who are not involved in such activities[15]. Religion may be particularly important for the elderly and for specific cultural groups such as African Americans[16]. The pathways through which religiosity affects mental health remain unclear. One plausible hypothesis is that the emotional support and instrumental assistance that might result from religious involvement contribute directly to better health as well as help one cope with the difficulties of life. Research in this area continues to confront difficult selection bias, in that persons in better health may be more able and inclined toward religious participation and that persons drawn to various religious practices may be different in their personalities, attitudes and behaviours than those with lesser or no participation[17,18].

While it remains difficult to control for selection effects when trying to untangle the causal roles of social factors, it seems clear that social causation more powerfully explains social patterns of less severe disorders such as depression and is less significant in explaining psychotic disorders such as schizophrenia[19].

Understanding the importance of social selection requires taking a life course perspective that highlights the importance of social or health experiences for understanding the occurrence and consequences of mental disorder among the elderly. People bring into later life all the experiences related to family, friends, stressful life events and strains, employment and socioeconomic status that they have accumulated over their lives. All of these experiences influence how we are sorted or selected into various circumstances as we age. The early onset of mental disorder is one such experience. Having a severe mental disorder early in life increases the likelihood of remaining unmarried, especially for men, and increases the risk of divorce and separation among those who do marry[20]. Thus many people with severe mental illness will enter their later years without the benefits of a partner to provide emotional and instrumental support. Early onset also shapes later opportunities for education, employment and earnings[21,22]. Even if symptoms remit later in life, it is difficult to overcome these early experiences, and persons with early onset of mental disorder are more likely to find themselves living with significant economic disadvantages in later life.

Selection effects are particularly important for understanding the social correlates of severe and persistent disorders such as schizophrenia. Scant research suggests that social factors cause schizophrenia, although early work in the area found that stress acts as a trigger affecting the occurrence and timing of episodes[23]. A significant body of work on 'expressed emotion' indicates how modification of interactions can prevent and/or reduce episodes[24]. Experiences subsequent to the onset of schizophrenia importantly shape one's life course. The weight of the evidence supports the view that the impairment associated with schizophrenia prevents upward mobility comparable to one's age cohort and loss of social position because of difficulties completing one's education and maintaining employment[19,25]. Older persons with schizophrenia often carry these deficits they acquired when they were younger.

It is clear that those persons who had their first onset of major mental illness early in life bring into their later years life histories likely to be characterized by significant periods of disorder and disruption. But, they also may bring an array of skills and coping strategies, acquired through dealing with illness over many years, and such adaptive skills may help mitigate the potential negative impact of illness during later life. Research indicates, for example, that having a sense of meaning in life, especially a sense of purpose, buffers the effects of traumatic events early in life on symptoms of depression in old age[26].

For the majority of older people who have a mental health disorder, it will be a recurrence or continuation of a condition that first occurred much earlier in life. By some estimates, 95% of all cases of major depression have first onset before age 65[2]. For the majority of persons with depression, age of onset is early in life and seems to be causally related to social factors such as socioeconomic status, exposure to stressful life events and chronic strains, limited coping resources, and deficient social support. Re-occurrence of depression when one is older is commonly associated with similar social factors. In contrast, for the minority of persons who experience first onset of depression in later life, health status may play a larger role. Some research suggests that first-onset of depression in later life is more driven by the experience of health problems than psychosocial circumstances[27]. Similar findings have been observed for first onset of bipolar disorder in later life[28].

Like depression, most persons with psychotic disorders such as schizophrenia have onset early in life. The prevalence and aetiology of late-onset psychoses remain unclear, although there is a growing literature devoted to the topic. It has been suggested that there may be two types of late-onset psychoses: schizophrenia that occurs first after the age of 40, and schizophrenia-like psychotic disorder that first occurs after the age of 60[29]. Both types of disorders are rare and few social factors seem to be associated with risk. One notable exception is gender; the bulk of research suggests that women are at greater risk for late-onset schizophrenia[29], although the reasons for this increased risk are not well understood.

It is also clear that social factors matter a great deal for understanding responses to symptoms of mental illness, treatment patterns and

outcomes. Processes of help-seeking are influenced by broad social beliefs about the nature and what should be treated, characteristics of the individual and the social context in which mental illness occurs, and the organization of services and their physical, social and economic accessibility[1]. Members of varying age cohorts have been socialized differently in relation to the recognition of symptoms, appropriate sources of help and social stigma of seeking help from particular types of providers. Selection from the community to varying types of service providers is a two-stage process, which depends on general factors affecting the inclination to seek assistance, and other factors more specific to choice among alternative practitioners. Recent evidence suggests that older persons with a mental disorder are less likely to receive care than their younger counterparts[30] and are more likely to seek care in the general medical care sector than in the specialty mental health sector.

Treatment for mental disorders in older age is shaped by other social factors. Women are more likely to receive care than are men[31]. Economic disadvantage is also a substantial barrier to access to health services and prescription medications in settings without adequate health insurance coverage[32]. While treatment of depression among older persons has increased dramatically in recent years, there remain significant ethnic and socioeconomic status disparities[33].

Differences in patterns of treatment may reflect variation in help seeking behaviours and differences in response to symptoms by health professionals. Older persons with mental disorder are less likely than their younger counterparts with the same disorder to perceive a need for mental health care[34]. Many may normalize the symptoms of depression as part of normal ageing[35] or perceive such symptoms as less important compared to competing physical and social problems[36].

Interpreting symptoms as indicative of mental illness is also complicated by common use of drugs to treat physical illnesses during this stage of life. Prescription and non-prescription drug use is high in elderly populations because of the prevalence of physical illnesses and dementia. The inappropriate use of pharmaceuticals among elderly persons is also common and includes physicians over-prescribing to older patients, self-medication and drug interactions[37]. Drug sensitivity changes with age-related changes in individuals' capacity to absorb and metabolize drugs; therefore dosages effective in young patients may be ineffective or excessively high for older patients. Antipsychotics are commonly used 'off-label' to treat older persons with dementia, but there is current controversy about such treatment practices because they appear to increase risk of mortality[38].

Social factors such as socioeconomic status put persons with mental illness at risk for a number of negative outcomes not directly associated with the illness. Inadequate housing or homelessness remain significant problems for persons with mental illnesses and compromise efforts to provide meaningful services, yet we know little about these issues in older populations[39].

Ageing brings more positive outcomes for persons with schizophrenia than might be expected based on research focused on younger persons and clinical samples who remain in treatment for long periods. Research indicates that with ageing, the positive symptoms of schizophrenia abate or remain in remission for longer periods, and that for a significant minority of persons complete remission is possible[40]. Longitudinal studies of persons with schizophrenia observe much heterogeneity in its long-term course, with many patients having long remissions, late course improvements and complete remissions[41,42]. Most make adequate adjustments to living in the community although social isolation and limited quality of life are common[1,43]. The impact of family on the course of schizophrenia has received the most research attention, although this research is focused on younger persons. This research suggests that a highly involved critical orientation contributes to relapse[24]. Other research suggests that maternal warmth and praise is associated with better quality of life outcomes among middle-aged persons with schizophrenia[44].

Social policies also influence the types of institutions where elderly people receive care. In the 1950s and 1960s, the organization of services in the United States and many Western nations meant that many persons with mental disorders ended up in psychiatric hospitals and nursing homes, and many elderly persons with mental illnesses had spent much of their lives in such institutions. In the United States large scale deinstitutionalization was only possible with the expansion of welfare programmes that provided subsistence and payment for alternative residential care for mentally ill patients in the community.

Current cohorts of elderly persons with major mental illnesses confront a much different landscape of services than their predecessors. Among those seeking help, most will be seen in primary care, not specialty mental health care[34]. Assessing depression within the constellation of physical concomitants that might be attributed to a variety of other conditions poses diagnostic challenges to the general physician. It is not surprising, therefore, that depression among older persons often goes undiagnosed[45]. This problem may be even more pronounced for African American patients[46].

There has been much recent effort to integrate mental health services into primary medical care. Large-scale multifaceted interventions bringing mental health care into primary care settings have been found to be effective in reducing symptoms and improving quality of life for persons with depression, while also being cost effective. These interventions are intensive, typically including enhanced screening to improve the identification of cases of depression, patient and provider education, case managers responsible for tracking patient outcomes and adherence to treatment, and the availability of a psychiatrist for consultations. However, even at their best, these interventions show how difficult it is address the needs of the elderly with depression. In the most widely replicated model, IMPACT, for example, only about one quarter of patients in the intervention (compared to less than 10% in usual care) achieved remission at 12 months[47].

While most of the research on how social factors impact the occurrence of mental illness or the response to symptoms of mental illness is based on community samples, nursing homes remain the social environment where many elderly persons find themselves. In some sense, the traditional nursing home echoes the conditions of the long term psychiatric hospitals that characterized care for the mentally ill in the past. Typically admissions to nursing homes occur when individuals are incapable of caring for themselves, when their physical and psychiatric problems create unmanageable burdens for their caretakers, or when community caretakers are no longer available. Admission is often triggered by such events as a loss of function following trauma, such as hip fractures, confusion and wandering, and incontinence. Traditional nursing homes, like the traditional long-term mental hospital, contribute to an institutional syndrome resulting from vulnerabilities of patients as they respond to decreased social participation, sensory deprivation, loss of efficacy and control over daily life decisions, institutionalization, routinization and the like. There is persuasive evidence that efforts to keep patients involved

and participating in valued activities help for both mental and physical function. Many nursing homes fail to give these social aspects of life adequate attention, and patients spend much of their time in isolation and uninvolved. Moreover, historically, there has been evidence that psychotropic drugs were being over-prescribed in nursing homes to control patients and ease staff workloads. Recent evidence suggests that these practices have been reduced as the result of legislation in the late 1980s in the United States[48].

Nursing care may be the best treatment context for some patients who are seriously incapacitated and require a broad range of services difficult to provide in the home or in other community settings, but most impaired elderly benefit from settings that are more successful in sustaining self-efficacy and social engagement. Recent developments in the nursing home industry suggest that such settings are possible; for example, the Green House model emphasizes small residential (family-like) housing, privacy, independence and control over activities of daily life as much as clinical status allows[49]. Early results indicate that functioning and quality of life, including emotional well-being, are more positive for individuals in such types of homes compared to traditional nursing home settings[50].

Demographic shifts mean that the social patterning of mental illness in later life and our responses to it may be very different with future cohorts of older persons than what we see today. The United States and many other nations are facing an ageing population, with the number of older persons with mental illness more prevalent. The capacity for any society to cope with mental illness depends on the organization of kinship groups and households, and the existing social institutions in a society. The growing prevalence of divorce, single-person households, small families, high female participation in the workforce, geographic mobility and other trends make it difficult to put increasing reliance on informal social networks for caretaking. Developing alternative structures that are financially viable and humane constitutes a growing challenge.

Classification of Dementia and other Cognitive Disorders in ICD-10 and DSM-IV

A. Jablensky and J.E. Cooper

Department of Psychiatry and Behavioural Science, Medical Research Foundation Building, Perth, Australia

The classification of mental disorders in the Tenth Revision of the International Classification of Diseases (ICD-10) includes a revised content that reflects the most important advances in research and clinical practice at the time of its conception. It is presented in different versions for different types of professional users. The differences are, however, in degrees of detail, and the versions are compatible with each other since they are all derived from the same basic document, the 'Clinical Descriptions and Diagnostic Guidelines'[1].

THE USES OF ICD-10

ICD-10 has necessarily retained its historical purpose of facilitating the recording of national and international statistics of morbidity and mortality, but has the added values of also being designed as a uniquely international aide to clinical work, teaching, and research. It achieves these objectives by means of an updated list of diagnostic rubrics, a set of glossary-type definitions of disorders, and additional explicit diagnostic criteria. The latter have been developed in two versions: (a) clinical diagnostic guidelines for routine use, allowing sufficient flexibility and discretion in the application of "clinical judgement" in the hospital ward or the out-patient clinic; and (b) diagnostic criteria for research (ICD-10-DCR) providing stringent decision-making rules to increase the specificity of diagnostic classification and thus ensure a high level of sample homogeneity for the purposes of clinical, biological and other research[2].

As a result of a great deal of collaboration between the advisers to the World Health Organisation and the several Task Forces that assembled DSM-IV on behalf of the American Psychiatric Association during the last few years of the preparation of both the classifications, there are very few important differences between them. Since the same body of internationally published research experience and literature was available to both sets of experts during the processes of development, those differences that remain are mainly differences of opinion rather than of fact. Some differences reflect the need for ICD-10 to accommodate a much broader base of international experience and opinions than a national classification. In the development of ICD-10, experts from many different cultures and languages were involved from the earliest stages.

As in ICD-9, Chapter V deals with "Mental and Behavioural Disorders", and is intended for the recording of the clinical syndromes as presented and experienced by the patient. If a specific underlying cause of the disorder is known (or highly probable), additional codes should also be used from other chapters of ICD-10, such as Chapter I; Infectious and parasitic diseases, Chapter II; Neoplasms, or Chapter VI; Diseases of the Nervous System.

DEMENTIA IN ICD-10

In ICD-10, the dementias are embedded in the section on organic and symptomatic mental disorders (codes F00-F09) which contains the following major rubrics:

- Dementia in Alzheimer's disease.
- Vascular dementia.
- Dementia in diseases classified elsewhere.
- Unspecified dementia.
- Organic amnestic syndrome, other than induced by alcohol and drugs.
- Delirium, other than induced by alcohol and drugs.
- Other mental disorders due to brain damage and dysfunction and to physical disease.
- Personality and behavioural disorders due to brain disease, damage and dysfunction
- Unspecified organic or symptomatic mental disorder.

In contrast to ICD-9, the distinction between psychotic and non-psychotic illnesses is of no taxonomic consequence in ICD-10, where disorders of different psychopathological expression are grouped together on the basis of established or presumed common aetiology. In the particular instance of section F0, in which the dementing disorders are included, the underlying classificatory characteristic of "organic" is defined in the sense that "the syndrome so classified can be attributed to an independently diagnosable cerebral or systemic disease or disorder". The subsidiary term "symptomatic" is not used in the titles of individual disorders but it is included in the overall title of the block F00 – F09. This is because it is widely used in many countries to indicate those organic mental disorders in which cerebral involvement is secondary to a systemic extra-cerebral disease or disorder. In other words, 'symptomatic' in this context is a subdivision of the wider term 'organic'.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

Another feature of ICD-10, as compared to earlier classifications, is the omission of any reference to age as a defining criterion of the disorders accompanied by a cognitive deficit. The terms "senile" and "presenile" are practically absent in the classification, and there is no provision for identifying any mental disorder as necessarily a result of aging. The classification does, however, allow the recording of an unusually early or late onset of the disorder. In other words, the mental disorders occurring in the elderly are no longer considered to belong in a separate category of morbidity. This is very much in line with research conducted in the past three decades which has demonstrated that the relatively high prevalence of mental morbidity in the elderly in Western cultures is related to a wide range of psychosocial factors (e.g. social isolation, cultural uprooting and institutionalization), as well as to physical co- morbidity, but that the aging process itself does not produce nosologically specific forms of disorders.

If section F0 of ICD-10 is used as a diagnostic decision tree, there is a choice of five entry points at the level of clinical syndrome: (i) dementia; (ii) amnesic syndrome; (iii) delirium; (iv) organic quasi-functional disorder (affective, delusional, hallucinatory or other); and (v) personality or behavioural disorder. Once a disorder is identified at this general syndrome level, the next step is defined by the diagnostic guidelines which lead into more specific diagnostic categories. The diagnostic decision rules for dementia illustrate the point.

The syndrome of dementia is defined in ICD-10 by "evidence of a decline in both memory and thinking, which is of a degree sufficient to impair functioning in daily living", in a setting of clear consciousness. For a confident diagnosis to be established, such disturbances should have been present for at least 6 months. Deterioration of emotional control, social behaviour and motivation represent significant additional features but the overriding criterion is the presence of memory, learning and reasoning decline. The ICD-10 DCR (research criteria) add anchor points for a grading of the deficits into mild, moderate and severe, separately for memory and intellectual capacity. The overall grading of the severity of dementia is made on the basis of the function which is more severely impaired.

Once the presence of the syndrome of dementia is established, the diagnostic process branches off into the different clinical varieties of dementia typical of Alzheimer's disease, vascular dementia, and dementia in diseases classified elsewhere (including Pick's disease, Creutzfeldt-Jakob disease, Huntington's disease, Parkinson's disease, HIV disease, and a range of systemic and infectious diseases such as hepatolenticular degeneration, lupus erythematosus, trypanosomiasis, and general paresis). Dementia in Alzheimer's disease is subdivided into Type I (onset after the age of 65) and Type 2 (onset before the age of 65). Although the ICD-10-DCR criteria emphasize the ultimate criterion of the neuropathological examination and the supporting role of brain imaging, they nevertheless allow for a confident clinical diagnosis to be made, if clear evidence of a memory and intellectual performance deterioration has been present for 6 months or more. The ICD-10 criteria for vascular dementia are broader than the corresponding DSM-IV criteria: they include not only multi-infarct (predominantly cortical) vascular dementia, but also the subcortical dementias (Binswanger's encephalopathy being an example), as well as the mixed cortical and subcortical forms.

As regards the diagnosis of delirium, ICD-10 has abandoned the distinction between acute and subacute deliria; the condition is defined as "a unitary syndrome of variable duration and degree of severity ranging from mild to very grave", with an upper limit of 6 months' duration and a subdivision into delirium superimposed on dementia and delirium not superimposed on dementia.

The rubric "other mental disorders due to brain damage and dysfunction and to physical disease" includes disorders with "functional" characteristics (e.g. hallucinosis, catatonia, schizophrenia-like disorder, and mood disorders) which arise in the context of demonstrable organic illness, such as cerebral disease, systemic disorders, and brain dysfunction associated with toxic disorders (other than due to alcohol or drugs). An important, not yet fully validated, addition to this rubric is the "mild cognitive disorder" attributable to physical co-morbidity which is defined as transient but nevertheless involving memory and learning difficulties. However, the requirement that "this diagnosis should be made only in association with a specified ohysical disorder" is in need of revision, since in a proportion of cases this diagnosis may reflect the early, pre-dementia stage of Alzheimer's disease.

Finally, personality and behavioural disorders due to brain disease, damage and dysfunction include familiar conditions such as organic personality disorder (the frontal lobe syndrome but also other lesions to circumscribed areas of the brain), postencephalitic syndrome, post-concussional syndrome, and some new entities, e.g. right hemispheric organic affective disorder (altered ability to express and comprehend emotion without true depression).

In conclusion, two features of ICD-10 should be emphasized. First, as already noted, it does not identify the mental disorders in the elderly as a separate or special category of psychiatric morbidity. In addition to the F0 section listing the organic and symptomatic mental disorders, psychiatric disturbances arising in the elderly population can be classified, according to their presentation and course, in any of the other major sections of ICD-10 (except for F8 and F9, which deal with developmental disorders and behavioural and emotional disorders occurring in childhood and adolescence).

Second, although ICD-10 is not explicitly a multiaxial classification, there are two ways in which multi-axial coding can be achieved if required. The simplest way is to use extra codes from the other chapters of ICD-10 in addition to those in Chapter V; any physical disorders present can be recorded by codes form Chapters I to XIX, and codes from the final two chapters can be used to cover other noteworthy aspects of the clinical picture. These are Chapter XX; External Causes of Morbidity and Mortality (the X and Y codes, covering drugs causing adverse effects in therapeutic use, and injuries and poisoning), and Chapter XXI; Factors Influencing Health Status and Contact With Health Services (the Z codes, which include a variety of social, family and life-style factors). Another and more comprehensive option is to use the special Multi-axial System now available, which was developed by means of an international collaborative study organised by WHO Geneva[3]. This provides three descriptive axes: Axis 1 – Clinical Diagnosis, Axis II – Disablements, and Axis III – Contextual Factors. These Axes are a convenient re-arrangement of the chapters of ICD-10 listed above, with the addition of a brief set of ratings covering physical disabilities.

DEMENTIA AND OTHER COGNITIVE DISORDERS IN DSM-IV

In DSM-IV (and its revised version DSM-IV TR) dementias and other mental disorders associated with brain disease are grouped into a section entitled "Delirium, dementia, and amnestic and other cognitive disorders". In contrast to ICD-10 and the earlier DSM-IIIR, the term "organic" mental disorders is no longer used in DSM-IV, to avoid the implication that "nonorganic" mental disorders do not

have a biological basis[14]. While ICD-10 retains a general description of dementia as a syndrome occurring in Alzheimer's disease, cerebrovascular disease and "other conditions primarily or secondarily affecting the brain", the DSM-IV classification lists dementias as specific disorders which "share a common symptom presentation but are differentiated based on etiology". Specific diagnostic criteria are provided for dementia of the Alzheimer's type, vascular dementia, and dementia due to other medical conditions (HIV disease, head trauma, Parkinson's disease, Huntington's disease, Pick's disease and Creutzfeldt-Jakob disease). A separate DSM-IV category, which has no counterpart in ICD-10, is substance-induced persisting dementia, defined as significant cognitive impairment persisting long after the symptoms of substance intoxication or withdrawal have abated. Another difference from ICD-10 involves the category of "dementia due to multiple etiologies", introduced to cover "the common situation in which the dementia has more than one etiology", such as a condition arising as a result of Parkinson's disease with co-occurring long-term substance use. Finally, the DSM-IV section contains residual categories for "dementia not otherwise specified" and "cognitive disorder not otherwise specified", to enable the coding of dementing illnesses or other cognitive dysfunction that do not meet the criteria for any of the specific types, or for which no specific etiology has yet been established.

While the DSM-IV diagnostic criteria and the ICD-10 diagnostic guidelines for delirium essentially agree, there are differences between the two classifications regarding the specific rubrics and their composition. Thus, the ICD-10 heading for the group of delirious disorders is "delirium, not induced by alcohol and other psychoactive substances", with separate coding provisions for delirium not superimposed on dementia, delirium superimposed on dementia, other delirium and delirium unspecified (alcohol or substance use induced delirium is coded in the ICD10 section "Disorders due to psychoactive substance use"). In DSM-IV, both "delirium due to a general medical condition" and substance-induced delirium are coded within the same section, along with "delirium due to multiple etiologies" and "delirium not otherwise specified".

Another difference between ICD-10 and DSM-IV concerns the placement of psychiatric syndromes and personality or behavioural disorders associated with cerebral disease. The ICD-10 section "Delirium, dementia, and amnestic and other cognitive disorders" provides a fairly detailed classification of "organic" hallucinosis, catatonic disorder, delusional disorder, mood and anxiety disorders, personality disorders and specific syndromes, such as postconcussional and postencephalitic syndrome. Notably, the same section contains the category "mild cognitive disorder" and provides diagnostic guidelines for this rubric, while acknowledging that "the boundaries of this category are still to be firmly established". In DSM-IV, "mild neurocognitive disorder" is an inclusion term under "cognitive disorder not otherwise specified", with diagnostic criteria contained in Appendix B "for further study".

Both ICD-10 and DSM-IV have proved to be essential tools for clinicians, epidemiologists, and – perhaps to a lesser degree – for researchers working in the rapidly evolving areas of the neuroscience and genetics of neurocognitive disorders. In a thoughtful commentary and critique of the two classifications, Reisberg[13] noted that in several respects the present diagnostic manuals reflect knowledge that is somewhat dated and fail to incorporate recent advances. Thus, the DSM-IV definition of dementia requires "impairment in memory" as a cardinal and necessary criterion, not acknowledging that diseases such as vascular dementia and frontotemporal dementia are not characterized by prominent memory impairment, at least in their early stages. The DSM-IV definition mentions disturbance in executive functioning but omits the behavioural and emotional changes, as well as the diminishing capacity to carry out activities of daily living. Importantly, the DSM-IV definition proposes that the diagnosis of Alzheimer's type dementia can only be made by exclusion, i.e. once other etiologies for the dementia have been ruled out. This is at variance with the current international consensus (including the American Geriatric Society) that Alzheimer's disease should be amenable to diagnosis by inclusion, rather than exclusion. Another suggested change is the removal, from both DSM and ICD, of the distinction between early onset (before 65 years of age) and late onset (after 65 years) Alzheimer's disease. Further proposals concern introducing in the future classifications staging procedures for dementia; broadening the definition of Pick's disease to include frontotemporal dementia; and revising the description of dementia in Parkinson's disease and Lewy body dementia.

PROSPECTS FOR THE FUTURE

It is only a few years before the next edition of the international classification, ICD-11 is ready for use, and there are at present plenty of issues worthy of debate. Both terminological and conceptual issues related to the current ICD-10 classification of this group of conditions have been raised since its introduction in the early 1990s. Thus, the term "organic", sitting uneasily within the title of the ICD-10 section, has often been singled out for critique as a legacy of a dualist tradition and a schism between brain-based "neurological" diseases and "functional" psychiatric disorders that is no longer tenable[4,5]. The non-invasive techniques for brain imaging, such as MRI, SPECT and PET-scans, are demonstrating a variety of structural and functional abnormalities in the brains of some (but by no means all) patients with the familiar clinical syndromes, that are also present in substantial proportions of normal subjects. These changes are 'organic' in a general sense of being something physical, but not in the way the term is used in the ICD (that is, to indicate a concurrent and diagnosable physical disorder).

It will probably soon be time to abandon 'organic' as a term to be used in a classification, and to develop new terms and concepts that will make these more subtle differentiations clear. The term "neurocognitive disorders", thought to capture both the concepts of cognitive disturbance and of an altered neural substrate, has been proposed in a recent review of the evidence supporting the grouping of the dementias, amnesic syndromes and deliria into a single classificatory "cluster"[6]. In addition, a critical examination of the very term "dementia" has also found it wanting for three main reasons[7]. First, it is now clear that memory impairment is just one of several cognitive domains that are affected to varying degrees in this group of disorders (other domains include language, attention, executive function, visuospatial ability, speed of information processing and manual dexterity). Secondly, the operational definitions of the diagnostic criteria for dementia in both ICD-10 and DSM-IV are insufficiently specific, leading on occasions to gross discrepancies in the assessment of the prevalence of dementia in population studies[8,9]. Thirdly, in its categorical usage the term is stigmatizing and has connotations of extreme disability and dependence that tend to arouse severe anxiety in patients and family members. As a possible remedy, terms like "vascular cognitive disorder", or "cognitive disorder in Alzheimer's disease" have been proposed.

Complex problems with far-reaching conceptual implications for the classification of this group of disorders arise out of recent advances in their study with the tools of molecular genetics, proteomics and biomarker research. While conditions such as Alzheimer's disease, Huntington's disease, or Creutzfeldt-Jakob disease have been traditionally regarded as being among the few "true" discrete disease entities within the psychiatric classification, owing to the presence of "hallmark" brain lesions, recent evidence challenges seriously this view[10]. Current molecular classifications distinguish between four groups of neurodegenerative diseases: tauopathies (e.g. Alzheimer's disease, Pick's disease, frontotemporal dementia, progressive supranuclear palsy); alpha-synucleinopathies (e.g. Parkinson's disease, dementia with Lewy bodies, multiple system atrophy); neurofilamentopathies (e.g. dementia with neurofilament inclusions); and prion diseases (e.g. Creutzfeldt-Jakob disease, Gerstmann-Sträussler-Scheinker syndrome, fatal familial insomnia). There is, however, increasing evidence of marked individual variability within the groups, as well as extensive overlap across the diseases and syndromes in terms of structure, molecular composition and distribution of brain lesions, raising the question of common aetiological and pathogenetic mechanisms[11,12]. In the presence of both genetic heterogeneity and clinical pleiotropy, the nosological status of the individual disorders becomes less certain that previously assumed. Generally, two positions have been articulated in the recent literature (Armstrong *et al*. 2005): (i) the benefits of retaining the concept of distinct nosological entities outweighs its limitations; the latter can be constrained by using the existing diagnostic criteria in conjunction with refined molecular and other biomarker analysis; (ii) the traditional disease entities represent points on a continuum of neuropathological change and a clinical spectrum of syndromes rather than diseases.

Whatever form the ICD-11 classification takes, it seems likely that the principle of recording the clinical picture by means of Chapter V and the underlying cerebral or other physical cause by means of other chapters will remain. Research is now providing many, though not entirely consistent, clues about the exact place and the histological and molecular nature of the lesions in the central nervous system that give rise to the clinical syndromes, but the clinical syndromes themselves will not change, and will always need to be reliably recorded.

Taking a Psychiatric History from Elderly Patients

Sunita Sahu and Monica Crugel

Oxleas NHS Foundation Trust, Memorial Hospital, Shooters Hill, London, UK

INTRODUCTION

When taking a psychiatric history from an elderly person, the general guidance on establishing rapport and taking a medical and psychiatric history apply, but there are also a few particularities. The great heterogeneity of this population in terms of general health and frailty, cognitive abilities and the need for support requires the approach to be adjusted in each case. Clinicians may often be enquiring about someone's life lived before 'their time' and can use this as an opportunity to allow the patient to feel empowered – after all the clinician might know better than the patient what their general and mental health problems are at the moment but only he/she is an expert in their own life history. Sometimes, a little more encouragement and verbal and non-verbal cues of friendliness, respect and openness than with an younger adult patient are needed for establishing a good rapport and obtaining the information. For fear of wasting your time or bringing irrelevant issues into discussion, your elderly patient might not tell you part of the story. Also, pre-conceptions about 'normal' ageing might lead to essential symptoms such as acute or chronic pains, low energy, lack of hope, poor sleep, boredom or lack of social interaction not being mentioned by the patient. Attention to non-verbal cues as well as reassurance that you are interested to hear it all and prompting can help complete the picture.

GETTING READY FOR THE INTERVIEW

Before meeting the patient prepare for the interview. Determine the reason for referral and look at the available medical and psychiatric history and current medication. Ask if the patient will be attending alone or accompanied and if special arrangements will be required in the room, for example if the patient is in a wheelchair.

THE INTERVIEW

After introducing yourself, make sure the patient and their companion are comfortable and check if the patient can hear and understand you. If not, can communication be improved with hearing aids or writing things down and/or involvement of interpreter or the sensory team?. Apart from sensory problems, cognitive deficits (short attention span, memory problems) and dysphasia can affect communication and prevent relevant information being obtained from the patient. In these cases an informant is essential for proper assessment. Adjust the pace of dialogue to the patient's needs: too slow for a cognitively intact patient can sound condescending, too fast for people who cannot keep up can be disastrous.

If the patient is accompanied, establish who the companion is and what their role will be during the interview. Are they an informant or will they provide support for the patient? Have they requested the assessment?

The first interview with the patient and the psychiatric history obtained in this session is extremely important as future assessments will refer to it. Thus, details on nature and onset of all previous episodes, triggers and prodromes, risk factors, duration of episodes, medical co-morbidities, interventions (medication, hospitalization, sectioning, psychotherapy, home help, etc.) and their effect, pharmacological history including compliance, quality of recovery and level of functioning when recovered, should be recorded whenever possible. Your knowledge in psychopathology should guide the questions into obtaining relevant information.

To start the interview, allow the patient or/and informant to explain their view of the presenting complaint.

Start with general questions such as 'Have you ever had any problems to do with your mental health?' and 'Have you ever seen your GP or a psychiatrist for these?', then explore each concern in turn. A patient with poor insight into his previous psychiatric problems might acknowledge having been under psychiatrists for a long time but not having had a mental health problem. Conversely, many people suffer from sub-clinical symptoms or even disorders of clinical severity but have never been assessed or had any treatment.

HISTORY OF THE PRESENTING COMPLAINT

The context of symptoms' onset is of great relevance in geriatric psychiatry. Social and medical factors can play a greater role than genetics in some psychiatric disorders with late onset and, without addressing these, the patient might not recover fully.

Consideration of recent losses such as retirement, bereavement, change in social and financial circumstances, social isolation, loss of abilities and increase in dependency etc. must inform therapeutic intervention, thus recording them is important.

Medical conditions as well as medications prescribed for these can be associated with psychiatric disorders: stroke[1] and cancer[2] have a high co-morbidity with depression; organ failure may cause delirium[3]; respiratory problems are frequently associated with anxiety or panic attacks[4]; some antihypertensives can cause depression[5]; cortisone[6] and anti-Parkinsonian drugs may cause psychosis; drugs

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

with anticholinergic effects can cause or accentuate confusion, to enumerate only some.

Conversely, care must be given to falsely perceived onset of symptoms. A classic example is memory problems starting 'suddenly' after the spouse's death; it is often the case that the patient's memory problems had been more longstanding but not apparent due to spouse's interventions and prompting. Careful questioning of relatives and other informants would probably reveal cognitive problems prior to bereavement. Sometimes the perceived onset is in fact an aggravation of pre-existing symptoms or the moment at which their intensity becomes significant.

An answer such as 'I have always had this problem' requires clarification as to why they presented for assessment now.

The present disorder might have started in a different form, for example psychosis or confusion following a long depressive episode pointing towards a diagnosis of psychotic depression; confusion following a serious illness, surgery or stroke suggesting delirium; depression with previous episode(s) of mania suggesting bipolar disorder; dementia starting with depression, anxiety or psychosis; substance abuse starting with anxiety or depression. A sudden onset of psychiatric symptoms can suggest organic aetiology.

After identifying the presenting complaint, brief questioning about any other problem, be it social, medical or psychiatric, will help complete the picture.

PAST PSYCHIATRIC HISTORY

One approach is to start with the personal history and once you have information about the patient's lifeline and major life events start asking about the psychiatric history. On one hand this reassures the patient that you are assessing them in an holistic way and are not only 'fishing' for symptoms and, on the other hand, it gives you a better view of the previous level of functioning and, if applicable, the impact of the psychiatric problem on their lives. Some patients may prefer to go straight to the problem.

It is not unheard of for serious lifelong psychiatric illnesses to be diagnosed in old age and a thorough psychiatric history is essential to achieve this. People suffering from generalized anxiety disorder, phobias or obsessive compulsive disorders, might never have seen a psychiatrist before. Careful questioning about long-lasting symptoms (e.g., 'Have you always been a worrier?' Have you always avoided travelling in cars/trains/planes?') can reveal a long history of psychopathology. The mood fluctuations in bipolar disorder sometimes accentuate with age and retrospective diagnosis of a sub-clinical lifelong disorder can be made on a thoroughly taken history.

You will need to actively ask about important issues such as mood symptoms, psychotic features, anxiety, sleep and appetite problems, suicidality.

PHARMACOLOGICAL HISTORY

Obtaining an accurate pharmacological history is important as response to previous treatments and their side effects can inform current prescriptions. However, this can be more difficult than with younger adults as elderly patients might not remember the names of drugs they have been taking over the years. Your knowledge of older psychiatric treatments and interventions as well as older indications for certain types of treatments will help put the information into the right context[7]. For example, ECT, lithium, chlorpromazine and haloperidol were the only treatments available for mental illnesses until the 1950s when imipramine (the first antidepressant) was introduced; although the current use of antipsychotics is mainly for psychosis, low doses of neuroleptics used to be prescribed in the treatment of depression, anxiety and somatic symptoms; ECT, now mainly used for severe depression and catatonia, was frequently used in the treatment of various psychiatric disorders 30–40 years ago; admissions for treatment were more frequent and much longer than nowadays.

Enquiring about the patient's previous compliance with prescribed treatments, as well as the reasons for non-compliance, when this was the case, can reveal important information. Poor compliance can have various causes and most are similar to those in younger adults, for example, the patient is not convinced that trying a treatment would help, is lacking insight into their psychiatric problem, is experiencing side effects or unpleasant effects from the drugs, stops treatment when they feel better, stops after just a few days due to lack of effect etc. In elderly patients, especially those with cognitive deficits, poor compliance can be due to forgetfulness. This is a serious problem in this population with high levels of co-morbidity and chronic conditions and can lead to relapse of physical or mental condition, under- or overdosing, withdrawal syndromes or other adverse drug reactions. There are various ways to address this such as, enhancing the doctor–patient relationship, psychoeducation, technical solutions (e.g. using dossette boxes), intensifying care (e.g, prompting by carer, administration of drugs by a carer, moving to a more supported accommodation) or, at the extreme, stopping some or all medication if none of the options work and there are associated risks[8].

FAMILY HISTORY

There are understandable differences between taking a family history in a younger adult and an elderly patient. In the elderly, usually the parents of the patient would have died a long time ago, possibly at a younger age than one would expect to now, as a result of which there may not be a history of any problems with an onset in old age, for example dementia. Often the condition from which the parent was suffering may not be known, as the diagnosis may not have been given or may not have been known. Siblings, children, grandchildren and great grandchildren would now be part of the family history. Family interactions can be complex and exploring them can shed light on factors associated with the patient's problems. It will be important to note if the patient is involved in looking after any young children in case child protection issues arise. The converse may also be true if the children or grandchildren are involved in caring for the patient and younger adult protection concerns arise.

Any history of mental disorders in the family must be recorded when available, be it in the patient's parents, children or grandchildren. This would represent third-party information and appropriate confidentiality must be maintained. A history of suicide in a first degree family member represents a risk factor for the patient[9].

PERSONAL HISTORY

This would usually be of much greater length than that of a younger patient. Information on developmental milestones might not be available or relevant but educational attainment and work history will be important for assessing the impact of the psychiatric problem on their lives or when interpreting test results for dementia. It is also an important indicator of the premorbid level of intellectual functioning. Your patient might want to tell you about their war experiences which

may have left important psychological marks on their lives. Many more significant life events would have taken place such as loss of parents, relatives and friends. Other kinds of losses such as perceived loss of social status due to retirement, loss of earnings and having to live on a meagre pension, are almost always present. They may have to be living at a lower standard than they were accustomed to and poverty is significant among the elderly[10].

Retirement is a stressful life event for some[11]. Circumstances of retirement may have precipitated depression. Symptoms of dementia interfering with their job may have led to early retirement on medical grounds.

Gross inaccuracies in recalling family history, names and birthdays can be a clue of memory problems.

PAST AND PRESENT SOCIAL SITUATION

This is a broad domain that must be explored in detail when assessing elderly patients. Social and medical care often go hand in hand in helping to improve the patient's quality of life and minimize the risks. For example, a social history revealing a patient living alone, unable to care for himself and under a significant risk to health, might be the single most essential information which will change your short-term treatment plan from prescribing a treatment at home to transferring to hospital or other care facility.

It may be helpful to start with the patient describing a typical day. This should yield rich information about their current circumstances, what they can and cannot manage and what help they are getting from family, friends and neighbours, and voluntary or statutory services. It will also reveal the degree of impairment and the risks to the patient and can point towards other available services which the patient would benefit from, for example day centre, sitting service.

Risks that might need immediate attention can be revealed by asking about the patient's participation in activities of daily living (ADLs). Can they attend to personal hygiene, are they able to do the house chores, use the cooker or the telephone, are they safe on the stairs, are they safe outside the house etc.? (see chapter 34).

Try and obtain information on the finances of your patient and most importantly their ability to manage them. It is necessary to enquire about their current pensions (state or private), benefits and savings, and think about any other benefits they might be entitled to. You can always request social services, working in partnership, to do a full financial assessment. If the patient is unable to manage their finances, arrangements for this to be done by someone else must be made. Family and patient may need to be encouraged to make a lasting power of attorney (LPA) for both property and welfare, a will or an advance decision or at least to start thinking about where they want to live in the future, what kind of care would be acceptable to them etc. Information about the patient's religion, values and beliefs must be recorded as this can play a great role in their life and must be taken into account when planning future care.

A driving history would indicate whether the patient is at risk when driving. If there are issues, the patient or you might need to inform the DVLA.

PERSONALITY

While a thorough personality assessment cannot normally be done in a first interview, keeping a careful eye on personality issues right from the beginning can be very useful. We usually take our personality into old age and a history of significant changes from the premorbid personality reported by the informant will sometimes be a clue to a diagnosis of frontal lobe dementia. Knowledge of premorbid personality traits can be helpful in identifying personality change caused by a mental illness. It may also suggest coping strategies which manifest as symptoms.

PSYCHOSEXUAL HISTORY

As in younger adults, this is an area that can be relevant to your patients' relationships and mental health as well as compliance with medication so offer to discuss this with them. Specific problems in the elderly include sexual dysfunction, the loss of sexual partner by death or serious illness and sexual urges in people with dementia living in care homes.

ALCOHOL AND DRUGS HISTORY

Incidence of alcohol misuse in elderly is thought to be lower then in younger adults but a failure to identify patient's presenting with alcoholism might contribute to the lower figures[12]. With the increase in life expectancy it is predicted the actual number of cases with alcohol-related problems will increase in the following years[13].

Presentation with a fall, confusion or medical complications may mask an underlying alcohol problem. Hence enquiring about current or past alcohol and drug use must be a routine part of the assessment. This should include the age when first used, development of the problem, quantity and frequency and presence of dependence syndrome for each substance used. If alcohol abuse has started in old age, the circumstances might reveal underlying loss, bereavement or depression.

In this age group physical or psychiatric complications of alcohol abuse (e.g. cirrhosis, peripheral neuropathy, cognitive impairment) might have already developed and can be found in the context of continuing or past alcohol abuse. Also, effects of previously well-tolerated quantities of alcohol may increase due to changed physiology.

Onset of memory problems can interfere with a person's usual pattern of alcohol use, for example, by precipitating withdrawal in someone with alcohol dependency who forgets how to obtain the alcohol or causing acute intoxication or even dependency in someone with no prior history of abuse, but regular use, who repeatedly drinks his usual non-harmful amount to intoxication levels.

Knowledge of the type of alcohol consumed can suggest strategies of changing the alcohol to one of lower strength and then gradually tapering the amount, effectively detoxifying the patient. One can use alcohol assessment screening tools but these need to be age-specific, as many of the more traditional rating scales lack validity. The Short MAST-G is commonly used, but others such as the Drinking Problems Index and Alcohol-Related Problems Survey, are used in more specialized settings.

Physical complications of alcohol misuse are numerous, but commonly affect the stomach (ulceration), liver (alcoholic hepatitis, progressing to cirrhosis), blood (anaemia), nervous system (peripheral neuropathy – lack of sensation in legs) and can lead to instability and falls related to episodes of intoxication. Falls may lead to head injury and subdural hematoma. Alcohol may also alter the way in which medication is metabolized by the body and can accentuate the side effects of drugs such as opiates (commonly found in prescribed painkillers).

Inadvertent benzodiapine dependence is common in the elderly. Again, this relates to a time when not enough was known about

benzodiazepines and they were prescribed for anxiety or depression and continued for long periods resulting in dependence. A thorough history of use of these drugs would provide useful information about past illness.

FORENSIC HISTORY

In elderly presenting for psychiatric assessment a forensic history is very rarely present. The number of elderly offenders has remained stable over the years; however, the number of elderly in prisons has increased sharply[14].

When taking a psychiatric history in a usual community or hospital setting the interviewer may feel that asking about forensic history can offend the patient and is not relevant. However, it is worth exploring and should not be ignored. There is a risk of offending in people with frontal lobe dementia when this is associated with disinhibition, hoarding or obliviousness to social rules. Also, aggressive behaviour in all types of dementia is frequent, especially towards the carer. In Lewy body dementia, vivid hallucinations, hallucinatory behaviour and cognitive fluctuations can sometimes lead to high risk of harm to others. But even when these lead to serious incidents. Police are rarely involved and charges are often not brought.

Mental State Examination in the Elderly

Joanne Rodda and Zuzana Walker

Department of Mental Health Sciences, University College London, UK

The Mental State Examination (MSE) provides a snapshot of a patient's symptoms and signs at the time of the interview. The approach to the MSE in older adults is very similar to that in the younger adult population, although there are a number of important considerations. For example, a significant proportion of patients in old age psychiatry services present with cognitive impairment and there are generational differences between older and younger adults. Physical illness can also complicate the MSE; the assessment of mood can be difficult if someone is frail, immobile or in pain, and acute confusion can be mistaken for dementia, psychosis or mania. These and other factors mean that the observable manifestations of mental illness in the elderly often differ from those in younger adults.

APPEARANCE AND BEHAVIOUR

A great deal of information can be gained from simple observation of the patient walking into the room; for example, posture, gait, presence of abnormal movements, level of personal hygiene and appropriateness of attire can immediately direct the clinician towards important areas for further enquiry.

A deterioration in dress presentation may reflect a decline in personal care; clothing can also give clues about disinhibition or dressing dyspraxia. The level of personal hygiene can clearly demonstrate personal neglect although a well-kempt appearance might be maintained by a carer.

The level of general awareness and alertness may be affected by physical illness or drugs, and fluctuations may be associated with delirium[1,2] or dementia with Lewy bodies[3,4]. Too little or too much eye contact might suggest low mood or disinhibition although it may be necessary to make allowances for visual impairment. Similarly, hearing or visual impairment may result in the appearance of distractibility and confusion. Irritability and hostility are sometimes said to be more common in mania in older adults. However, objective evidence from the few studies available suggests that the presentation of mania in older adults is similar to that in their younger counterparts[5,6].

Over-familiarity or disinhibition is suggestive of mania or frontal lobe syndromes and can be a feature of many types of neurodegenerative disorder. An older person may be more reserved in their interactions with others and so a level of familiarity or inhibition that fits into the realms of social acceptability may still represent a change from normal for that individual. Conversely, a gregarious person may always have been that way; information from relatives or carers is therefore often important to determine whether the current presentation represents a change from the patient's usual way of interacting.

Psychomotor changes are often prominent in depression in the elderly[7–9] although bradykinesia and reduced mobility in Parkinson's disease can be difficult to distinguish from psychomotor retardation or apathy. There are a host of motor signs – e.g. dystonic movements, mannerisms and stereotypies – that may occur as a feature of schizophrenia, mania or organic disorder[10,11] or as a result of side effects of medication. Hyperorality and stereotyped, utilization or repetitive behaviours are suggestive of pathology involving the frontal lobes, e.g. frontotemporal dementia[10].

SPEECH

In the elderly, speech can be affected by a number of factors unrelated to mental state, including ill-fitting dentures or oral pathology. An increase or decrease in the rate, quantity and/or volume of speech can be associated with mania and depression, respectively. Pressure of speech is characteristic of mania or frontal lobe involvement. In depression, poverty of speech may occur to a degree that the patient appears to be mute or dysphasic, although such a severe impairment in language is more frequently a result of neurodegenerative or cerebrovascular disease than functional illness. Circumstantiality and tangentiality occur in psychosis and mania, but are often related to dementia in the elderly. Similarly, flight of ideas is characteristic of mania but can also occur in frontal lobe syndromes.

Nominal dysphasia is common in the early stages of Alzheimer's disease when it would normally be associated with at least some degree of memory impairment. Conversely, in primary progressive aphasia (PPA) impairments in language precede deficits in other cognitive domains[12,13]. Language deficits in PPA are predominantly expressive and usually associated with loss of fluency; in semantic dementia there is loss of expressive and receptive vocabulary in the presence of fluent but 'empty' speech[10,14]. Clearly, it is important to ensure that any apparent receptive dysphasia cannot be accounted for by a hearing impairment and that an apparent expressive dysphasia is not in fact the result of dysarthria. Dysphonia is a disorder of phonation due to inability to produce voice sounds using the vocal organs; this is distinct from dysarthria and can occur in Parkinson's disease, stroke and other organic disorders[15] or as a psychogenic phenomenon[16].

Other abnormalities of speech are suggestive of specific disorders. For example, perseverative speech is almost pathognomonic of organic brain disease, particularly involving the frontal lobes. Verbal

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

stereotypies, mannerisms, echolalia, paraphasia and neologisms also occur in organic (often frontal) syndromes although may also occur in mania and psychosis.

MOOD

Elderly people may be less likely than younger adults to report sadness or dysphoria. This does not appear to be a cohort effect and has been reported in different generations of older adults[17]; whether this will hold true for the current young-old population is not known. The concept of 'depression without sadness' has, however, been criticized by some, who suggest that apathy, withdrawal and loss of vigour can represent a depletion or disengagement syndrome that reflects normal age-related changes[18]. A similar picture may also result from physical illness due to chronic pain, fatigue and disability. Likewise, the bradykinesia and bradyphrenia of Parkinson's disease can lead to difficulties in differentiating depressive from physical symptomatology. Apathy, loss of interest and motivation and even abulia may occur in dementia, particularly in subcortical[19,20] and frontotemporal subtypes[21], and can overlap with or be misinterpreted as depression[22,23]. Changes in mood may be also present in the prodromal stages of dementia, before cognitive deficits are apparent[24]. In established dementia, affective disturbances are common and may present with behavioural changes[25–27].

Given the overlap of symptomatology, it is helpful to pay close attention to the presence of biological features of depression, particularly diurnal mood variation, appetite, early morning waking and anhedonia. Cognitive symptoms of guilt, helplessness and worthlessness are also useful pointers towards a depressive disorder.

Emotional lability can be present in affective disorder and psychosis but can also be a feature of organic syndromes, e.g. cerebrovascular disease[28], Parkinson's disease[29] and other brain pathology[30], and may be confused with depression. Euphoria is a feature of mania and frontal lobe dysfunction, and may be present in other organic disorders.

THOUGHT

Thought Form

As in younger patients, psychotic illness in the elderly can be associated with a broad spectrum of abnormalities of thought form, e.g. circumstantiality, flight of ideas, loosening of associations (from tangentiality through to word salad) and, at the other extreme, thought block. However, apparent thought disorder in the elderly may represent confusion or language disorder as a result of delirium or neurodegenerative illness. Careful attention to the overall picture, including the context of the patient's presentation and simple cognitive testing, can help to clarify the situation.

Thought Content

Delusions are fixed beliefs out of keeping with an individual's social, cultural and religious background, which are based on unsound reasoning and are maintained even in the presence of evidence to the contrary. In the elderly, delusions may form part of a psychotic or affective illness but are also common in delirium and dementia. In delirium, delusions are often fleeting and persecutory. In dementia, delusions of theft are common and often relate to misplacement of objects. Well-formed delusional systems are uncommon in dementia but do occur. Delusional misidentification is also common in organic disorder[31], e.g. patients with dementia may insist that their spouse or even their own reflection in the mirror is an impostor.

As in young adults, delusions can be sub-classified into several types, e.g. persecutory, grandiose, nihilistic and bizarre delusions, and delusions of jealousy. Autochthonous or primary delusions arise spontaneously and 'out of the blue' while secondary delusions occur as a result of some other experience, e.g. secondary to hallucinations or affective disturbances. Primary delusions in the elderly suggest functional rather than organic disorder. Delusions must be differentiated from overvalued ideas, which are beliefs that may not be unreasonable but are pursued to an unreasonable degree by the patient. Overvalued ideas are often associated with personality disorders.

Obsessions are recurrent and persistent thoughts, images or impulses that the patient tries to but is unable to resist. They may occur in the context of an obsessive disorder but can also be a feature of depression or dementia. Sometimes repeated checking in dementia is related to anxiety and forgetfulness rather than obsessive–compulsive behaviour and can present a diagnostic challenge, particularly in the early stages.

Passivity Phenomena

Thought insertion and withdrawal, thought broadcast and 'made actions' represent a disintegration of boundaries between the self and the outside world and are typical of a functional psychotic disorder rather than dementia or delirium.

PERCEPTION

A hallucination is a perception in the absence of an external stimulus and may occur in any modality (auditory, visual, tactile, olfactory, gustatory, somatic) in the context of psychosis, affective disorder, organic disorder or delirium. Sensory impairment, both visual and auditory, is particularly important in older people and predisposes to hallucinations. Charles Bonnet's syndrome of visual hallucinations in people with visual impairment in the absence of psychiatric or neurological illness is well known. These hallucinations are typically complex, not distressing and are usually associated with a good degree of insight. The most common cause is age-related macular degeneration (see Schadlu *et al*.[32] for a recent detailed review). Auditory hallucinations (typically of music) occurring in clear consciousness in people with hearing impairment are also common and have been described as an auditory form of Charles Bonnet syndrome[33]. The pathophysiology underlying these experiences may relate to deafferentiation of visual or auditory cortical structures, resulting in hyperexcitability and increased spontaneous activity[34]. Sensory impairment is also an important maintaining factor for hallucinations occurring in the context of schizophrenia or other disorders.

Auditory hallucinations occur in schizophrenia regardless of the age of onset, although in late-onset psychotic illness visual and olfactory hallucinations are also relatively common[35]. It is important to ensure that an acute confusional state or other organic cause is excluded before new-onset hallucinations in the elderly are attributed to functional illness. Visual hallucinations, typically of people or animals, are one of the core features of dementia with Lewy bodies and are often associated with some degree of insight[4].

Illusions are false internal perceptions that result from a combination of imagery and the perception of a real external object. They are common in people with visual impairment as well as in psychotic

or organic disorder and are accentuated by affect and poor attention. Sensory distortions are changes in the perceived quality or intensity of a stimulus (e.g. hyperacusis) and are suggestive of organic disorder or drug intoxication. Perceptual abnormalities must be discriminated from visual agnosia, which is the failure to recognize objects despite normal function of the eye.

COGNITION

General observation throughout the interview will provide information about cognition, e.g. the general level of orientation, the presence of confabulation, repetition of questions or statements and the ability to follow the conversation and to remember facts and names. The presence of hearing impairment, anger, irritability, anxiety, depression and psychosis can lead to an underestimation of cognitive ability and it is important to bear these factors in mind. Conversely, older people with marked cognitive impairment can maintain a façade that is convincing enough to mask their deficits in the absence of collateral history or objective cognitive testing, particularly in the context of a high premorbid level of intellectual ability. Memory is relatively well preserved in the early stages of some dementias and in these cases deficits in other cognitive domains may only become apparent on formal testing. Examples include visuo-spatial impairments in dementia with Lewy bodies[4] or deficits in sequencing and executive function in frontotemporal dementia[10].

Relatives' accounts of cognitive function can also be inaccurate, e.g. due to expectations of increasing forgetfulness with ageing, the insidious nature of their relative's decline or difficulties in accepting the change in their loved one and its significance. It is therefore important to include at least some form of objective cognitive testing during even the most basic examination of mental state. The Mini Mental State Examination (MMSE)[36] is the most widely used cognitive screening tool in clinical practice, although it is weighted towards verbal memory and does not include items to assess executive function. Furthermore, individuals with high premorbid intellectual function may score well within the normal range despite marked cognitive and functional decline from previous levels[37].

More detailed brief assessment scales include the Addenbrooke's Cognitive Examination – Revised (ACE-R)[38], Modified Mini Mental State Examination (3 MS)[39] and Cognitive Abilities Screening Instrument (CASI)[40], although all take longer to complete than the MMSE[41]. Supplementing the MMSE with other brief tests like letter fluency (FAS)[42] and the clock drawing test[43,44] may be a practical compromise for the initial assessment and to guide the need for more detailed neuropsychological assessment.

INSIGHT

Insight is a fluid and multifaceted phenomenon and has been conceptualized in many ways. The dimensions of insight in psychosis have been summarized as: (i) recognition of the illness, (ii) attribution of the illness to a mental disorder, (iii) awareness of the benefit of treatment, and (iv) awareness of the social consequences of the mental disorder[45]. Insight in dementia is also a complex entity, and both explicit and implicit awareness are worth considering[46]. For example, an individual may deny any problem with their memory but acknowledge that they have performed poorly on a test or need to use memory aids at home to ensure that they remember appointments. It can sometimes be difficult to discriminate between lack of insight and cognitive impairment itself; this is particularly relevant when considering medication compliance.

It has been suggested that some individuals have insight into subtle cognitive deficits before they are apparent on objective testing, and that as these objective cognitive deficits develop, insight progresses in an inverse U-shaped curve so that ultimately there is established dementia with little insight[47]. However, insight in mild cognitive impairment is variable[48] and the significance of subjective memory complaints in the absence of objective cognitive deficits is as yet uncertain.

The Physical Examination: A Guide for Old Age Psychiatrists

Stephen Todd, John O'Hare, Bernadette McGuinness and A. Peter Passmore

Centre for Public Health, School of Medicine, Dentistry and Biomedical Sciences, The Queen's University of Belfast, Belfast, UK

INTRODUCTION

The medical and psychiatric history obtained from the patient and informant, together with the mental status assessment, provide the majority of the information required in the evaluation of the older person presenting to the old age psychiatrist. However, the physical examination retains a crucial role in the evaluation of the older person for several reasons (Table 22.1).

First, it is an expected component of the consultation by the patient and/or their relative or carer and assists in developing the doctor–patient relationship. Second, a particular physical sign or constellation of signs will increase or decrease the pretest probabilities in the differential diagnosis under consideration following the history. Third, a more rational and focused plan of investigation will be instituted. Fourth, serial examination over time allows the clinician to observe the course of the disease, assess the effectiveness of any treatments commenced, and, if necessary, reconsider the diagnosis in the light of these data. Fifth, on occasions, an adequate history may not be obtainable, for example in delirium. The physical examination therefore assumes greater weight in determining further management until such history becomes available. Finally, co-morbidity is the rule rather than the exception in the older person. Commonly, there will be several aetiologies for a particular presenting complaint. The old age psychiatrist assesses the older person in a variety of settings, including the home, clinic, hospital ward, or institution, and may be the first or only contact that person may have with a clinician. Therefore, the old age psychiatrist should have the skill and ability to perform a brief but thorough physical examination, interpret the findings, plan a logical series of investigations, and determine if referral to a specialist, including other members of the multidisciplinary team, is indicated[1].

Table 22.1 Role of the physical examination in the older person

Expectation by patient and/or relative in consulting a doctor
Provides additional, pertinent information to history obtained
Allows judicious use of investigations and resource
Repeated assessment permits observation of disease course and therapeutic effects
Detection of contributory or important co-morbidity

CONSIDERATIONS

A number of differences between older and younger people are reflected in the pattern and presentation of illness (Table 22.2). First, diseases that commonly occur in older people have taken many years, sometimes decades, to develop. Examples of such chronic 'degenerative' diseases are atherosclerosis, cancer, degenerative joint disease, and neurodegenerative disorders, such as Parkinson's and Alzheimer's diseases.

Second, co-morbidity is common and interacts with normal physiological ageing changes of the body to modify presentation of disease. Impairment of physiological homeostatic mechanisms results in reduced capacity to cope with changes in the body (brought about by disease) or in the environment (such as absence of a carer or admission to hospital). Thus, the older person will be more severely affected by an insult that might be relatively minor to a younger adult. These 'reduced reserves' of older age also lead to slower recovery from an acute insult. For example, hospital length of stay is twice that of younger adults. However, even old, seriously ill individuals can recover if given sufficient time and support.

Third, in older people symptoms of disease often are less specific and uninformative, making the task of establishing the diagnosis/diagnoses more challenging for the clinician. This non-specific mode of presentation often takes the form of a 'giant of geriatrics' syndrome – instability (falls); immobility ('off feet' or 'off legs'); incontinence; intellectual impairment (delirium and dementia). However, a thoughtful approach and careful attention during physical examination will frequently direct the choice of investigations and treatment.

Some practical considerations in the conduct of the physical examination should be kept in mind and will reap considerable reward in the information obtained (Table 22.3). Time and patience are necessary virtues of clinician and patient.

Table 22.2 Differences between older and younger people

Background of chronic disease
Impaired homeostasis/physiological changes of ageing
Less specific presentation of disease

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Table 22.3 Practice points when examining the older person

Older people may require longer, and need assistance, to:
- Transfer from chair to standing
- Mobilize into the consulting room
- Transfer from chair to examination couch
- Remove items of clothing
- Replace items of clothing

The examination may also be limited by:
- Fatigue
- Frailty
- Pain
- Breathlessness
- Poor hearing or eyesight and missing aids
- Confusion

The student and doctor in training are encouraged to take the time to follow a standard scheme of examination for each body system and to repeat this scheme again and again not in a thoughtless way but with consideration to each point in the scheme, the finding elicited being examined for its significance in light of the other available data. Such an approach will produce a skilled clinician who can not only perform a rapid and seamless physical examination but also detect pertinent physical signs of relevance to the care of the older person.

GENERAL EXAMINATION

During the Interview

Physical examination commences on first meeting the older person, continues during the interview, and concludes with the 'formal' examination. Observation is thus the key initial tool, later to be supplemented, to a greater or lesser degree, by inspection, palpation, percussion and auscultation. Brief mention is made of the carer. Attention to carer demeanour and their relationship with the patient is important. Mental and physical ill health in the carer may adversely impact on the patient.

The general appearance of the clothes, face and hands, including nails, may be the first clue to self-neglect or neglect or abuse from a carer, depression, or functional decline in completion of basic activities of daily living due to underlying disease(s). Body habitus may suggest malnourishment or cachexia.

The handshake allows closer inspection of hands and nails and will also permit observation of tremor, whether resting or action, wasting of the small muscles, joint swelling or stiffness, or loose jewellery, for example, that will assist in directing enquiry and subsequent examination. Ability to transfer, requirement for an aid or an arm, and gait provide information on functional ability and may suggest dysfunction at various levels of the musculoskeletal and neurological systems which will require more detailed scrutiny.

Observation of the face during the interview may reveal the blank appearance of Parkinson's disease or the lack of expression and poor eye contact of depression. Asymmetry in facial appearance may indicate neurological dysfunction, for example due to stroke or Bell's palsy. Less obvious, perhaps, are symmetrical changes in facial appearance, such as the pallor of anaemia, the fat deposition and telangiectasia of Cushing's syndrome, or the proptosis and lid retraction of an overactive thyroid gland.

Abnormal movements may be noted during the interview. In the head and face, titubation, orofacial dyskinesia, facial tics or myoclonus, or fasciculation of the tongue all require explanation. Wincing or grimacing indicates uncontrolled pain, which requires evaluation and alleviation. In the limbs, tremor may again be apparent. The position and posture of the limbs may suggest current or previous musculoskeletal or neurological problems.

Speech will be assessed during the interview and might direct further testing to determine if there are one or more problems affecting comprehension, such as loss of hearing or receptive dysphasia; articulation and pronunciation, such as dysarthria, expressive dysphasia and dysphonia; or content, such as confusional states, delusional or psychotic disorders, or depression. Limitation of speech due to pain or dyspnoea indicates serious cardiovascular and/or respiratory compromise or perhaps profound anaemia.

Examination

The general examination continues from and expands on observations made during the interview. A general 'head to toe' inspection of the patient will take closer note of the hands, face, head and neck, nutritional and hydration status, and the presence of abnormal swellings and masses.

A systematic approach to the hands will inform the examiner on the presence of a multitude of systemic disorders. The nails may be pitted in psoriasis or clubbed in a number of respiratory, cardiac, gastrointestinal and other disorders. The pattern and distribution of swelling and deformity of the small joints may suggest the presence of osteoarthritis, rheumatoid arthritis or psoriatic arthropathy. Abnormal pigmentation of the skin may indicate anaemia if pale or chronic liver disease if jaundiced. Atrophy of the small muscles may be a marker of generalized weight loss and ill health or suggest median nerve entrapment at the wrist if isolated to the thenar eminence.

Closer inspection of the eyes may also suggest anaemia or liver disease if there is pallor of the conjunctiva or jaundice of the sclera, respectively. Aphthous ulceration of the mouth is a marker of ill health. The presence of oral thrush can suggest recent antibiotic therapy, deficient oral hygiene or poorly controlled diabetes mellitus. Poorly fitting dentures can cause trauma. The condition of teeth that are present should be noted. Poor dentition can cause pain and reduction in oral intake.

The neck should be inspected for the presence of masses and the thyroid gland palpated before and while the patient swallows a glass of water. This should prompt general consideration of thyroid status and evidence of over- (warm sweaty hands, tachycardia, particularly atrial fibrillation, or tremor) or under- (cold, hoarseness, bradycardia, 'peaches and cream' complexion) activity. The cervical lymph nodes should be palpated. Localized or generalized enlargement will be confirmed by subsequent palpation of axillary and inguinal chains.

The skin should be exposed, with judicious use of a gown or drape, to assess colouration and pigmentation and characterize contusions, rashes, masses or tumours. Skin turgor in older people is less reliable than in younger adults as an indicator of hydration. Dryness of mucous membranes or axillae and sunken eyes are suggestive of dehydration whereas a moist tongue is evidence against dehydration. Further evaluation of hydration follows in the cardiovascular section.

CARDIOVASCULAR SYSTEM

The patient should be positioned at forty-five degrees with neck and chest exposed. While palpating the radial pulse at the wrist, the examiner should note the rate and rhythm. Atrial fibrillation is

the commonest arrhythmia in older people and is a strong risk factor for cerebral infarction. The character of the pulse is better assessed by palpation of the carotid artery. The blood pressure is measured both lying and after standing for two minutes. Falls are common in older patients, particularly in those with dementia. Postural hypotension is indicated by a fall of 20 mmHg or greater on standing for at least one minute.

The face should be inspected briefly with consideration of jaundice or xanthelasma at the eyes and cyanosis of the lips and tongue. In the neck, the right internal jugular vein is inspected for the jugular venous pressure (JVP), noting the vertical height above the sternal notch and the character. The carotid arteries are palpated separately, noting the character.

Inspect the praecordium for scars, deformity, position of the apex beat and pulsations. Palpation for the apex beat should consider the position and character. A laterally displaced apex beat can denote left ventricular dilatation. Tapping, thrusting and heaving beats occur in mitral stenosis, mitral regurgitation and left ventricular hypertrophy, respectively.

Auscultation is done in the area of maximal acoustic advantage for each of the four valves – apex (mitral); lower left sternal edge (tricuspid); second left (pulmonary) and right (aortic) intercostal spaces. The examiner listens separately to each phase of the cardiac cycle. The first and second heart sounds should be identified and considered normal or abnormal in intensity. The presence of added sounds (extra heart sounds or murmurs) is considered, noting location in the cardiac cycle, character and position heard maximally. Added sounds may be accentuated by repositioning the patient – left lateral for mitral stenosis and upright for aortic regurgitation.

With the patient sitting forward, the examiner may inspect and palpate for sacral oedema. The peripheral pulses should be palpated and other evidence of peripheral vascular disease, such as cool dusky skin, loss of hair and prolonged capillary refill, and peripheral oedema sought.

Other signs to consider during later examination are dullness to percussion and reduced breath sounds (pleural effusion), inspiratory crepitations (pulmonary oedema), hepatomegaly (right ventricular failure) and a pulsatile epigastric mass (abdominal aortic aneurysm).

RESPIRATORY SYSTEM

During the general inspection, notice whether the subject is dyspnoeic or using accessory muscles of respiration. In the hands, observe for tar staining, clubbing, anaemia or wasting of small muscles. The respiratory rate should be counted. In the face, unilateral meiosis and ptosis may suggest Horner's syndrome (damage to the sympathetic nervous system). The contents of the sputum pot should be inspected. Listen for the high-pitched inspiratory note of stridor. In the neck, palpate for tracheal position and presence of cervical lymphadenopathy.

Expose the chest completely and place the patient in a seated position. Both front and back of the chest should be examined with the following suggested scheme. First, inspect for scars and deformity and assess the degree and symmetry of expansion on maximal inspiration. Expansion is then assessed by palpation. Next, palpate for tactile vocal fremitus. The position of the apex beat may suggest mediastinal displacement.

Chest percussion compares left side with right side as the examiner progresses down the chest, not forgetting apices and axillae. The percussion note may be dull, for example with pleural effusion or consolidation, or resonant, with pneumothorax or emphysema. Finally, the chest is auscultated. The character of the breath sounds, whether normal or bronchial, and their intensity is noted. The presence, location and timing of added sounds are then considered. Crepitations or crackles may be pan-inspiratory and in the lower zones in pulmonary oedema or end-inspiratory and with either an upper or lower zone location in pulmonary fibrosis. Wheeze is generally expiratory and polyphonic in chronic obstructive pulmonary disease (COPD). Expiration is prolonged in COPD. Asthma is less prevalent than COPD in older people.

GASTROINTESTINAL SYSTEM

The abdomen should be completely exposed and the patient recumbent with one pillow to support the head. On general inspection, the examiner should have appreciated body habitus. In the hands, evidence of chronic liver disease such as clubbing, white nails, palmar erythema or Dupuytren's contracture may be noted. Bruising, scratch marks and spider naevi may be noted on the torso. Jaundice is best appreciated at the sclera. The mouth should be illuminated and inspected for stomatitis, glossitis and ulceration. Parotid enlargement and, in men, gynaecomastia are also pointers to chronic liver disease.

The abdomen should be inspected for scars, masses, bruising, distension, hernia and prominent veins. The examiner should also bend down to inspect from the side as masses may be visible. Abdominal movement on respiration is then noted.

The patient should be asked to indicate the site of pain, if present. On light palpation of all areas of the abdomen, the examiner should observe for evidence of pain, including wincing, grimacing or guarding. Each region should be deeply palpated in turn for masses if no pain is elicited. Continue to palpate specifically for the presence and location of hepatomegaly and splenomegaly. The kidneys may be bimanually palpable. The groins are palpated for adenopathy and hernia. Percussion of the abdomen starts in the midline and works toward the flank. If dullness is noted the examiner should seek to demonstrate if it shifts on repositioning the patient. Auscultate for the presence of bowel sounds and for bruits over the renal areas. The gastrointestinal examination is completed with digital rectal examination.

NEUROLOGICAL SYSTEM

Neurological examination is an essential component of the evaluation of every older person presenting to the old age psychiatrist. An experienced clinician will complete a thorough screening assessment in a few minutes and conduct a detailed follow-up examination as indicated with only minimum further effort. Neurological examination is crucial for several reasons (Table 22.4).

Observation during interview and general examination of tremor or blank facies will direct the examiner towards other evidence of Parkinsonism, whereas a drooping lip or stiff, immobile limb might suggest stroke and a search for asymmetric upper motor neurone deficits. However, it is recommended that a standard scheme is followed to ensure thorough assessment.

Table 22.4 Importance of neurological examination

Diagnostic criteria specify neurological signs[2–4]
Development of signs can mark disease progression
Recognize side effects of psychiatric medications
Ability to localize pathology by pattern of signs

Cranial Nerves

Assessment of olfaction is generally limited to an enquiry regarding the sense of smell.

The eyes are examined 'from out to in'. Visual acuity, corrected with the person's glasses, is assessed in each eye with a Snellen chart. If the top line cannot be read, acuity should be recorded as the best of finger counting, hand movement, or light appreciation. Knowledge of visual acuity is important in cognitive testing. Visual fields are assessed by confrontation to the examiner's (which are assumed to be normal). The examiner should be seated at least one metre from the patient and on the same level. Each eye is tested in turn and, as a minimum, all four quadrants in each eye should be probed. Any deficit detected must be mapped in detail. The presence of visual inattention is assessed by stimulating both fields simultaneously. Extraocular muscle function is assessed by asking the subject to track a moving object through a horizontal and then a vertical arc from the neutral point. The examiner may place a hand on the patient's forehead to prevent movement. In addition to the direction of reduced or absent movement, the presence of diplopia and direction and speed of nystagmus is noted. The pupils are inspected for size, shape and regularity and compared for equality. The direct reaction of the pupil to light and the consensual reaction of its pair are tested with a bright light shone from the temporal side. Reaction of the pupils to accommodation is tested by asking the patient to change focus from the distance to an object placed close to the face. Cataract may be detected by absence of the red reflex. The corneal reflex is elicited using a strand of cotton wool advanced from the temporal side. On fundoscopy, evidence of retinopathy from diabetes mellitus or hypertension and papilloedema from raised intracranial pressure should be sought.

A scheme of examination of lower cranial nerves is described, although it should be noted that this does not follow each nerve in sequence. Thus, the examiner should remain cognisant of what is being tested. A simple command, followed by demonstration of the desired manoeuvre facilitates compliance with motor examination not only of cranial nerves but also the limbs, to be described below.

Instructions to 'raise your eyebrows', 'close your eyes tightly', 'puff/blow out your cheeks', 'show me your teeth' and 'clench your teeth' assess motor function of the facial and trigeminal nerves. The ability to raise the eyebrow in the presence of ipsilateral lower facial palsy indicates upper motor neurone aetiology. Sensation is tested in the dermatome of each of the three branches of the trigeminal nerve by touching forehead, cheek and jaw on each side. The sensation of taste is not routinely assessed clinically.

Several functions should be assessed once the patient is instructed to 'open your mouth'. While the tongue rests in the floor of the mouth fasciculation may be noted. Movement of the uvula to one side on the command 'say ah' indicates a palsy of the contralateral glossopharyngeal nerve. The gag reflex is tested using an orange stick to press on each side of the oropharynx. Finally, the patient is asked to 'stick out your tongue'. A deviated tongue points to the side of the lesion. Assessment of motor function is completed by asking the patient to 'look to the side' (sternomastoid) and 'shrug your shoulders' (trapezius). Hearing is assessed informally by asking the patient to repeat a phrase whispered into each ear in turn.

Primitive reflexes, such as pouting or palmo-mental, may be present in advanced dementia.

Limbs

Tables 22.5 and 22.6 summarize the scheme of neurological examination of the limbs.

• vibration	
• joint position	
• light touch	
Gait	

Upper limbs (Table 22.5)

Assessment of tone may be affected by voluntary or involuntary movement and is often confounded by the instruction to 'relax' or 'let your arm go floppy'. Asking the patient to tap the foot can help. Reduced tone occurs in the early stage following stroke but usually indicates lower motor neurone pathology. The increased tone of longstanding upper motor neurone lesions eventually releases in a 'clasp-knife' pattern. In Parkinsonian syndromes, tremor superimposed on rigidity leads to a 'cog-wheel' pattern. Extrapyramidal signs may be caused by chronic neuroleptic use.

Pronator drift remains a sensitive marker for weakness. One muscle group innervated from each cranial nerve root should be tested (Table 22.5). It is prudent to assess grip strength and function of the hand and fingers. Power is tested in the position of maximal activity and graded on a standard scale, according to age, build and gender. Stroke predominantly affects flexor muscles.

If the deep tendon reflexes are increased, a positive Hoffmann's reflex (flicking the nail of either the second, third or fourth finger will cause a flexion of the thumb) and finger jerk confirm hyperreflexia. Reinforcement, for example by clenching the teeth, may be required if a reflex appears absent. Coordination is assessed by the finger–nose test – assessing for intention tremor and past-pointing – and rapid, alternating hand movements – which may be slow and clumsy in cerebellar and extrapyramidal disorders.

When testing sensation, the distribution of any abnormality should be determined and may be dermatomal (nerve root or spinal cord lesion), involve a single peripheral nerve territory (for example, carpal tunnel syndrome) or the 'glove' loss of a peripheral neuropathy. Testing for sensation may be unrewarding in subjects with dementia.

Lower limbs (Table 22.6)

Tone is assessed during hip rotation and knee flexion. Clonus, a sustained, rhythmical contraction of muscles under sudden stretch, is checked at the knee and ankle and is present with increased tone from an upper motor neurone lesion. Each lumbosacral nerve root is tested for motor and sensory function. Loss of posterior column modalities is often found in normal elderly people.

The plantar reflex (Babinski sign) is elicited by drawing the stimulus along the lateral border of the sole of the foot from posterior to anterior and then medially across the ball of the foot. Spreading of the toes and dorsiflexion (extension) of the great toe due to upper motor neurone pathology must be distinguished from a withdrawal response.

In the heel–shin test the patient is instructed to slide the foot smoothly down the shin from the knee to the ankle and repeat. Rapid, alternating movement is tested by the patient tapping the foot on the ground.

Finally, the gait is observed with the patient walking normally, turning and walking back. Walking heel to toe and performing Romberg's test (the patient stands with the feet together and is asked to close their eyes) assesses cerebellar and posterior column function.

Investigations in Old Age Psychiatry

Sujatha Merve[1] and Robert C. Baldwin[2]

[1]*Chasefarm Hospital, Enfield, UK*
[2]*Manchester Royal Infirmary, Manchester, UK*

INTRODUCTION

This chapter reviews a range of laboratory and imaging investigations with which an old age psychiatrist should be familiar. Physical illness has been shown to be present in 20–80% of psychiatric patient populations surveyed[1]. Physical illness of relevance to the presenting psychiatric symptoms is reportedly in the range 9–46%[1]. Concomitant medical disorder was found in up to 63% of psychiatric patients presenting to an emergency department[2]. However, a retrospective study demonstrated that only 0.8–4.0% of abnormal tests were clinically significant[1] (defined as those that contributed to a diagnosis of a medical disorder not identified by history taking and physical examination and which led to a medical consultation or changed further management). Accordingly, some have argued against using routine batteries of tests[1,2].

The older adult population may be an exception to this, as the chances of a physical illness presenting primarily with psychiatric symptoms is increased. Examples include delirium (infections, metabolic abnormalities, polypharmacy); dementia (thyroid disease, B_{12} deficiency); psychosis (substance withdrawal/toxicity, space occupying lesions in the brain); depression (anaemia, thyroid disease, some drugs, malignancy); mania (stroke, drug side effects); anxiety (thyroid disease, cardiac arrhythmia); and perceptual abnormalities (visual defects, migraine, temporal lobe epilepsy, withdrawal from drugs). Further, mental disorder may contribute to the onset of new physical illness or deterioration in an existing one due to factors such as self-neglect or cognitive difficulties.

Investigations should be guided by findings from history taking, mental state examination and relevant physical examination. Unlike in general medicine, the role of laboratory and other investigations is mainly supportive and to rule out an organic aetiology of psychiatric presentations. However, there are several other reasons for conducting physical investigations in the older patient (Table 23.1).

Ancillary investigations can aid diagnosis, especially in the dementias and in delirium. Many older patients have known physical comorbidity that requires further evaluation or are at high risk of common morbidities, which can affect management (ischaemic heart disease, anaemia, etc.). Because of self-neglect, those with dementia and depression may suffer under-nutrition and require investigation for this. Last, some psychiatric procedures and medication require pre- and/or post-testing (Figure 23.1).

Investigations may therefore be classified as primary or 'routine' (most patients receive them), secondary (indicated only in patients with certain clinical characteristics) and mandated (patients meeting certain criteria must have them) (Figure 23.1). The limitations of this approach should be recognized. Some tests (e.g. for neurosyphilis, see below) will show abnormal results very rarely but with important clinical implications. Others (e.g. full blood count or plasma viscosity) will often be slightly abnormal and of uncertain significance. A good deal of skill is required to interpret results in relation to a particular patient.

An example of an investigation of immediate relevance to management is a patient with a history of depression now presenting with what appeared to be a recurrence but also with recent confusion and difficulty in walking. On computerized tomography (CT) brain scan he was found to have a glioma. In another instance a patient with dementia deteriorated with poor appetite and weight loss. Investigations revealed anaemia and a markedly raised C-reactive protein, found on further testing to be due to inflammatory bowel disease. Here investigations helped clarify whether it was dementia or comorbid pathology causing physical deterioration. Sometimes investigations are of uncertain relevance. An example is a patient presenting with late-onset psychosis and who was found to have a sodium of 125 mmol/l due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH; see below) and a raised thyroid stimulating hormone (TSH) level caused by not taking thyroxine for former radio-iodine treated thyrotoxicosis. Optimizing these abnormalities made no obvious difference to her mental state, which improved only after the introduction of an antipsychotic agent. This also illustrates that even when there is an apparently obvious physical cause for an observed mental state, it is often necessary to treat psychiatric comorbidity as well as optimizing the management of physical disorder.

HAEMATOLOGICAL INVESTIGATIONS

The full blood count (FBC) and differential count help detect various conditions, including anaemia (low haemoglobin, low red cell count, micro/macrocytosis), infections (raised white cell count, neutrophilia), allergies or parasitic infections (eosinophilia), blood malignancies (raised cell count, abnormal cells in blood smear) and effects of drugs on particular cell lines (neutropenia or

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

Table 23.1 Reasons for conducting investigations in old age psychiatry

To rule out causative organic physical illness
To aid in the diagnosis of some psychiatric conditions (e.g. dementia)
To assess secondary physical effects of the presenting psychiatric disorder
To help assess the impact of known medical co-morbidities
To screen for common co-morbidities not obvious at presentation but likely to affect management
To screen prior to the commencement of some medications and procedures
To monitor drug levels in the blood
To monitor potential side effects of prescribed drugs

agranulocytosis with clozapine). The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are non-specific tests that can point to infection, inflammation, anaemia, malignancy, temporal arteritis and autoimmune conditions. The ESR rises with advancing age and so becomes more difficult to interpret.

The incidence of psychiatric symptoms with B_{12} deficiency has been reported to vary between 4% and 50% depending on the population studied[3]. A correlation between serum cobalamin level and measures of cognitive function has been noted in some studies, although this has been disputed in those aged over 60[4]. Deficiency of folate may be more likely to cause depressive symptoms and a low B_{12} has been linked to psychosis[5]. The true nature and reversibility of a B_{12} deficiency-induced dementia has been debated. In addition, deficiency of folate has been linked to poorer response to antidepressant treatment[6]. Confirmatory tests for the aetiology of vitamin B_{12} deficiency include gastric parietal cell antibodies, intrinsic factor antibodies and the Schilling test.

BIOCHEMISTRY

Routine biochemistry may detect electrolyte disturbances, dehydration and abnormal organ functioning (kidney, liver). The commonest psychiatric presentation of most of these is delirium. In addition, biochemical investigations are used to monitor the metabolic side effects of antidepressants or antipsychotics (e.g. SIADH and abnormal liver function tests [LFT]) and mood stabilizers (urea and electrolytes and thyroid function with lithium). SIADH is characterized by hyponatraemia (levels below 125 mmol/l are usually symptomatic), low serum osmolality and inappropriately elevated urine osmolality. SIADH can develop early after initiation of drug therapy, especially with selective serotonin re-uptake inhibitors (SSRIs). Increasing age, female gender and medical co-morbidities are risk factors.

Transient asymptomatic rise in LFT is not uncommon during the first few weeks of prescribing psychotropic drugs. Gamma glutamyl transpeptidase (γGT) is elevated in liver disease, pancreatic disease, obesity and enzyme induction by drugs or alcohol, and 52% of alcohol dependent patients have been reported to have high γGT[7]. Due to its low specificity, γGT is not indicated as a screening test for alcohol misuse. More specific is the carbohydrate-deficient transferrin (CDT) enzyme immunoassay.

A random glucose above 11 mmol/l suggests diabetes. Hypoglycaemia can cause delirium and can be seen in depressed diabetic patients who take their medication but neglect to eat.

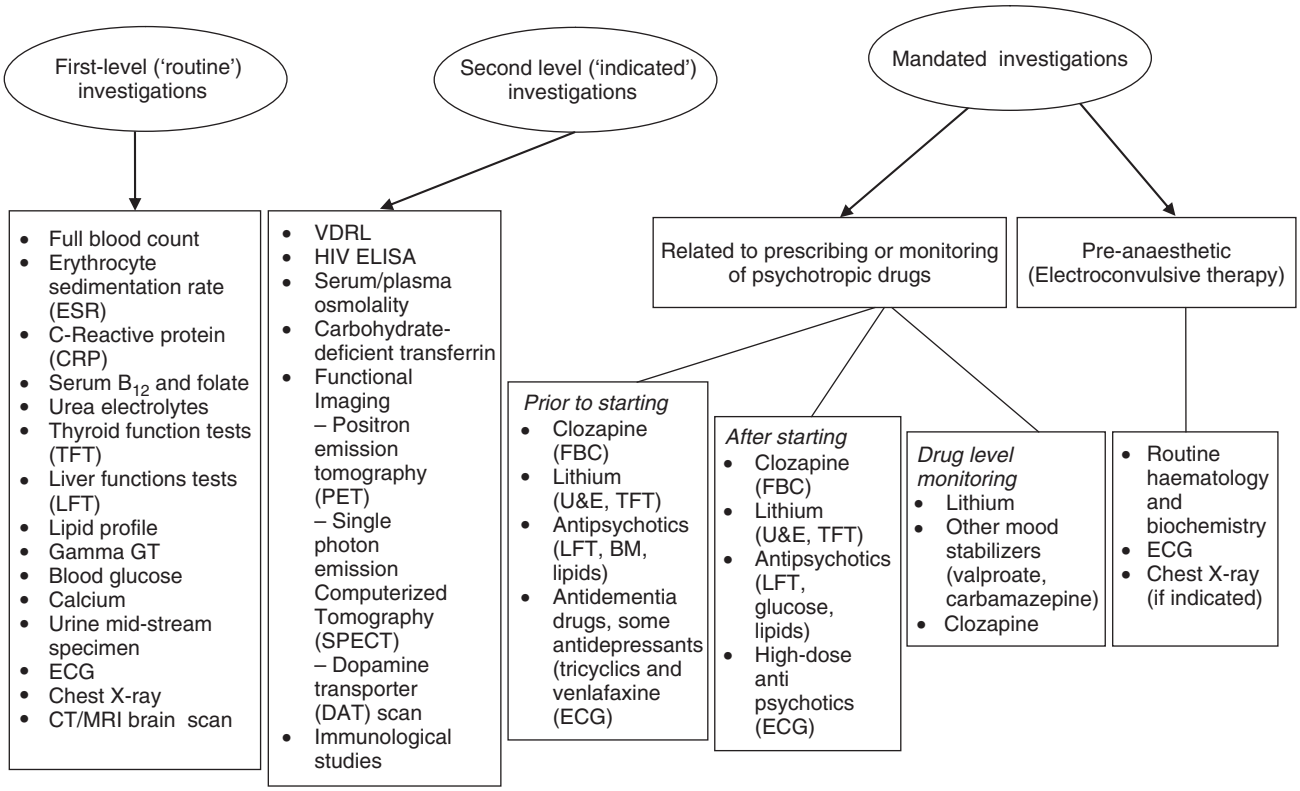

Figure 23.1 Types of investigations in old age psychiatry (see text for meaning of abbreviations)

Thyroid function testing (TFT) should be performed because of the well-known association of depression and hypothyroidism, easily overlooked in the elderly, and because 'apathetic hyperthyroidism' can be mistaken for depression. Patients on lithium should undergo TFT every six months. Raised corrected serum calcium can indicate malignancy (metastasis, multiple myeloma and lung cancer) and these patients may present with depressive symptoms. Iron studies including serum ferritin and total iron binding capacity are performed to help diagnose the type of anaemia (iron deficiency, sideroblastic or anaemia of chronic disease).

Because of the risk of the metabolic syndrome, fasting lipid screening is important in patients receiving antipsychotics. Waist measurement is a simple test of risk for this syndrome and there are international guidelines on waist measurement[8].

MICROBIOLOGY

Mid-stream urine (MSU) assessment is usually carried out to assess patients with confusion. In a sample of 68 patients Gregory *et al*.[2] reported an overall percentage of significant results in 3.1% of their review of general psychiatry patients. Kolman[9], though, studied older patients and found positive test results in 21% of patients. Non-contaminated samples are hard to obtain from patients with delirium or dementia.

RADIOLOGY

The patient's age correlates with the frequency of abnormal findings on chest X-ray[10]. A review of 746 psychiatric admissions[11] identified that the 9% of patients who had a significant X-ray finding also had concomitant physical signs and symptoms. Chest radiology of all patients presenting with psychiatric symptoms is not warranted, and clinical suspicion remains the best yardstick. It should always be performed on patients at risk of conditions like tuberculosis (homeless persons, alcohol/drug misuse and patients with HIV infection) and (ex-) smokers with weight loss.

Chest radiography is usually performed routinely as a pre-anaesthetic screening tool prior to patients receiving ECT (some centres perform it on a mandatory basis on patients aged above 35).

Endoscopy and barium X-ray tests of the gastrointestinal system may be indicated for patients with weight loss and microcytic anaemia. These investigations are sometimes poorly tolerated by psychiatric patients so advances in CT imaging are important. Helical CT scanning of the abdomen with oral contrast, besides being rapid and non-invasive, can identify a range of pathologies of the gut and other structures.

SPECIALIZED BLOOD TESTS

Syphilis

The Venereal Disease Research Laboratory test, commonly known as the VDRL test, is a screening test for syphilis that measures antibodies to the spirochete *Treponema pallidum* in the blood or cerebrospinal fluid (CSF). The newer test analogous to this is the rapid plasma reagin (RPR). *Treponema pallidum* haemagglutination assay and the fluorescent Treponema antibody tests (TPHA/FTA ABS) are highly specific for Treponema antigens and are used at some centres as confirmatory tests, especially of CSF.

Clinically significant results were found in 0.3% (0–0.6%) of psychiatric patients routinely screened[1]. A retrospective study of all inpatients (mean age 74.5) undergoing syphilis screening in a UK hospital[12] revealed that 16 of 423 tests were positive (3.8%). In four of the seven patients who received treatment, syphilis was identified as a likely contributor to the psychiatric presentation. The authors suggested that routine screening of elderly patients was justifiable where an organic aetiology was suspected, especially in dementia. Hilton[13], though, highlighted the importance of considering local epidemiology, risk factors, neurological/neuropsychiatric features and ethics prior to the routine screening of patients. In the guidance on dementia issued by the National Institute for Health and Clinical Excellence (NICE), routine testing for syphilis is not recommended[14].

Immunology

Psychiatric symptoms may be caused by systemic autoimmune diseases such as systemic lupus erythematosus, scleroderma, sarcoidosis, Sjögren syndrome, primary vasculitides and antiphospholipid syndrome. The range of autoimmune antibodies found in the spectrum of conditions include antinuclear antibody (ANA), anti-DNA (single stranded or double stranded), anti-Ro, anti-La, anti-phospholipid antibodies, anti-smooth muscle, rheumatoid factor (RF), anti-neutrophil cytoplasmic antibodies (ANCA) and antibodies to thyroid peroxidase. Table 23.2 illustrates the more common tests in relation to some immunological conditions. Catatonia and some rare encephalopathies are associated with autoimmunity, e.g. anti-NMDAR antibodies[15].

NEUROIMAGING

Focal neurological signs on physical examination or an acute change in the mental status not completely explained by other causes require

Table 23.2 Autoimmune conditions and relevant investigations

Condition	*Psychiatric presentation*	*Relevant tests*
Systemic lupus erythematosus	Psychosis, delirium, depression, global cognitive deficits	Anti-nuclear, anti-double stranded DNA, antiphospholipid, anti-neuronal
Hashimoto's thyroiditis	Dementia, delirium, hallucinations	Thyroid antibodies (antithyroid peroxidase and antithyroglobulin), anti-neural antibodies
Sjögren's syndrome	Cognitive dysfunction	Anti-nuclear, rheumatic factor
Polyarteritis nodosa	Delirium, auditory and visual hallucinations, dementia	Raised erythrocyte sedimentation rate (ESR), arterial biopsy
Temporal arteritis and polymyalgia rheumatica	Delirium, depression, hallucinations, cognitive dysfunction	Raised ESR, arterial biopsy

consideration of neuroimaging. Subdural haematoma is easily overlooked in older adults, especially when chronic. Fluctuating confusion, unsteady gait, falls and heavy alcohol use are all clues. Imaging is important if normal pressure hydrocephalus (cognitive impairment, gait disorder, incontinence) is suspected. On magnetic resonance imaging (MRI) the typical 'fluid void' sign may be seen but imaging alone is often not diagnostic.

There are clinical diagnostic rules for assessing which patients with dementia should undergo neuroimaging but they are not precise enough to ensure that patients with potentially reversible lesions are not missed[16]. The cost-effectiveness of routine imaging in patients with suspected dementias has been questioned but with the likelihood of more effective treatments emerging in the future the situation may change. Guidelines concerning the indications for neuroimaging are available from the National Institute for Health and Clinical Excellence[14], the Scottish Intercollegiate Guidelines Network[17] and the American Psychiatric Association (APA)[18]. NICE recommends MRI scanning as the preferred modality to assist early diagnosis and detect subcortical (vascular) white matter changes. The APA recommends neuroimaging in cases with subacute onset (less than one year), symptom onset before age 65, vascular risk factors suggesting a higher likelihood of cerebrovascular contributory factors or a history or neurological examination findings suggesting a possible focal lesion. The usefulness of neuroimaging in late stage disease has not been established[18].

CT is widely available and may be acceptable for anxious/disturbed patients. In one study[19] of 178 CT scans carried out, only 4 cases of potentially reversible neurological conditions were identified and in no case did this knowledge change treatment. On the other hand 32.8% had evidence of ischaemic white matter disease. As CT is not as sensitive as MRI (see below) in detecting this, when unequivocally reported on CT scanning such ischaemic changes ('leukoaraiosis') support a diagnosis of mixed type dementia.

MRI provides more detail of brain structure and function. As the patient must remain motionless in a tunnel for up to 20 minutes, MRI is not suitable for anxious or claustrophobic patients nor for those with metallic implants (pacemakers, aneurysm clips). There are few diagnostic signs relevant to psychiatry with MRI. An exception is the pulvinar sign in variant Creutzfeldt–Jakob disease (CJD), which has been found to be highly accurate and may obviate the need for more invasive testing[20]. More usual is the frequent finding on MRI of white matter hyperintensities, which are commonly interpreted as evidence of small vessel ischaemia but are of uncertain diagnostic significance unless graded as severe.

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) utilize radioactive isotopes to assess brain metabolism (PET) and perfusion (SPECT) and provide information about the functional status of brain tissue. These investigations are discussed in detail elsewhere. Although clinical criteria may be more sensitive than SPECT, the latter is more specific in differentiating different types of dementia[21] and so is recommended to aid in the differential in cases of doubt[17].

Functional imaging of the dopamine transporter to assess the integrity of the nigrostriatal dopaminergic pathways is the basis of the DAT scan. DAT scanning can be helpful in distinguishing drug-induced Parkinsonism from idiopathic Parkinson's disease and in the diagnosis of Lewy body dementia. In the latter, low striatal DAT occurs whereas DAT activity is normal in Alzheimer's[22].

The development of additional imaging tools such as quantitative MRI, functional MRI, investigational PET compounds, and other methods aimed at imaging senile plaques in the brain may help improved diagnosis, early recognition, and more precise assessment of disease progression in the future.

ELECTROCARDIOGRAPHY (ECG)

The main use of ECG in psychiatry is to monitor serious cardiac side effects of psychotropic medication (Table 23.3). It is ordered in at-risk populations, e.g. those with pre-existing cardiac abnormalities or

Table 23.3 Summary of common cardiac effects of psychotropics

ECG parameter	*Drug*	*Effect*
Heart rate	Clozapine; drugs with antimuscarinic side effects: TCAs, MAOIs	Sinus tachycardia; clinicians should suspect myocarditis/cardiomyopathy in patients on clozapine if patients have fever or other cardiac symptoms such as persistent tachycardia
Heart rate variability	Clozapine	Reduced variability associated with increased risk of cardiac death
Cardiac conduction	Tricyclic antidepressants	Prolong QRS complex; such changes in a patient with pre-existing conduction defect can cause complete heart block; in toxic doses (overdose) this can prove fatal
	Antipsychotics	Can prolong QTc interval
	Haloperidol in high doses	At-risk patients can develop torsades de pointes and fatal ventricular arrhythmia
	Any intravenous antipsychotic	Some antipsychotics may cause atrial fibrillation, heart block, changes to P and T waves
	Lithium	May affect T waves and rarely cause heart block
Cardiac rhythm	All drugs that have an effect on cardiac conduction	Torsades de pointes, ventricular arrhythmias and sudden cardiac death have all been reported; monitoring mandatory for at-risk population (pre-existing cardiac disease, high-dose antipsychotic use, overdoses especially TCAs and those with metabolic/electrolyte abnormalities)
Cardiac conduction and rhythm	Acetylcholinesterase inhibitors	Can cause bradycardia, atrial arrhythmias; angina, syncope

conduction defects, those on other drugs that have an effect on cardiac conduction (antiarrhythmics), those with or at risk of metabolic abnormalities (anorexia, renal failure) and patients who have taken an overdose. An ECG should be performed prior to the commencement of a tricyclic antidepressant or a cholinesterase inhibitor.

Patients on high-dose antipsychotics are at increased risk of arrhythmias and sudden cardiac death, and hence ECG monitoring in this group of patients is mandatory[23,24]. Lithium can change the morphology of T waves and in rare instances has been associated with heart block (Table 23.3).

ELECTROENCEPHALOGRAPHY (EEG)

The EEG is no longer widely used in assessment of patients in old age psychiatry and has been largely superseded by structural neuroimaging. However, in some cases the EEG can provide valuable additional information, e.g. in differential diagnosis of rapidly progressive dementia, episodic neurological symptoms and signs, or complex presentations with inconsistencies in the clinical picture and investigations.

The EEG in patients with Alzheimer's dementia may show non-specific abnormalities even in the early stages of the disease. In frontotemporal dementia the EEG remains unremarkable until late in the disorder. Although not routinely recommended. The EEG can be highly specific (although not sensitive) in cases of sporadic CJD[17], in which case a lumbar puncture to assess for the presence of protein 14-3-3 may help with the diagnosis. The role of MRI in CJD has been discussed.

Patients with dementia of Lewy body type show a characteristic early slowing of dominant EEG rhythm and 50% show focal delta wave activity in temporal regions[25]. The EEG in patients with vascular dementia is more likely to be normal in the early stages. Abnormality correlates with the amount of damage in the underlying brain structure, often with focal or asymmetrical changes.

EEG findings of pseudo-periodic sharp wave activity (triphasic) are found in 70% of cases of CJD.

Quantitative EEG (qEEG) uses a computerized programme to statistically analyse EEG recordings and may assist in diagnosis. A literature review[26] suggests that abnormalities in qEEG tend to increase with the severity of the dementia. Studies have reported a moderate to high accuracy of differentiating EEG recordings in normal ageing populations and patients with dementia.

PSYCHOTROPIC DRUG MONITORING

Therapeutic drug monitoring is primarily used for drugs with a narrow therapeutic index or which show high inter-patient pharmacokinetic variability[27]. Drug monitoring is mandatory for some drugs that are toxic in higher concentrations such as lithium. Monitoring can also help confirm treatment adherence. Serum monitoring was useful for tricyclic antidepressants where there was known to be a therapeutic window but with the newer antidepressants, where effective doses are close to starting doses, the need has disappeared.

Most drug levels are measured when they reach steady state concentration; this takes four to five drug half-lives[28]. Also sample collection should be made within 1–2 hours of the recommended time (trough or pre-dose and 12-hour post-dose, as with lithium). Mood stabilizers are one of the most commonly monitored classes of psychotropic drug (Table 23.4), although lithium is the most important because of its narrow therapeutic-to-toxic ratio. Blood levels of valproate and carbamazepine do not necessarily relate to clinical effectiveness.

For clozapine, a number of patient factors have been identified that influence the serum levels. These include the age of the patient,

Table 23.4 Serum monitoring of mood stabilizers

Drug	Investigations prior to prescribing	Side effects	Average daily dosages	Target serum levels
Lithium	Renal function	Polyuria, gastrointestinal upset, tremor, neurological disturbance (toxicity), weight gain, oedema, psoriatic rash		
	Electrolytes ECG Thyroid function Blood glucose (preferably fasting)		400 mg (slow release)	0.6–0.8 mEq/l
Valproate	Liver enzymes	Sedation, nausea, unsteadiness, tremor, weight gain	500–1500 mg	65–90 µg/ml (not definitely established)
	Full blood count ECG (if history or clinical condition suggests)			
Carbamazepine	Liver enzymes	Sedation, ataxia, nystagmus, blurred vision, agranulocytosis, hyponatraemia	400–800 mg	4–12 µg/l (levels for epilepsy)
	Full blood count ECG (if history or clinical condition suggests)			

ethnicity, smoking status and interactions with other drugs. Plasma levels of 350–500 μg/l have been suggested for optimal clinical response. Seizures have been identified to be commoner in patients with levels higher than 1000 μg/l[29]. Some authors have suggested the prophylactic use of valproate to prevent seizures when the plasma levels are >600 μg/l.

OTHER INVESTIGATIONS

Cerebrospinal Fluid Analysis

Lumbar puncture (LP) is generally performed under the care of physicians or neurologists with the main indications being confirmation of CNS infections (bacterial, tubercular, fungal), inflammatory conditions (vasculitis) or malignancy. With the developments in neuroimaging, many of these conditions can be identified on scans. The role of LP in suspected CJD can be diagnostic and has been discussed.

Sleep Studies

Common sleep complaints include insomnia, excessive daytime sleepiness and parasomnias such as REM sleep behaviour disorder (SBD), as seen in dementia with Lewy bodies. Other conditions that may be misdiagnosed as primary psychiatric illnesses include narcolepsy and sleep apnoea syndrome. The latter is increasingly recognized as a cause of or contributory factor to confusional states.

Primarily the assessment of sleep-related disorders relies on clinical evaluation and sleep charts. Polysomnography is available in specialist centres and involves measurement and observation of different stages/components of sleep along with recordings of EEG, electro-oculogram and electromyogram. Sleep apnoea is diagnosed with simultaneous monitoring of respiratory effort and oxygen saturation overnight and is offered by respiratory medicine departments.

Genetic Studies

Genetic screening and prediction of risk raises many ethical dilemmas. However, old age psychiatrists increasingly see younger patients with dementia for whom genetic considerations apply and they should know when to refer to a colleague specializing in psychiatric genetics.

Ethical issues of confidentiality and information sharing pose a great challenge to clinicians and geneticists. The experience may be emotionally challenging to patients and the results may not be conclusive. Issues of 'the right not to know' and implications for the individual's future employment and discrimination in access to insurance policies need to be considered. Some tests can result in stigmatization and unwarranted anxiety among family members. Genetic testing is predictive for only some conditions.

Alzheimer's disease has been associated with mutations in amyloid precursor protein (APP) and presenilin 1 and 2 genes. Frontotemporal dementia studies have suggested mutations in *tau* protein (in some families involving autosomal dominance) and *α-synuclein* has been recognized in Parkinson's disease. Early onset (<65 years) Alzheimer's disease is associated with gene mutations that are transmitted in an autosomal dominant fashion.

While late onset Alzheimer's disease (>65 years) is generally considered to be idiopathic or sporadic, numerous studies have shown increased risk of developing the disease (odds ratio between 3 and 15) in individuals with APO E4 allele on chromosome 19[30].

However, testing for apolipoprotein E4 (*APOE4*) is not recommended for use in the diagnosis of dementia[31]. Commercial kits are available for testing certain genes, for example presenilin 1 (*PSEN1*) on chromosome 14 but careful interpretation is required and should only be undertaken in the context of pre- and post-test counselling[18]. In addition, specific genetic testing is available for Huntington's disease and CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy – Notch 3 gene polymorphisms). Lastly, there is current interest in the glucocerebrosidase gene in Lewy body dementia, which may in the future have implications for genetic testing[32].

LEGAL CONSIDERATIONS

Always record whether the patient consents to undergoing investigations and if they are unable whether it is in their best interests to undergo them. In English law, in an emergency, the Capacity Act (2005) permits reasonable and proportionate force for necessary testing and the Mental Health Act (2007) allows the Responsible Clinician to make arrangements for testing of detained patients where this is of direct relevance to their mental disorder (this includes withdrawing blood for clozapine monitoring). It does not, however, mandate testing of an unrelated condition, e.g. an endoscopy for incidental anaemia. Colleagues responsible for carrying out the investigation must conduct their own assessment of capacity. For example, an endoscopist must be satisfied that the patient understands the procedure and if this is not clear they will often seek the advice of the psychiatrist who has referred the patient. Colleagues undertaking investigations for the psychiatric team should be forewarned if the patient lacks capacity, both for their own safety and because certain tests will be difficult to perform without collaboration of the patient.

Testing of a patient for the good of others without consent is not permitted. The Human Tissue Act (2004) makes this clear. For example, this includes a member of staff who has been bitten by a patient with dementia and who may wish to know the patient's hepatitis and AIDS status. The Capacity Act (2005) may permit testing if it can be demonstrated that such knowledge is in the patient's interest, e.g. if it might lead to less restrictive nursing. Legal advice would still be needed regarding the disclosure of results to a third party.

Bedside Assessment of Cognitive Functioning

Richard Perry

Department of Neurosciences, Imperial College and Imperial College Healthcare NHS Trust, Charing Cross Hospital, London, UK

INTRODUCTION

In the future, clinicians are likely to make ever more use of newer diagnostic techniques such as multimodal MRI imaging, PET imaging and CSF analysis. These ancillary investigations are only helpful in the appropriate clinical context in terms of their ability to discriminate between various diseases and in how their results are interpreted. As always in medicine, this clinical context comes from careful and considered history and examination.

HISTORY TAKING IN COGNITIVE ASSESSMENT

One key aspect of the cognitive history is the necessity of gaining a witness or corroborative account. By their nature, cognitive impairments may include lack of insight and impaired ability to express details of the history as a result of memory, language or other cognitive deficits. It is therefore strongly recommended that a witness history is taken and it is often beneficial to perform this separately from the patient, particularly if personality or behavioural changes are to be exposed.

An in-depth discussion of all aspects of the cognitive history is beyond the scope of this chapter and we have excluded the well-known aspects of past psychiatric history, past medial history, educational and occupational history and social and family history in favour of highlighting some tips specific to cognitive history taking, which although not meant to be foolproof, nevertheless may provide helpful clues to direct the clinician.

Initial Presentation and Impressions

Although not without exception, on the whole, if a spouse, friend or carer is the instigator of the referral, this is more suspicious of an underlying organic brain disorder than patients who self-present. Patients who attend a clinic alone have a much greater chance of having an underlying affective cause of their symptoms than those who are accompanied.

Many patients who are 'brought' to a consultation adopt this role very quickly and defer to their spouse or friend in sitting down and answering questions. A common occurrence is the response to the first greeting or question – when the examiner asks why the patient has come to see them, the patient may immediately turn to their spouse for help or confirmation without actually addressing the question. Anecdotally this reaction seems to have a fairly high specificity for underlying organic brain disease.

Presenting Complaint

It is important to clarify the first symptom that has been noticed by the patient or carer. Patients presenting with moderate stages of dementia may have a multitude of symptoms that overlap between dementia subtypes and often the first symptom can be instructive regarding diagnosis. For example, memory deficits are invariably the earliest feature of Alzheimer's disease whereas behavioural changes are invariably the initial feature of frontotemporal dementia despite both sets of symptoms being present in both conditions as they progress.

It is often difficult for patients or informants to be accurate about the duration of symptoms which are usually underestimated. A little gentle probing can often extend the history from an initial estimate of six months to several years, thereby narrowing the differential diagnosis. It is useful to ask such questions as 'how were they three years ago – were they the same as 20 years ago?'

Behavioural and Personality Changes

To get a clear history of behavioural or personality change, the interviewing of an informant is critical as lack of insight often accompanies such behavioural changes. Major personality change is usually a result of pathology in the limbic, paralimbic and frontal-striatal systems. They may be seen in space occupying lesions of the frontal lobe and subcortical dementias but the condition where specific personality changes are virtually diagnostic is frontotemporal dementia.

A simple question such as 'have you noticed any changes in X's behaviour or personality?' is usually a helpful opening gambit. A not uncommon response in frontotemporal dementia is that 'they are not the same person that I married'.

Behaviours to probe for include apathy, passivity and lack of initiation. Indeed some patients are often content to let others discuss less than complimentary changes in their behaviour or personality without need to interject or justify themselves in any way. Disinhibited behaviour can be enquired about in terms of whether the patient has done or said anything that causes embarrassment or is inappropriate, especially in public. Rigidity in behaviour may be evidenced by strict and unnecessary time keeping or eating habits such as always eating the same food at the same time of day. Obsessive and compulsive

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

behaviour should be questioned and the duration of this ascertained to differentiate from longstanding personality traits. Gradual loss of empathy and blunting of emotional repertoires should be sought and a change in food preferences for sweet things or the development of a catchphrase are both behavioural changes that are virtually pathognomonic of frontotemporal dementia.

Autobiographical History

It is useful to go through details of schooling and major life events in early adulthood, primarily to see if the subject has impaired autobiographical memory. An inability to remember where they went to school, when they were married and where, or what their first job was, is concerning for an organic dementia as these memory abilities are not usually affected in psychiatric disorders.

Medications

Elderly populations may have a multitude of medical and psychiatric co-morbidities and hence multiple medications, many of which may affect cognition. Particular medications to note are opiate-based analgesics such as codeine or tramadol, medications with anticholinergic properties such as tricyclic antidepressants, antispasmodics, anti-emetics, anti-parkinsonian medication, bronchodilators, or antiarrhythmics.

Activities of Daily Living

Ask about performance at work if appropriate, ability to travel to new locations alone, handling of finances and bank accounts, social events, use of household devices including telephones, TVs etc., preparation of meals, organizing of family events such as trips and holidays. A gradual change of responsibilities from patient to spouse or other carer over several years is revealing.

BEDSIDE COGNITIVE ASSESSMENT

Initial Observations

The bedside cognitive assessment starts with observation of the patient. Watch how the patient enters into the consultation room, paying particular attention to their gait and observe how they sit down in a chair.

The gait abnormality of idiopathic Parkinson's disease is easy to recognize if one is watching for it. Slow and shuffling with short steps, narrow base, stooped posture with decreased arm swing. It is surprising how often this is overlooked. If a diagnosis can be made before the patient has sat down, it is very helpful for the rest of the consultation! The gait of cerebrovascular disease is characterized by the sense that the feet are rooted to the ground with a more wide-based gait, again with small steps. The gait of normal pressure hydrocephalus is usually more wide-based than that of cerebrovascular disease and is unsteady with less adherence of the feet to the floor.

Further useful information can be taken from watching the patient sit in a chair – difficulty in orienting to the chair or sitting on the edge or armrest of a chair by mistake suggests significant apraxia. If a patient falls back heavily into a chair, be on the lookout for additional signs of progressive supranuclear palsy.

Throughout a cognitive assessment it is useful to keep the question in mind of whether one is dealing with a predominantly cortical or subcortical picture of impairment. The cardinal features of a subcortical cognitive impairment are slowing of thought, response and movement with impaired attention. The major cortical deficits to look out for are language impairment (aphasia), visuospatial impairment and praxis and so the finding of one of these deficits suggests cortical involvement (note the rare exceptions of aphasia from basal ganglia lesions). Memory deficits may be present in both cortical and subcortical syndromes.

Another important question to return to during the consultation is whether the patient has an organic or psychiatric origin to their symptoms. Although it is not always possible to be certain, there are certain clues from both the history and examination that may guide the examiner. Symptoms that are fluctuating or specific to either the home or workplace are suspicious for psychiatric symptoms, as are symptoms that are noticed solely by the patient rather than others. In the examination, psychiatric syndromes may often manifest with impaired memory, executive functions and processing speed deficits but the presence of real language deficits, apraxia or visuospatial function is far more concerning for organic brain disease.

Cognitive Rating Scales

The most widely used screening tool for bedside cognitive assessment is the Mini Mental State Examination (MMSE) which typically takes 8–10 minutes to administer and assesses orientation, memory, language and visuospatial function and is scored out of 30 points. As the MMSE is the subject of a separate chapter (see Chapter 27), it will not be described in detail here, but it is worth considering a few of its major advantages and disadvantages.
Advantages:

- ease of administration;
- wide use helps comparison of scores across patients and testing centres;
- suitable for longitudinal assessment;
- quick.

Disadvantages

- does not assess speed of information processing or executive function;
- minimal assessment of memory;
- ceiling effect in mild cognitive impairment and frontotemporal dementia;
- test–retest reliability (intra-rater) of $+/-3$;
- inter-rater reliability suspect on serial 7s and 'world' backwards.

Because of these limitations, which are likely to be inherent in any short screening tool, various adaptations of the MMSE have been devised. The most promising of these is the Addenbrooke's Cognitive Examination (ACE) which includes all of the subtests of the MMSE but is expanded to include more detailed tests that provide scores for each of the five domains of episodic memory, verbal fluency, naming, language and visuospatial function. The latest revised version, the ACE-R, comes on six pages of A4, takes approximately 20 minutes to administer and is scored out of a total of 100. The full ACE-R with administration and scoring guidelines is available on line at http://pn.bmj.com/supplemental.

The memory domain includes a seven-item name-and-address test in which the patient is asked to register a name and address (e.g. Simon Williams, 17 Somerfield Road, Croydon, Surrey) across three learning trials and then recall after a 10-minute delay. There are

two tests of verbal fluency. In letter fluency, the patient is asked to produce as many words beginning with 'p' as possible in one minute and in category fluency, as many animals as possible. The naming section is far more sensitive than that on the MMSE and consists of 10 line drawings of low-frequency items.

The authors of the ACE-R have carried out validation studies suggesting two cut-off scores of 88/100 or 82/100 for clinical practice. In the initial publication the upper cut-off score of 88 has a good sensitivity for dementia of 94% and a specificity of 89%[1]. This high sensitivity was reproduced in a later study although specificity was considerably lower with many false positives[2]. The specificity of the ACE for dementia is increased at the lower cut-off score of 82 without a major loss of sensitivity.

Proponents of the ACE have examined its potential to differentiate between dementia subtypes. The initial reports used a ratio of the domain scores of verbal fluency + language/orientation + memory (VLOM ratio) to differentiate between Alzheimer's disease and frontotemporal dementia and found that a ratio >3.2 supports Alzheimer's disease whereas a ratio of <2.2 is in favour of frontotemporal dementia[1]. Follow-up studies have confirmed the ratio of >3.2 as being reasonably sensitive and specific for AD although the sensitivity of a ratio of <2.2 for frontotemporal dementia is probably too low for clinical utility, especially when such studies do not take into account the pre-test probability of a diagnosis[2]. In clinical practice a diagnosis is not based on the ACE alone but in combination with the history, examination findings and imaging investigations.

A more recent study has attempted to use the ACE in conjunction with episodic memory tests such as the Rey Auditory Verbal Memory Test and the CANTAB Paired Associates Learning to identify MCI cases at greatest risk of conversion to Alzheimer's disease[3]. There was reasonable evidence that the combination of a broad screening tool of multiple cognitive domains such as the ACE plus two or more episodic memory tasks was effective in terms of both positive and negative predictive value. Indeed it is likely that this combination, which could be performed in a clinical assessment, is almost as effective as a more formal and extended neuropsychological assessment.

In the author's own practice, the subtests that appear to be the most helpful in adding to the MMSE to aid differential diagnosis are the episodic memory task, the verbal fluency task and the naming task. If the ACE were to be improved upon, it would be to further develop the episodic memory task to a word-list learning task with trials of registration and delayed recall. In clinical practice we are often trying to reliably identify which patients have impaired episodic memory that may be the earliest stages of Alzheimer's disease and the current name-and-address task may be too insensitive to fulfil this role, particularly in patients who have been cognitively high performing. Despite this limitation, the ACE is already becoming more widely used and appears to be an easily administered and helpful tool in the memory clinic.

Assessing Different Cognitive Domains

Orientation to time usually includes an assessment of day, month and year. In general, orientation to time is lost before orientation to space and this is particularly true of Alzheimer's disease. Not knowing the date is not specific and indeed many normal subjects are unaware of the date. Usually when testing date with the MMSE a margin of +/− two days is given. It is notable that disorientation to person in the absence of obtundation of conscious level is suspicious of factitious disorder. The catch is with severely and suddenly aphasic patients who can present to the unwary as confused and even as functional in origin.

Attention can be tested at the bedside with the *serials 7s* or *'world' backwards* of the MMSE or ACE.

Memory. The history informs us about autobiographical memory and further assessment can probe for deficits in episodic, working or semantic memory.

Working memory refers to information that is kept 'online' and in constant rehearsal for periods of up to around 30 seconds. It can be disrupted by interference and memories are not actually laid down for later recall. At the bedside this can be tested by forward and backward digit spans: In *forward-digit span*, a series of numbers, usually starting with three (e.g. 492) is read to the subject evenly at one integer every second who then repeats the numbers back. The digit span is taken as the maximum number of digits repeated back until two successive failures at a string length have occurred. The normal range is 6 +/− 1. *Backward-digit span* is performed in the same way except that the subject is asked to repeat the string of numbers backwards (e.g. examiner reads 947, subject repeats 749). The normal range is 5 +/− 1.

Episodic memory refers to memory for events that have been personally experienced. It has two main components: *anterograde memory* (new learning) and *retrograde memory* (memory for past events). The functional neuroanatomy of episodic memory involves the limbic-diencephalic system and its frontal connections and most importantly the hippocampal complex. Patients with disorders of episodic memory will present with forgetfulness for recent events, have difficulty keeping to the plot of novels or even films, may forget messages and rely on lists and may be repetitive.

Assessment of retrograde memory is predominantly from the history including the autobiographical history (see above) and specific questions related to more recent events such as details of holidays over the last year or two, details of family events such as weddings or Christmas and knowledge of recent major news events.

Anterograde memory can be assessed at the bedside and clinicians often use the memory subtests of the MMSE although the seven-item name-and-address task of the ACE is more sensitive. A patient's previous level of performance should be taken into account and even recall of all seven items may be obtained in those high functioning but in the earliest stages of a degenerative disease.

Semantic memory refers to our memory for facts, word meanings and general knowledge. The neural substrate that appears to be important for semantic memory is the cortical area of the anterior/inferior temporal lobe. Deficits can be apparent from the history by 'empty speech' with circumlocutions. Speech content is diminished and words are replaced with generics such as 'things'. Bedside assessment can be with verbal fluency tests, naming of objects or line drawings, tests of verbal knowledge and reading of regular or irregular words. Verbal fluency, as used in the ACE, can test both phonemic fluency (words beginning with 'p', 'd', 'f' etc.) in a minute or with semantic fluency (e.g. animals, tools, fruits etc.). In conditions characterized by semantic memory impairment there tends to be a discrepancy between semantic and phonemic fluency whereas predominant impairment of phonemic fluency is typical of subcortical syndromes such as cerebrovascular disease, parkinsonism, or depression[4,5]. Tests of semantic knowledge in the verbal domain include questions such as: what colour is grass? where do elephants live? which animal has four legs, a hump and lives in deserts? The ACE language subtests probe for impairment in the reading of irregular words, a difficulty which is often associated with semantic memory impairment. In this context, patients may have difficulty in

reading irregular words such as height or yacht and when asked to read 'mint', 'pint' and then 'rint' may read 'rint' as in 'pint'.

If significant and disproportionate semantic impairment is suspected, further assessment of knowledge about famous people or famous faces can be helpful. Right temporal lobe atrophy and involvement of the fusiform gyrus as seen in the right temporal variant of frontotemporal dementia seems to be particularly associated with face recognition and knowledge impairments[6]. This is one of the only uses the author has found for publications such as *celebrity* magazines!

Language. It is important to differentiate actual language disorders (aphasias) from *dysarthria* which refers to the impairment of the mechanical aspects of sound production. From the history, the examiner will be able to gather important information about spoken language such as its degree of fluency, whether there are any articulatory problems, difficulties with word finding, impairment of intonation, rhythm or musicality (*dysprosodia*), or paraphasic errors. When assessing fluency, the most important issue will be whether the person is able to produce language effortlessly or not, regardless of the actual content. Non-fluent speech is effortful and halting with reduced sentence length, agrammatism and impaired prosody where the normal rhythms and undulations of speech are affected. Phonemic paraphasias may be detected where the sounds within words are incorrect, e.g. incollect rather than incorrect. Where the speech deficits are characterized by slow speech, increased pauses between words and distorted sounds but without phonemic problems, the term apraxia of speech may be used. Fluent speech is characterized by lack of effort and normal articulation but with lack of content and circumlocutions. After listening to speech output a simple assessment of comprehension is valuable using simple instructions in a graded manner. It is helpful to start with one-stage commands such as 'close your eyes' before more complicated commands such as 'lift up your left hand and then stick out your tongue' or 'after touching the desk, touch your left ear with your left hand'

Repetition is likewise tested in a graded manner starting with simple words such as 'toaster' before more complicated and polysyllabic words such as 'accordion' or 'catastrophe' and then on to short sentences such as 'The orchestra played and the audience applauded' as in the Cambridge ACE. Watch for phonemic paraphasias as described above and whether these are consistent mistakes.

Naming is tested by asking the patient to name particular objects or line drawings. There is a *frequency effect* in which commonly used words are less affected than uncommon words. For example, patients might be able to name high-frequency objects such as 'pen' and 'watch' (MMSE), but may have problems with more low frequency ones such as 'anchor' or 'barrel'.

Reading and its testing at the bedside is influenced by educational factors which need to be taken into account. An in-depth assessment of reading is not frequently required unless the history and general cognitive screen (e.g. 'close your eyes' from the MMSE) identifies specific problems in this area. The Cambridge ACE is a suitable screening tool as it includes regular and non-regular words which can help determine the presence of a surface dyslexia. This form of dyslexia is typical of semantic memory impairment, possibly because these words require semantic knowledge of the word in order to read it, unlike regular words or non-words which can be read without understanding the meaning of the word.

Like reading, writing may not require a detailed assessment unless there are specific symptoms or a fairly circumscribed language deficit is suspected. In these situations, assessment of written spelling and sometimes writing of individual letters is required.

Calculation. A few simple tests of calculation can be extremely useful in a bedside assessment, especially in the situation of progressive aphasia where the clinician wish to differentiate between a perisylvian or frontal opercular syndrome. This cognitive function is highly susceptible to the person's previous arithmetic ability, which will have to be taken into consideration in order to interpret the findings but a few simple examples of mental arithmetic will usually suffice.

Visuospatial function. These can be easily assessed at the bedside by asking patients to copy simple line drawings such as the intersecting pentagons from the MMSE or the cube or clock face from the ACE. If there is disproportionate visuospatial impairment further analysis should include examination for features of *Balint's syndrome*. Although it often presents in a partial or impure state, it classically has several components, the most striking of which is simultanagnosia, which refers to the inability to widen a visual focus and synthesize a wider scene. Often described as a narrowed spotlight of attention, subjects may report only one part of a scene and ignore the wider picture. This can be picked up at the bedside by dot counting (as in the ACE) or in describing visual scenes from magazine photographs. The other features of Balint's syndrome include optic ataxia, which is the inability to accurately reach for objects in the absence of limb ataxia and optic apraxia or sticky fixation which is the inability to move the eyes to a target. The neural substrates of Balint's syndrome are invariably bilateral damage to the parieto-occipital cortex which may result from watershed infarcts or from neurodegenerative conditions such as the posterior cortical atrophy variant of Alzheimer's disease.

Praxis is typically defined as the inability to perform skilled motor movements in the absence of any deficit of power or sensation. Although usually associated with lesions in the left parietal lobe, apraxia may also be seen after lesions to the right parietal lobe, frontal lobes and subcortical structures in the basal ganglia. The description of many subtypes of apraxia such as ideational or ideomotor apraxia has led to considerable confusion due to the inconsistency with which different terms are used by different investigators but in practice such differentiations rarely help in differential diagnosis. The most important aspect of bedside assessment is to demonstrate impaired praxis, which, like visuospatial impairment, is rarely seen in purely psychiatric disorders. This can usually be achieved by asking the patient to copy a series of hand gestures, e.g. 'hitchhiking sign', or by asking them to mimic the use of objects e.g. 'show me how you brush your teeth' or 'show me how you comb your hair'. The presence of impairment in praxis usually suggests organic cortical dysfunction.

Executive function refers to those higher order cognitive capabilities that are called upon to formulate new plans of action and to select, schedule and monitor appropriate sequences of action. A lot of these functions are mediated by the dorsolateral prefrontal cortex and the subserving fronto-subcortical circuit. However, other aspects of the prefrontal cortex are also involved in some of these functions, such as the inferior frontal areas, in abilities that relate to impulse control and inhibition.

Although best tested with formal neuropsychological measures, some assessment is possible at the bedside. Verbal fluency, as described above and assessed in the ACE, is invariably impaired in dysexecutive syndromes, particularly phonemic or letter fluency. Studies show that 15 items in one minute represents a normal performance. Less than 10 items is definitely abnormal. Marked and particular impairment in letter fluency is a hallmark of subcortical disorders. Another bedside task of executive function is cognitive estimates where a subject is asked to make an educated guess to a

question to which they are not expected to know the exact answer. Examples include 'how many people live in London?', 'how fast can a horse run?', or 'how many camels are there in Holland?'. Patients with marked executive impairment tend to give answers that are completely off the mark such as 3000 people living in London. Proverb interpretation, e.g. 'what is the meaning of the phrase 'people in glass houses shouldn't throw stones'?' can be helpful although a patient's age and cultural background may affect their knowledge of such proverbs. A particular aspect of executive function called response inhibition can be tested with the go-no-go test. In this test the examiner asks the subject to place a finger on the desk. The examiner can then tap with their own finger under the desk either once or twice. The subject is instructed to tap once when the examiner taps twice and to tap twice when the examiner taps once. The examiner then begins a series of taps, either once or twice and switches between the two stimuli. Normal subjects pick up the rules to this quickly and can switch without perseverating in their responses.

It is important to remember that executive functions and 'frontal lobe' functions are not synonymous. Executive impairment can manifest from brain injury outside the frontal lobes. A case in point is the cerebellar affective syndrome where cerebellar injuries produce a range of behavioural and neuropsychological deficits very like those seen in frontal lobe syndromes.

The Neurological Examination in Bedside Cognitive Assessment

Specific neurological signs often accompany cognitive and neurobehavioural disorders and although a full discussion of the relevant neurological examination techniques is outside the scope of this chapter, there are some specific systems that should be examined. These should be taken in the context of the observations made of the patient throughout the consultation regarding speed of movement and thought, speech and other motor deficits.

Eye movements. In the context of the bedside cognitive assessment the most important aspects of the eye movements are to look for evidence of cerebellar dysfunction or of supranuclear gaze palsy. Probably the most sensitive measure of dysfunction of the cerebellar system and its connection to the brainstem is the examination of eye movements and nystagmus should be observed for in lateral gaze, upgaze and downgaze. Pursuit movements refer to the smooth tracking of a target from one side to the other and saccadic movements refer to the rapid movement of the eyes from one target to another. All of these eye movements may be affected in cerebellar disease.

Evidence of impairment of supranuclear gaze can be sought by asking the patient to look up to a target and then down while the examiner gently holds the head still. Restriction of upgaze is common with age and is a non-specific marker for extrapyramidal degenerative syndromes. Impairment of downward saccades, particularly slowed downward saccades may support a suspicion of PSP in the right clinical context.

Extrapyramidal signs The cardinal extrapyramidal signs are bradykinesia, rigidity and involuntary movements such as tremor or chorea. Bradykinesia refers to a gradual decrease in speed of movements with repetition and can be elicited in repetitive hand movements or foot tapping. Limb rigidity is suggestive of parkinsonism and axial rigidity, particularly when accompanied by a history of falls and a supranuclear gaze palsy is suggestive of PSP. The tremor of Parkinson's disease is usually, but not always, more prominent at rest and increases with distraction. Lower limb tremor, particularly unilateral, is very suggestive of Parkinson's disease. Chorea is usually seen as restless flowing involuntary movements, which if mild may just give the impression of a patient being fidgety and should prompt for further exploration of a family history consistent with Huntington's disease and previous psychoactive drug use. Myoclonus refers to intermittent sudden jerks, usually of the limbs and may be stimulus sensitive. Provocation of stimulus sensitive myoclonus may be with a loud clap out of the patient's field of vision. Alternatively upward flicking movements on the underside of fingers of outstretched hands may elicit myoclonic jerks of the same or even contralateral limb. While myoclonus may be present in many neurodegenerative diseases such as Alzheimer's disease, dementia with Lewy bodies and corticobasal degeneration, it is most commonly associated with prion diseases such as Creutzfeldt-Jacob disease, particularly in the presence of a rapidly progressive dementia.

Primitive reflexes. These reflexes are present in newborn babies and tend to disappear with brain maturation. Their re-emergence in adult life suggests disconnection of the fronto-striatal circuits and hence brain pathology. The grasp reflex refers to the involuntary gripping of the examiner's hand when this stimulates the patient's palm. The examiner must tell the patient to let go off the hand. Often attempted withdrawal of the examiner's hand leads to more pronounced grasping. The pout reflex is elicited by putting an orange stick vertically onto the closed lips of the patient and tapping. Other primitive reflexes such as the glabellar tap or palmomental reflex seem to have less discriminatory value.

CONCLUSIONS

As with all aspects of clinical medicine the history is paramount and should be used to guide the clinician to an initial differential diagnosis that can be refined with the examination. While further diagnostic tests are often necessary after bedside assessment, these are most directed and informative if based on a sound clinical assessment.

During this process it is helpful for the clinician to keep in mind a few cardinal questions that can be answered along the way. What were the first presenting symptoms and how long ago did they really start? How is the patient moving and can this help me? Have I got a reliable witness history? Is the presentation psychiatric or organic? Is the pattern cortical or subcortical and what cognitive domains are involved?

By reference back and forth to these questions during the assessment the clinician can interpret the pattern of deficits of a simple cognitive screening tool such as the MMSE or ACE and add refinements to the examination to probe different cognitive functions in more detail. This should lead to a formulation of 'where' the problem lies in terms of the functional neuroanatomy of the brain, which when considered in the light of the onset and progression of the symptoms, can guide towards an accurate differential diagnosis.

Neuropsychological Assessment

Linda Clare

School of Psychology, Bangor University, Bangor, Gwynedd, UK

Neuropsychological assessment offers a rigorous method of identifying the presence, extent and severity of cognitive impairments. Brief observation and informal interaction can yield valuable information about a patient's condition, but this level of assessment does not usually provide a sufficient foundation for evaluating the degree or extent of cognitive difficulties, and may mean that subtle or mild difficulties are missed. Therefore, a more systematic approach to assessing patients' cognitive functioning is often needed. Neuropsychological assessment achieves this aim through the use of standardized tests.

THE USE OF STANDARDIZED TESTS

Standardized tests assess aspects of current functioning in a systematic way, providing results that can be compared with normative data[1]. They are developed with the aim of maximizing reliability and validity; that is, they should provide a consistent measure of the construct of interest. Standardized tests are always administered in the same way, following administration procedures set out in the test manual. Thus, the instructions given to each person taking the test, and all the parameters of the test such as the length of time for which stimuli are presented, are identical. These conditions are exactly the same as those used to obtain data from the reference group or normative sample against which the individual's test scores will be compared, ensuring a valid comparison. Norms typically take into account the effects of age, providing stratified norms for different age groups, and adjustment may be made for other demographic factors that affect test performance, such as level of education. It follows that familiarity with the test procedures is essential in order to administer the test appropriately. Similarly, familiarity with the scientific basis and technical properties of the test, as well as the ability to consider the complex range of factors that may impact on test performance, is necessary for accurate interpretation of test results. For this reason, use of many standardized tests is restricted to those professionals who can demonstrate either by virtue of their professional education or as a result of further training that they are specifically trained in test administration and interpretation.

Neuropsychological assessment of older people combines two traditions of standardized testing: psychometric testing and clinical neuropsychological assessment. These two approaches have been described as *population-based* and *deficit-oriented*, respectively[2]. In practice, the two approaches are typically used alongside one another, with an emphasis on considering patterns of scores across a range of tasks.

Psychometric testing assumes that the ability or factor being tested is normally distributed in the general population, and seeks to establish how the individual's scores relate to those found in a representative sample of that population; for example, whether scores are close to the average for the reference group, or whether they are exceptionally high or low, and thus unusual. The classic example of this would be the measurement of IQ. Standardized tests of this kind typically include items across the range of difficulty, such that there will be some easy items that just about everyone should be able to do and some very challenging items that hardly anyone will be able to answer. Some tests identify different starting and finishing points for different age groups so that a range of items of appropriate levels of difficulty is administered, and some tests have rules specifying that the task should be discontinued in the event of incorrect answers being given on a specified number of items, on the basis that further, more difficult items would not be expected to be answered correctly. Therefore, these tests are suitable for individuals across the ability range and provide a challenging test for even those individuals with the highest levels of ability.

Clinical neuropsychological assessment sets out to determine whether there is evidence of impairment in a particular ability, such that the individual's scores are different to what they would have been if illness or injury had not intervened. This may be determined by comparing performance on abilities thought to be affected by the illness or injury with performance in areas thought to remain intact, or may be inferred from a comparison of the individual's scores with scores obtained by a normative sample, taking into account what would be expected on the basis of the individual's background. In the latter case, normative data will typically have been used to identify a cut-off score, signifying that scores more extreme than this value are unlikely to occur within the normal range. Standardized tests based on this approach rest on the assumption that the normal population will generally perform well and that poor scores are indicative of neurological abnormality.

Scores on standardized tests may be expressed in a number of ways. Most frequently, raw scores are typically converted to either a standard score or percentile rank, allowing comparison across subtests and against norms. The standard scores corresponding to given raw scores on a test are calculated on the basis of normative data collected from a large sample, taking into account the distribution of scores in the sample and the mean level of achievement. Where age is likely to affect performance, the standard scores derived from the raw scores are compared to norms for the relevant age group. The

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

use of percentile ranks serves a similar purpose, indicating whether a score is in the average range or is very infrequent and therefore unusual. Standard scores provide a consistent scale with a defined mean and standard deviation; for example, in the Wechsler Scale of Adult Intelligence (WAIS-III)[3], a scale with a mean of 100 and a standard deviation of 15 is used. Subtest scores are converted to this scale and overall scores are calculated on the same scale. Scores that are two standard deviations above or below the mean are generally considered exceptional, in that they arise very rarely. Scores of 70 (two standard deviations below the mean of 100) or below occur in approximately 5% or fewer of the population. Some tests use a mean of 10 and a standard deviation of 3; in this case, scores of 5 or below occur only in 5% or fewer of the population.

With tests that use population-based norms, the fact that a score is unusual does not in itself indicate that there is an impairment. The observed score may simply reflect the individual's long-standing ability level: the individual may be one of the 5% of the population who score very poorly on the task. Therefore, information about the expected level of performance is needed in order to interpret the results. If the individual's performance is widely discrepant from what would be expected for that individual, this suggests there may be a difficulty or impairment resulting from illness or injury. In practice, expectations about likely performance are usually based on consideration of a number of factors such as the individual's educational and occupational background and level of achievement. For a very high-achieving individual, a score that is in the low average range may reflect a significant decline from previous, superior performance levels. However, in some cases, tests are available that can provide an estimate of expected performance levels. For example, in the English language, the ability to read irregularly-spelled words can be tested with the Wechsler Test of Adult Reading (WTAR)[4] or the National Adult Reading Test (NART)[5]. Since this is considered a 'crystallized' ability, and fairly resistant to many forms of brain injury as well as the very early signs of dementia, scores on this task can be converted to obtain a predicted score on the WAIS-III[3]. If comparing this predicted score with the observed score yields a significant discrepancy, with the observed score lower than the predicted score, this is suggestive of a decline in overall intellectual functioning. Similarly, a comparison might be made between the WAIS IQ score and the Wechsler Memory Scale (WMS-III)[6] score; normative data are available to indicate whether or not a discrepancy in scores is large enough, and unusual enough, to be considered a significant indicator of an impairment in memory relative to what would be expected on the basis of the IQ score.

With deficit-oriented tests, a score that would be unusual in the reference group is generally considered to provide an indication of impairment, given that the poor score cannot be explained by other, contextual factors. The 5th percentile often provides in effect a cut-off for identifying impairment. Scores at or below the 5th percentile in the normal population may be defined as falling into the impaired range. An example of a test using this approach is the Visual Object and Space Perception Battery[7]. For tests using standard scores, as noted above, a score at or below the 5th percentile approximately translates into a score of 70 or below (on the scale with a mean of 100 and standard deviation of 15) or a score of 5 or below (on the scale with a mean of 10 and standard deviation of 3). Some tests use their own classifications, indicating whether a particular score is 'impaired', 'poor', or 'normal'. An example of a test using this approach is the Rivermead Behavioural Memory Test[8]. Some tests reflect tasks that should be achievable by anyone with normal functioning and thus the presence of errors in itself reflects likely impairments; for example, the Behavioural Inattention Test[9] identifies scores as impaired if they are below those of the lowest performing normal controls.

Provision of appropriate test norms is not straightforward, and this is especially the case with older age-groups (for a fuller discussion of this issue, see Busch *et al*.[2]). Where tests were initially developed for younger adults, norms for older people may be unavailable, or may relate to a restricted age range. They may be based on more limited sample sizes than those for younger age groups, or may have drawn upon a non-representative sample containing only those highly motivated to assist with research. Some measures have only one set of norms available, while other frequently used measures offer numerous sets of norms among which the clinician can select those that are most appropriate for the patient and for the questions being addressed in the assessment. Details of many of these can be found in the compendium compiled by Strauss *et al*.[10]. Cultural differences may mean that the available norms are not directly appropriate for the individual; for example, an individual who has grown up in a developing country and immigrated to the United Kingdom or United States as an adult will have had different formative and educational experiences from the indigenous population, and thus norms based on a United Kingdom or United States indigenous population may be inappropriate. This in itself does not necessarily preclude the use of the test, but the lack of appropriate norms will place constraints on the interpretation of results. Availability of neuropsychological tests in languages other than English is limited, and use of interpreters during testing is unsatisfactory, especially where these are family members. Translation of tests is a highly skilled and complex task and cultural, as well as linguistic, equivalence must be established. For a fuller discussion of cultural issues in assessment, see the review by Manly[11].

Comparison with test norms provides an indication of the degree to which the observed score would be infrequent or unusual in a healthy population of the same age. In some cases, this is sufficient to clarify the presence of an impairment in a particular area. However, as noted above, the situation is not always clear-cut. Furthermore, individual test scores elicited on a given occasion may be affected by a range of factors. Some of these relate to the individual, for example low mood, anxiety about being tested, physical health problems, pain, drug effects or fatigue. Some relate to the testing environment, for example uncomfortable seating, inadequate lighting or high levels of noise. Other factors relate to the tests used, for example the extent to which they require dexterity or mobility, whether stimuli are in large enough print to be easily visible, and so forth. The extent to which the assessor is able to build rapport with the individual, and respond to any emotional reactions to the assessment, may influence motivation and willingness to engage. Therefore, individual scores must be interpreted in the context of the overall situation. The neuropsychologist's observations of the individual during testing, and comments on the testing situation, will form an important part of the picture when drawing conclusions based on the test results.

The neuropsychological assessment provides a profile of the individual's strengths and difficulties. This profile may be used to contribute to problem identification or diagnosis, to inform decisions about treatment or management, or to monitor change over time. In so doing, information from the neuropsychological assessment must be considered alongside information obtained from other sources[12]. The pattern of scores on neuropsychological tests is only one part of the picture, and needs to be considered alongside the medical history

and the results of other tests, for example those that can detect possible physical causes of cognitive impairment, such as heart disease, vitamin deficiency or infection. It is also important to consider information about functional ability. Although cognitive status is related to functional ability[13], performance on cognitive tests does not fully predict functional ability. Therefore a direct assessment of activities of daily living may be advisable. See Little and Doherty[14] and Chapter 34, for a discussion of assessment of functioning, behaviour and daily living skills. An informant perspective is extremely important and should be obtained wherever possible, with the informant interviewed separately in order to obtain a full account. A home visit can provide valuable insights into the person's living situation and social networks.

If results are unclear, they can be seen as providing a baseline, and testing can be repeated after a suitable interval (e.g. one year) to see if there has been any change. However, repeated testing may give rise to practice effects and therefore needs to be undertaken with a degree of caution, and only in those cases where it is really essential. Some tests provide parallel versions of equivalent difficulty which can be used for repeated testing, for example the Rivermead Behavioural Memory Test[8] and the Test of Everyday Attention[15]. The need for repeated assessment is particularly likely to arise in cases where the aim is to differentiate the very early stages of dementia from normal ageing, given the range of factors that can affect test performance on any given occasion. Sometimes the appropriate outcome of a neuropsychological assessment is a decision to re-evaluate after a period of time has elapsed. While there is sometimes pressure to assign a diagnostic category following initial assessment, it is very important for the sake of the individual and family to avoid the risk of a false-positive diagnosis, and in many cases the best approach is to reassess after a period of time has elapsed in order to monitor the presence or absence of change over time, which in itself may be the most significant diagnostic indicator[1].

AIMS AND SCOPE OF NEUROPSYCHOLOGICAL ASSESSMENT

Usually a neuropsychological assessment will be indicated where information about the cognitive profile will assist in answering a specific question or set of questions. Perhaps the most common situation is the need to distinguish between normal ageing, mild cognitive impairment and the early stages of dementia, or to identify whether cognitive difficulties are the result of depression or mental health issues or an indication of early-stage dementia, or to distinguish between different subtypes of dementia or help identify the precise nature of the progressive neurological condition involved (see also Chapters 42 and 62). An assessment might be required in order to identify the presence and nature of cognitive difficulties following a stroke or in the context of other conditions such as Parkinson's disease. In some cases, information from the neuropsychological assessment may be needed to contribute to decisions about ability to continue driving or about the extent to which the individual has capacity to make specific decisions and choices regarding, for example, medical treatment, financial affairs, or where to live.

When conducting neuropsychological assessment with older people, it is important to have a sound knowledge of the profile of cognitive changes arising as a part of normal ageing, including the underlying neuroanatomy, as well as the diagnostic profiles of the range of relevant neurological and psychiatric disorders and their behavioural presentation in older people, and an understanding of the potential impact on cognition of neurological injury (for a fuller discussion of these issues, see by Potter and Attix[16]). Special considerations arise with regard to particular groups of older people, such as those with lifelong intellectual disability or those with long-term mental illness, where the availability of suitable tests may be limited and change may be especially difficult to detect (e.g.[17]). It is also necessary to be aware of the way in which neuropsychological factors relate to abilities such as driving or to definitions of capacity (for a fuller discussion, see pp. 175–87 in Zarit and Zarit[1]).

While we typically think of cognitive functions as somewhat discrete entities, such as memory, attention or language, in practice these functions are closely interrelated. Changes in one may be mistaken for problems with another; for example an impairment in attention may mean that information is not encoded, giving the appearance of a problem with memory. Furthermore, if the assessment is contributing to a diagnostic process, sampling just one cognitive function will be inadequate; for example, a diagnosis of Alzheimer's disease requires impairment in memory and at least one other cognitive domain. In most cases, it will be necessary to sample a broad range of cognitive functions. Generally it is the pattern of results across domains that is most informative.

The questions that will be asked are first whether there is an overall decline in cognitive functioning; second whether there are impairments in specific domains and processes; and third, if the answer to either of these is affirmative, whether there are any factors other than neurological impairment that could account for the poor performance. Where neurological impairments are identified, this leads to the questions of what the pattern of impairments suggests, what are the implications for the individual's daily life, and for the family where appropriate; and whether intervention is indicated. If there are factors other than neurological impairment that may be affecting performance, such as depression, then these may be treated prior to reassessment. It is also worth noting that some patients may not show any objective impairment, and in such cases it is necessary to consider the reasons for the expressed concern and how best to respond.

In gathering the necessary information, various approaches can be taken. An extensive standard battery of tests can be applied to every individual, or tests can be selected on an individual basis for each new patient. Most commonly, clinicians use a combination of these two methods. A comprehensive selection of tests that covers the essential cognitive functions and is likely to help in answering the most important kinds of questions can be supplemented by the selection of particular tests that are appropriate for the particular questions raised by the individual patient's profile and that make it possible to follow up on particular hypotheses that the clinician may have developed based on the initial test responses. For example, if initial testing suggests an impairment in language, attention or executive function, further tests can be selected to provide a more detailed profile. It is important to tailor the selection of tests to the level of functioning of the individual patient and the aims of the assessment. Thus, an assessment aimed at identifying very subtle difficulties that might constitute the earliest signs of dementia in a 65 year old would require a challenging and extensive set of tasks, while it would be more appropriate to test a patient who showed more obvious signs of impairment, or who was very frail, with a briefer neuropsychological screening battery, perhaps supplemented by one or two brief tasks.

A comprehensive assessment will usually include an evaluation of general intellectual functioning (IQ). The most widely used test for

this purpose is the WAIS-III[3]. This includes seven tests of verbal ability (e.g. vocabulary, comprehension, digit span) and seven tests of performance ability (e.g. block design, picture arrangement, matrix reasoning). The full test is lengthy to administer but an overall score can be obtained by administering selected sub-tests or by using the Wechsler Abbreviated Scale of Adult Intelligence[18]. Alongside this, a test that predicts lifelong optimal level of intellectual functioning, such as the WTAR[4], is usually administered. As discussed above, a significant discrepancy between predicted and current IQ would indicate a decline in current functioning. Several specific cognitive domains will also be assessed, typically visuo-spatial perception, language, attention, executive function (the capacity for abstract thinking, planning, problem-solving and inhibition), and memory. For a full discussion of these areas and of the tests that can be used to assess them, see books by Lezak *et al*.[19] and Strauss *et al*.[10].

Memory assessment will usually cover both long-term memory, comprising episodic memory (memory for personally experienced events) and semantic memory (memory for factual information) and working memory. It may also cover prospective memory (ability to remember future intentions) and autobiographical memory. As well as these types of memory, assessment should consider the processes that constitute memory and learning: registration and encoding of information, storage of information and recall of information. Memory should be tested in various ways including recognition, immediate recall and delayed recall, and in various modalities including visual and verbal. Where there has been a discrete injury or insult, such as a closed head injury or stroke, it is useful to consider whether memory difficulties relate to information acquired before the injury (retrograde) or since the injury (anterograde). One of the most widely used memory assessments is the WMS-III[6], which includes 11 subtests providing scores for general memory, working memory, immediate memory, auditory immediate memory, visual immediate memory, auditory delayed memory, auditory reception delayed and visual delayed memory. As with the WAIS-III[3], the WMS-III is a lengthy test and in some cases it may be appropriate to use only a selection of subtests. Many other tests are available to assess specific aspects of memory, for example the Rey-Osterrieth Auditory Verbal Learning Test (RAVLT)[10] or California Verbal Learning Test (CVLT-II)[20]. The Rivermead Behavioural Memory Test[8] focuses on everyday uses of memory, testing memory through the kinds of activities that require memory skills in daily life.

Visual perception can be assessed with subtests from the Visual Object and Space Perception Battery[7], with figure drawing using the Rey-Osterrieth Complex Figure Test[10], or with the clock drawing test[10]. Language is often assessed through tests of naming such as the Boston Naming Test[21] or Graded Naming Test[22]. Attention can be assessed with subtests from the Test of Everyday Attention, and executive function with subtests from the Delis-Kaplan Executive Function System (D-KEFS)[23], which include trail-making and verbal fluency.

As noted above, neuropsychological screening batteries can be employed where patients have obvious impairments or are unable to complete a full assessment. An example of the latter is the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS)[24]. This includes 12 subtests, providing scores in five categories: immediate memory, delayed memory, attention, language and visuo-spatial/constructional ability. The availability of parallel versions of equivalent difficulty is an advantage where repeated testing is indicated. For people with very marked impairments, the Severe Impairment Battery[25] assesses various aspects of cognition using a range of simple tasks.

THE PROCESS OF NEUROPSYCHOLOGICAL ASSESSMENT

The process of conducting a neuropsychological assessment will be influenced by whether the neuropsychologist works as part of a multidisciplinary team or receives referrals as an individual professional. If working as part of a team, information about medical history and factors such as mental state and mood may be available from the psychiatric examination. These areas may therefore require less extensive evaluation as part of the neuropsychological assessment, although some investigation will still usually be made, and standard questionnaires such as the Hospital Anxiety and Depression Scale[26] or Geriatric Depression Scale[27] (see Chapter 29) may be used. The advantage of teamwork lies in drawing together the results of the neuropsychological assessment with the findings from other aspects of the assessment, including for example functional assessments conducted by an occupational therapist.

In planning a neuropsychological assessment, the first consideration will be to ensure that sufficient time is available. A comprehensive assessment may require several hours' contact with the patient and may need to be conducted over more than one visit. Even a brief assessment using a neuropsychological screening battery may take 1.5–2 hours. The neuropsychologist will require sufficient information to select an appropriate set of tests. It is particularly important for the neuropsychologist to be made aware of any factors that would influence the selection of tests, including illiteracy, sensory impairment, restricted mobility and likelihood of fatigue. It is essential that patients are asked to bring with them reading glasses and hearing aids if they use these. Cultural factors should also be considered. In particular, if English is not the patient's first language, this will place constraints on the assessment. Even if the patient speaks very good English, comparison with norms derived from native speakers is unlikely to be appropriate.

On meeting the patient, the neuropsychologist will be concerned to establish a good rapport and ensure that the patient fully understands the nature and aims of the assessment process. At this stage informal discussion can help to elicit the patient's views about his or her difficulties, about the assessment and about the reasons for attending. If an informant is available, the neuropsychologist will want to talk with him or her individually as well as together with the patient. Patients are often anxious about being tested and worried about giving the wrong answers. It can be helpful to explain to them that the tests are designed to challenge everyone, so there is no expectation that anyone would get all the answers right, and the important thing is just to do the best they can. There is no doubt that patients, especially those in the older age groups, often find the neuropsychological assessment a strange process, but there is no need for it to be aversive if the neuropsychologist is able to develop a good rapport and show sufficient sensitivity. Throughout the assessment the neuropsychologist must be attentive to signs of fatigue and to expressions of frustration or distress. The former can be alleviated by suggesting a short break and offering refreshments, while the latter can be addressed by sequencing tasks so that tests which the patient finds difficult are followed by tasks that can be completed more easily. The neuropsychologist will also carefully observe the patient's reactions and behaviour during the session in order to gain

an impression of the patient's level of motivation and awareness, and identify any factors that may have affected performance.

Following the assessment, the neuropsychologist will calculate the patient's scores on the various tests administered, a process which can be quite time-consuming, and will usually prepare a concise but comprehensive report detailing the results of the assessment[28]. This will typically contain the following sections: background to the referral and any relevant history, and the reasons for the assessment; outline of the neuropsychologist's observations of the patient's behaviour and responses during testing; details of the tests administered; profile of results for each domain of cognitive functioning assessed; any additional data such as findings from questionnaires assessing mood; summary and recommendations. In the summary and recommendation section, the neuropsychologist will usually comment on the profile of results and what this implies; for example, he or she may comment that the profile is, or is not, consistent with a diagnosis of Alzheimer's disease. This section will also contain any practical recommendations that the neuropsychologist is able to make regarding how to assist or support the patient and family, or improve management of the patient's condition.

The neuropsychologist will generally aim to meet with the patient, and if appropriate the family as well, to provide feedback on the results of the assessment. Feedback should be tailored to the needs and concerns of the patient and family. In the team context this meeting may be jointly arranged with another professional such as the psychiatrist. In some cases it may be necessary to convey unwelcome news such as the diagnosis of dementia. Diagnostic disclosure should be 'patient led' and based on the individual situation[29]. The process should be conducted sensitively and sufficient time should be allowed to ensure that discussion is not rushed and that the patient and family are able to ask questions. A single meeting may not be adequate and it may be advisable to arrange a follow-up discussion. Emphasis should be placed on linking the patient and family with appropriate support networks and on identifying any possible treatment approaches.

Finally, it is important to emphasize that the scope of the neuropsychological assessment is not restricted to assisting in reaching a diagnosis. Ideally, and perhaps particularly so in the case of older people, the knowledge gained about the patient's strengths and difficulties in cognitive functioning as a result of the neuropsychological assessment will form a basis for offering information and advice about managing the patient's condition or informing the development of a treatment plan[30] based on principles of neuropsychological rehabilitation.

Overview of Rating Scales in Old Age Psychiatry

Kenneth C. M. Wilson, Ben Green and Pat Mottram

Department of Psychiatry, University of Liverpool, UK

SOME OF THE ISSUES

The needs which rating scales are expected to fulfil in the psychiatry of old age differ little from those in other age groups. However there are a few issues, which are worth considering.

The rating of behaviour concerned with the ageing process remains a contentious issue and does not play a significant role in driving the development of rating scales designed for this age group. The main influences have been the problems imposed by the measurement of psychiatric symptoms in the context of co-morbidity and the relatively high prevalence of organic cerebral disease experienced by older people. These two issues have informed the development of numerous rating scales for the assessment of cognition and have led to adaptation and subsequent development from many well-recognised rating scales used for the assessment of functional symptoms in younger people. Both significant physical morbidity and cognitive dysfunction will impact on the design as well as the content of the rating scale. Such rating scales need to be brief, allowing for problems in concentration and fatigue. Data may have to be recruited from sources other than the patient. In addition, it is important to emphasise the influence of age related cultural differences. It is usual for the interviewer to be as much as two generations younger than the interviewee. Such a generation gap will carry with it differing expectations, understandings and experiences.

An interesting example of this is that up to one third of older people say that they do not feel depressive mood when many other symptoms point inevitably to the presence of a depressive syndrome. This is unlike the experience of other age groups. It is tempting to introduce the concept of denial when trying to explain this. However, it is just possible that older people understand the term differently or have, throughout their life described the feeling of depression differently; such as feeling 'empty inside'. If a particular rating scale is weighted so as to emphasise the importance of experiencing depressed mood then it may well not address the experiences of a significant proportion of older people with depressive syndrome.

A well-recognised book, devoted to the compilation of rating scales in old age psychiatry lists well over 200 different rating scales[1]. It is well beyond the scope of this brief overview to provide a comprehensive review of each of these instruments. However, as the field of instrumentation expands it is equally important to draw attention to issues relating to the development and selection of these rating scales.

THE DEVELOPMENT OF A RATING SCALE

A number of approaches have been taken in developing rating scales. Good examples are found in scales designed to rate depression; some are developed from 'gold standard' diagnostic criteria. For example, the OARS Depressive scale[2] is derived from depressive symptoms listed by DSM III diagnosis. Other scales have been developed from already existing rating scales. A good example of this is the Carroll Rating Scale (CRS)[3] which was developed from the Hamilton Depression Rating Scale and the Beck Depression Inventory. Being aware of the developmental source of an individual instrument will inform choice in the context of the purpose and population in which the instrument is to be applied. For example, there are significant and important questions relating to the validity of DSM criteria in the diagnosis of depression in people with other disorders such as Parkinson's disease[11]. This generates the obvious question as to whether rating scales derived from these criteria are suitable for, or have been validated in these specific populations. Likewise, those rating scales that have been developed from other rating scales pose the same questions; have the source rating scales been validated in the target populations? Has there been subsequent validation of the specific rating scale in the relevant population? An obvious example is the use of rating scales for rating depression in patients with dementia. Another lies in the problem of rating depression in people with significant physical illness, where some of the physical illness symptoms, such as appetite loss; may be the same as some of those that are rated as depressive symptoms by the scale.

The same issue relates to rating scales designed to rate cognitive symptoms. The Mini Mental State Examination[4] is probably one of the most commonly used cognitive assessment instruments. Its original purpose was to differentiate organic from functional disorders and was designed to quantify change in cognitive state. Despite its popularity, the instrument does have its critics as a screening instrument[5]. There are two important issues worth highlighting in relation to its use. Firstly, the instrument does not and should not be used to allocate a diagnosis. When used in the context of an acute medical ward, it is as likely to pick up cognitive deficit in people with acute confusional states as a consequence of physical illness as it is to identify cognitive problems associated with dementias. Secondly, the instrument fails to assess all cognitive domains, in particular, failing to address specific deficits relating to frontal cortex. This problem is reflected in the adaptation of the instrument over many years of use.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

A good example of this is the development of the ACE-R[12], which was derived from the Mini Mental State Examination but includes a section addressing frontal lobe assessment.

VALIDITY OF AN INSTRUMENT

Many of the above issues fall within the over-all heading of 'validity'. Proving the validity of an instrument is seminal to its development. The concept addresses a number of issues in which the characteristics of the instrument in terms of its performance are addressed within defined populations. Hence, an instrument may be valid in one setting (or in rating symptoms in one type of population) but may not be valid in another. In testing the validity of an instrument; the degree to which it adequately probes the specific issues that are being rated is tested. Its ability to differentiate between people that are known to be dissimilar is tested, and finally, the instrument is examined in terms of the demonstrating that certain explanatory constructs account to some degree for the performance of the test. From a practical point of view it is critical that the choice of an instrument is informed by evidence of validation in populations similar to those that are intended to be interviewed.

Many rating scales have been developed as potential 'case' finding instruments. Usually a rating scale will generate a numerical 'score', often purported to represent severity of a particular set of signs or symptoms. Common examples include the Geriatric Depression Scale.

The scale is not a diagnostic instrument in that it does not exclude conditions, other than depression, which might affect its performance. However it can be used as a screening instrument in that, using a 'cut-off' score it will identify individuals with a degree of symptom severity that correlates with a depression diagnosis. This is done by examining the sensitivity and specificity of the instrument in relationship to an already established instrument or other clinical criteria. In the case of the full, 30-item Geriatric depression Scale; a cut-off score of 11 has been established[6]. However this is further complicated by subsequent developments of the instrument. There now exist shortened versions of 15, 10 and four items, all of which have different 'cut-offs'. It is self-evident that when choosing an instrument the right 'cut-off' score should be used. Many studies fail to report which version of the instrument is used, making comparisons between studies and study replication very difficult.

RELIABILITY OF THE SCALE

Understanding why the instrument was developed in the first place, the subsequent evolution of the instrument and being aware of the populations in which the instrument has proven validity are critical in informing choice of instrument. The 'Relaibility' of the instrument must also be considered. This is a technical term referring to a number of concepts.

Firstly; the internal consistency of an instrument refers to the reproducibility of measurement across different items within the rating scale. The 'test-retest reliability' refers to the likelihood of the instrument producing similar ratings when consecutively conducted on the same patient (assuming the condition being measured has not changed in the intervening period).

Secondly; the inter-rater reliability refers to the likelihood of the instrument producing similar results when delivered by two different interviewers simultaneously. Obviously, the interviewer plays an important role in terms of reliability performance. This issue is generally addressed (particularly in the context of research) through training and standardisation. Unfortunately, this is not common practice in clinical settings. The implications of this can be fairly profound in terms of patient care. Again, taking the example of the Mini Mental State Examination; which is recommended in the rating of change in cognition in the context of prescribing anticholinesterase inhibitors in England and Wales. If the instrument is not used in a standardised way then the generated scores will vary; affecting patient care. However, when used appropriately the reliability is fairly good[7]. Another area of potential concern lies in applying those rating scales employing graded or continuous variables in rating individual items. An example of this is the Nursing Home Behaviour problem Scale[10]. This instrument requires a rating of 'never', 'sometimes', 'often', 'usually' and 'always'. Each of these options is associated with a different score. One of the problems facing the rater will lie in the differentiation between these grades. For example, how does one consistently differentiate between' often' and 'usually'? The answer lies in clear instructions/descriptions and standardisation through training of the raters. A good example of a well-established and reliable instrument of this nature is the BECK Depression Inventory[13] (not specifically designed for older people), which rates each item 0–3. Each score has a brief but clear description associated with it, facilitating high levels of reliability. This is one of many self-rating scales.

DIFFERENT METHODS OF DELIVERY

Another typical example of a self-rating scale, specifically designed for older people is the SELF-CARE D rating scale[9]. It is derived from the Comprehensive Assessment and Referral Evaluation Schedule (CARE)[8] and is used to differentiate between people with and without depression in primary care settings. It takes about 15 minutes to complete. The advantages of using self-rating scales have to be balanced by the disadvantages. Experience suggests that the apparent time and resource savings may be offset by the frequent need to help people complete them. Obviously, the patient population must be able to read the questions (if required) and understand the instructions. The BASDEC is a hybrid rating scale, designed to measure depression in institutionalised settings in which patients may be over-heard or embarrassed by answering sensitive questions out loud. Nineteen cards with statements on are presented to the patient and the patient indicates whether each statement is true or false. Each 'True' answer generates a score of '1', 'don't know' generates a score of half a point and 'false' generates a '0' score.

Some scales are specifically designed to capture information about the patient from other sources. The Cornell Scale for Depression in Dementia has been designed to capture information from informants and through observation[14]. The Dysfunctional Behaviour ~Rating Scale[15] was designed for carers to make observations relating to older people with cognitive impairment. In particular cases, data may be gleaned from either the patient or the rater; as is the case in the 'Quantification of physical illness in psychiatric research in the elderly'[16].

TYPES OF INSTRUMENTS

Even though some rating scales have been developed as screening or 'case finding' instruments; these should not be confused with diagnostic instruments that have been specifically designed to enable an allocation of a standardised diagnosis. Such instruments are usually derived from diagnostic systems such as the International Classification of Diseases (ICD) or the Diagnostic and Statistical Manual (DSM criteria). These are usually semi-structured interviews in which a psychiatric syndrome is established. Importantly, they will often include' exclusion criteria' in which specific psycho-syndromes are excluded as part of the process in establishing a diagnosis. For example, the exclusion of cerebro-vascular disease will influence the certainty by which Alzheimer's Disease may be diagnosed.

Rating scales are specifically designed to rate specific variables and can usually be classified by the nature of the variables that they are designed to rate. This overview has already drawn on rating scales designed to measure depression severity, physical illness severity and behavioural problems in people with cognitive disturbance. There are of course, a wide variety of instruments including those designed more specifically for rating aspects of the dementias, quality of life, morale, issues relating to carers and activities of daily living performance. In addition to the Mini Mental State Examination, there are a number of rating scales designed to rate memory and other aspects of cognition. A good example of a practical and innovative instrument is the IQCODE[17], which is used with an informant to quantify cognitive decline over time. These rating scales should not be confused with formal psychometric assessments usually carried out by experienced and trained psychologists.

RATING SCALE SELECTION

In the first instance it is important to establish why and when a rating scale should be used. Staff on acute medical wards often use rating scales for the identification of patients with dementia and may use these to trigger referral for psychiatric assessment. Often enough, the psychiatrist will be referred a patient in an acute or sub-acute confusional state as a consequence of unstable physical illness. This is a classical mistake in that the rating scale is being used as a surrogate diagnostic instrument for dementia as opposed to a screening instrument for cognitive impairment. Inherent to this, is the question 'what is intended to be measured?'. Once the answer to this question has been established then a rating scale developed and designed to measure particular criteria can be selected. The next issue to determine is whether the rating scale is designed to measure the symptoms in populations similar to that in which it the ratings are intended. Determination of this will go some way in establishing the valid use of the rating scale in any particular setting.

The next question worth considering is whether the rating scale is to be used as a screening instrument or to measure change over time. If used as a screening instrument then it is important to determine the appropriate 'cut-off score'. Again this might be specific to a particular population and may need some background literature research. As already mentioned, rating scales can be completed by the individual target patient or carer, by the interviewer or by a third party and by a mixture of agents. The choice will depend on the reasons why a scale is being used and whether or not the person who is subjected to the interview is able to actively contribute towards the rating.

Other considerations relating to choice include; the length of the procedure. In patients with severe illness or short attention span, long interviews may prove problematic. As already indicated, training is required for some rating scales. This is important in terms of validity, reliability and generalisability of the findings. Research protocols in which rating scales are utilised will often include training and subsequent standardisation and inter-rater reliability sessions over the period of data collection. Lastly, the use of many commonly used rating scales are restricted by copyright.

SUMMARY

This brief overview of the use of rating scales in old age psychiatry has attempted to provide a general background to the development of rating scales, drawing on examples of commonly used rating scales in Old Age Psychiatry. The practical implications of validity and reliability of rating scales have been exemplified in the context of selection of rating scales within this age group. As rating scales develop, health expectations increase and resources become more limited, rating scales may offer an apparent, easy alternative to comprehensive psychiatric assessment. It is important to remember; rating scales are refined and specific and if used inappropriately are likely to cause as much harm as they can good.

The Mini-Mental Status Examination (MMSE) is a scored, 10-minute form of the traditional cognitive mental status examination. The items include orientation to place and time; registration and recall; attention and calculation; language function; and praxis. It is 'mini' because it tests cognitive aspects of mental functions, but excludes mood, abnormal mental experiences, and the form of thinking[1].

It has been standardized with normative values for age and education and is used by physicians and other clinical professionals worldwide to estimate and communicate the presence and severity of cognitive impairment[2,3]. The easily understandable items are useful for helping subjects and caregivers to understand the overall severity of cognitive impairment, as well as particular areas of deficits. For example, caregivers benefit from knowing that the patient can understand a one-stage command: 'put on your socks', but not a three-stage command: 'put on your socks, your shoes, and your pants'.

We highlight several instructions from the manual. First, a single administration given under supervision is adequate for training. Second, subjects should receive an explanation of why they are being tested and how the answers might help in their care or, in the case of research, accomplish the aim of the study. Third, successes should be praised, but errors ignored to avoid inducing emotions that might lower the subject's cognitive capacity. Fourth, fearful subjects can be reassured by early success by beginning with easier items such as naming a pencil and watch. Finally, we recommend that the serial sevens test be given, followed by world-backwards only if the subject refuses to do serial sevens, or refuses to complete one subtraction. The world task is easier than serial sevens and decreases the sensitivity of the test.

A score below 24 detects cognitive impairment in most populations[4] while a score below 27 suggests the need for an evaluation of individuals with greater than a 10th grade education. The MMSE has significant floor and ceiling effects. Many severely impaired patients score zero and the MMSE does not assess superior cognitive capacity.

The MMSE can be used in any population or cultural group; authorized translations are available from the publisher. The distribution of scores in some populations is lower than those established in the United States. This mainly is due to lower education. In the cultures studied to date, the scores are comparable when education is taken into account. The relationship between education and MMSE reflects social class, nutrition, intelligence and other exposures that affect cognition. Low education is also a risk for some diseases that affect cognition. The MMSE score is thus a snapshot of the end result or composite of the many factors that have influenced cognition over the life span: social class, nutrition, intelligence, disease, and other exposures that have occurred throughout life. If the effects of disease and education are controlled, the effect of age on the MMSE is small.

RELIABILITY AND VALIDITY

The MMSE has excellent test–retest and inter-rater reliability. The MMSE accurately reflects the results of psychological tests and structural and functional measures of brain pathology. For example, the MMSE correlates significantly with the Wechsler Adult Intelligence Scale and many other neuropsychological measures of memory, attention, executive function and language. MMSE has been shown to decline on average 3.3 points per year in Alzheimer's disease and correlates with the severity of pathology found at autopsy or by structural and functional imaging[5]. The MMSE score improves in response to treatments such as donepezil for Alzheimer's disease[6].

The score of MMSE is more similar in elderly identical twins than fraternal twins, suggesting a strong genetic component to the score. By these methods, the MMSE is 50% heritable in older adults from several countries, i.e. genetic factors account for about half the variance in scores.

Low MMSE scores occur with dementia, delirium, mental retardation, cortical and subcortical dementia and discrete cognitive disorders such as amnesia, aphasia and executive dysfunction. Hearing-impaired and vision-impaired subjects obtain lower MMSE scores. However, if instructions are written, MMSE can be used with hearing-impaired persons. Vision is required for only two points on MMSE.

Although the MMSE is often low in frontal/subcortical dementia as occurs in Huntington's disease, Parkinson's disease, AIDS

*Disclosure: The Mini-Mental State Examination (MMSE) and all its authorized translations are published by PAR, from which the authors receive royalties. Manuals and forms are available at Mini-Mental.com.

dementia and frontal dementia, MMSE is less sensitive to early frontal/subcortical than to cortical dementia. Because of these limitations, we have recently published a revision of the MMSE (MMSE∼2), which includes tests that are more sensitive to subcortical cognitive impairment. Low MMSE scores occur in elderly depressed patients; many depressed patients with cognitive impairment later show cognitive deterioration. The MMSE can be used to track delirium but because the cognitive state in delirium fluctuates, MMSE reliability and sensitivity are difficult to determine. The reliability and validity of the MMSE has not been established for children or for developmental disorders of cognition.

The MMSE score does not provide a diagnosis, pathology or aetiology, which must instead be established from the patient's history, physical examination and laboratory findings. Nor does the MMSE define competency to perform complex social functions, such as giving informed consent or driving an automobile; these functions must be tested directly.

The Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE)

Nicolas Cherbuin[1] and Anthony Francis Jorm[2]

INTRODUCTION

Efficient early detection of cognitive decline and dementia is becoming increasingly important. A large number of screening instruments are available, but they vary greatly in their ease of use, psychometric properties and validity in differing cultural contexts, as well as in the presence of co-morbid conditions. In addition, there is a need for cost-effective screening tests which can be administered to large populations across a variety of mediums (orally, paper and pencil, by mail, by telephone, or by computer).

The Informant Questionnaire on Cognitive Decline in the Elderly (IQCODE) is a brief questionnaire for the assessment of change in cognition which shows very good psychometric properties, has been validated across multiple cultural contexts, and which can be used in clinical practice as well as in large-scale epidemiological studies.

The IQODE was developed to assess cognitive decline from a pre-morbid level based on informant reports[1]. The parent instrument was composed of 39 interview questions assessing memory function (acquisition and retrieval) and intelligence (verbal and performance). Informants were asked to rate the magnitude of change over the previous 10 years in these domains. After initial evaluation, the number of items was reduced to 26 which correlated well together and were relatively easy to rate. The questionnaire was formatted for self-completion and named IQCODE. In its present form the IQCODE requires each item to be rated on a 5-point scale from 1, 'much improved' to 5, 'much worse'[2]. The questions are framed in the form: 'Compared to 10 years ago, how is this person at . . . ' (e.g. remembering things about family and friends such as occupations, birthdays, addresses, etc.).

A short version of the IQCODE consisting of 16 items has been developed[2]. It was found to correlate highly (0.98) with the full version and to have equivalent validity against clinical diagnosis. Consequently there is little advantage in using the longer version.

Versions of the IQCODE have been developed and validated in other languages (Chinese, Dutch, Finnish, French, Canadian French, German, Italian, Japanese, Korean, Norwegian, Persian, Polish, Portuguese, Spanish, and Thai) and copies are available for download at cmhr.anu.edu.au/ageing/iqcode.

Other variations on the IQCODE have also been produced, including questionnaires based on shorter[3,4] or more flexible[5] retrospective time frames, as well as short forms in Spanish[6], Chinese[7], Portuguese[8] and in other languages (which to our knowledge have not been validated).

SCORING

Scoring the IQCODE involves summing the items and dividing by the number of items, thus producing a measure ranging from 1 to 5, however, some investigators have preferred adding up all items. Norms have been developed by Jorm and Jacomb[9] for five-year age groups from 70 to 85+ years, but in practice individual researchers have generally chosen to use an absolute cut-off ranging from 3.3–3.6 in community samples to 3.4–4.0 in patient samples. A practical strategy to choose a cut-off is to identify studies (e.g. in Table 28.1) with characteristics most similar to the target population and select their cut-offs.

ADMINISTRATION

The IQCODE is a pen and paper test which takes between 10 and 25 minutes to complete, depending on the form chosen (long/short) and is generally perceived as relatively easy to answer. It can be mailed to informants and could potentially be administered by telephone or by computer (although we are not aware of any validation data with these administration media). The IQCODE can also be used as an alternative screening test when individuals are not able to complete another test such as the Mini-Mental State Examination (MMSE). In a survey of 839 community-based older individuals, Khachaturian *et al.*[10] found 74 subjects who were unable to complete the 3 MS but the IQCODE could be completed by an informant. Seventy-one of these were subsequently diagnosed with dementia. In addition, Cherbuin *et al.*[11] reviewed the literature to assess the suitability of dementia screening instruments for self- or informant-assessment, particularly in an electronic format (local computer or web-based). They concluded that the IQCODE was one of three most

promising tools and they recommended further validation studies for these delivery platforms.

PSYCHOMETRIC CHARACTERISTICS

The IQCODE's reliability and validity have been extensively researched. A number of studies have assessed the internal consistency of the scale using Cronbach's alpha. Alpha was found to range between 0.93 and 0.97 across nine studies[1,7,9,12–17] which can be regarded as excellent. The stability of scores over short periods was found to be high, with test–retest reliability showing correlations of 0.96 over three days and 0.75 over one year[9,18].

Other studies have conducted factor analyses to investigate the factor structure of the IQCODE. They all found a large main factor accounting for 42–73% of the variance which is thought to represent 'cognitive decline', while other factors were generally small with the second factor explaining less than 10% of the variance[7,9,13,14,17,19].

VALIDATION AGAINST CLINICAL DIAGNOSIS

Many studies have assessed the validity of the IQCODE against clinical diagnosis. Table 28.1 contrasts measures of sensitivity and specificity of the long and short forms of the IQCODE and the MMSE[11,20] and shows comparable findings for the two tests, confirming that the IQCODE is a valid screen for dementia. However, moderate correlations between the IQCODE and the MMSE in 15 studies ranging from −0.37 to −0.78[20] with a sample size weighted average of −0.58 suggest that these two tests, although largely overlapping, each have some unique variance. As a consequence, a number of studies have investigated whether the concurrent administration and scoring of the IQCODE and the MMSE improves dementia detection. They generally reported somewhat increased sensitivity and/or specificity of the combined tests, but cost-benefits of this combination varied depending on the methodology or the type of sample used[20]. The IQCODE has also been investigated as a predictor of conversion to mild cognitive impairment over three years and was found to be as sensitive as the MMSE for this population (sensitivity 0.82, specificity 0.71 for a cut-off of 3.19)[21].

In addition, the IQCODE has been shown to be a predictor of incident dementia in stroke patients[22] and in non-demented hospital inpatients[23] over 2–3 years follow-up. However, application of the IQCODE to complex clinical populations should be considered carefully, as one study found that the IQCODE and the MMSE were poor at detecting dementia in a sample of first-ever stroke patients[24].

VALIDATION AGAINST NEUROPATHOLOGY AND NEUROIMAGING

Diagnoses of dementia based on post-mortem histological examinations have been compared to pre-mortem IQCODE scores in two studies. Using a cut-off of 3.7 and a neuropathological diagnosis of Alzheimer's disease, Thomas *et al*.[25] found the IQCODE to have a sensitivity of 73% and a specificity of 75%. While Rockwood *et al*.[26], with a cut-off of 3.42 and a diagnosis of Alzheimer's disease, vascular or mixed dementia, reported a sensitivity of 97% and a specificity of 33%. Another six studies found associations between neuroimaging measures and the IQCODE. Jorm *et al*.[27] found significant associations between the IQCODE and the width of the third ventricle ($r = 0.29$), and infarcts in the left ($r = 0.35$) and right ($r = 0.26$) hemispheres in a community sample of older ex-servicemen. Cordoliani-Mackowiak *et al*.[28] reported significant correlations between leukoaraiosis ($r = 0.38$) and IQCODE in elderly stroke patients. Henon *et al*.[29] found significantly higher mean IQCODE measures in individuals with smaller medial temporal lobe measures. And in a diffusion tensor imaging study of stroke patients, Viswanathan *et al*.[30] detected lower diffusion measures in the non-affected hemisphere, which were interpreted as showing decreased cerebral tissue integrity in those whose pre-morbid cognition was below a cut-off of 3.4 on the IQCODE. High scores on the IQCODE have also been associated with greater cerebral atrophy[31,32].

BIAS AND LIMITATIONS

One complicating issue associated with many cognitive tests is that they can be open to bias when applied to specific sociodemographic, ethnic, language, gender, clinical or cultural groups. For example, scores on the most widely used dementia screening test, the MMSE, have been shown to be affected by gender, age, education, cultural background, language spoken at home, socioeconomic status, occupation and presence of a mood disorder[33,34]. The IQCODE has been shown to be minimally influenced by education[2,7,9,12,35–38] and by proficiency in the language of the country of residence[39]. However, small associations between the IQCODE and anxiety and depression have been reported[14,37,38,40]. They may be due to a direct link between mood disorders and cognitive function or to the fact that the informant may have difficulty differentiating between cognitive decline and depression and anxiety.

In addition, the influence of informant characteristics has also been investigated as possible bias. Jorm *et al*.[41] found that measures of informant anxiety, depression and their perception of how caring or controlling the subject was perceived to be were more strongly correlated with IQCODE scores than with the MMSE score. This suggests some contamination of the informant's ratings by the respondent's characteristics but these influences appear to be relatively weak and account for less than 6% of the variance in IQCODE scores. In contrast, the length and type of relationship and the age and education of the informant have not been found to be associated with the IQCODE[7,42].

OTHER APPLICATIONS

Although the IQCODE was developed to assess cognitive decline from a premorbid state, it has also been used for other purposes. Priner and colleagues[43] assessed the short form of the IQCODE as a screen for the prediction of postoperative delirium following hip or knee surgery and found that those with a score greater than 3.1 had a more than 12-fold increased risk of delirium. In another study, the premorbid cognitive status of stroke patients was assessed retrospectively with the IQCODE and those with a score greater than 4 were found to be at higher risk of developing epileptic seizures[44] and of dying[45]. Pasquini *et al*. also investigated the risk of institutionalization in stroke patients[46] and found that those with an IQCODE score greater than 4 at admission had a higher risk of being institutionalized three years later.

Finally, the feasibility of using the IQCODE as a self-report instrument has been investigated by Jensen *et al*.[16] who administered the questionnaire by mail to 2841 individuals (58.9% of target population) initially recruited during general practice visits. They found

that more than 60% reported completing the questionnaire without help and, although responses were not validated against full clinical diagnoses, mean IQCODE scores were higher (3.7 versus 3.3) in patients suspected of having dementia by their GP and the authors commented 'the IQCODE-SR meets the basic requirements of a good measurement'.

CONCLUSION

The IQCODE is a valid screening instrument for dementia and cognitive decline. It is particularly useful in assessing individuals with less proficient language skill, lower education levels or different cultural background or when direct cognitive testing is not possible. Its administration in conjunction with other tests (e.g. MMSE) can improve overall detection rates. Its ease of use and format make it suitable for use in clinical settings as well as in large epidemiological studies.

Geriatric Depression Scale

Meghan A. Marty, Renee Pepin, Andrea June and Daniel L. Segal
University of Colorado at Colorado Springs, USA

The Geriatric Depression Scale (GDS) is a popular and well-validated screening measure for depression among older adults. It consists of 30 self-report items and is widely used in research and clinical services. This chapter provides an overview of its development, psychometric properties, alternate forms, and use with special populations.

DEVELOPMENT, ADMINISTRATION AND SCORING

The GDS was developed to address the limited applicability of existing depression scales with older adults[1,2]. One such problem with scales that were developed and validated with younger populations relates to somatic complaints. Though somatic complaints can be a useful indicator of depression in younger samples, it is common for older adults to report somatic problems that can skew the sensitivity and specificity of a screen where older adults are more likely to have false positive depression scores. As such, the GDS does not include many somatic components in the scale and also consists of questions that are appropriate for the ageing population both in content and format. Initially, 100 questions were selected by researchers and clinicians with geriatric experience and administered to both non-depressed and depressed older adults. Of the original 100 items, the 30 items that correlated most highly with the total score were included in the final scale.

The scale was designed so that it could be administered easily in a self-rating format that would not be cumbersome for patients or medical personnel[2]. Most individuals complete the GDS in under 10 minutes. The GDS has a forced-choice response format where individuals are asked to respond *yes* or *no* to each item. However, some patients have problems with the yes/no dichotomy, instead preferring to answer 'sometimes' by either writing it in or by circling the space between the yes and no responses, though neither is a scored answer. It can help if explicit instructions are provided to patients to respond to each item in the way that *best* answers the question. In the initial validation study, the examiner read the items orally and recorded responses for individuals who could not complete the form without assistance. However, later studies found significant differences between mean scores for self-administered and staff-administered modes of presentation, with higher scores reported for self-administered scales[3,4]. There is no significant difference between scores of a card-based administration and verbal administration of the GDS[5].

For each of the 30 GDS items, the depressive response garners 1 point for a maximum total of 30 points. Regarding general cut-offs, total scores ranging from 0 to 9 indicate normal mood; scores ranging from 10 to 19 indicate mild depressive symptoms, and scores ranging from 20 to 30 indicate severe depressive symptoms. The measure is free to use and in the public domain. It can be accessed at www.stanford.edu/~yesavage/GDS.html.

PSYCHOMETRIC PROPERTIES

Reliability

The GDS has been shown to be internally consistent and reliable over time. In the original reliability study, split-half and alpha coefficients were both 0.94[2]. Other studies have demonstrated similar findings with diverse populations, showing alpha and split-half coefficients ranging from 0.80 to 0.99[6–8]. Several studies have examined reliability of scores over time, finding high test–retest correlations between 0.85 and 0.94[2,7–9].

Validity

An important psychometric property of a depression screen is its ability to differentiate between depressed and non-depressed individuals (i.e. criterion validity). The sensitivity of the GDS refers to its ability to correctly identify individuals who are depressed whereas the specificity refers to its ability to correctly identify those individuals who are not depressed. Brink *et al.*[1] found an 84% sensitivity rate and a 95% specificity rate for the GDS among community-dwelling older adults. Several other studies have examined the sensitivity and specificity of the GDS with diverse populations, finding acceptable levels above 80%. These have included medical patients, stroke patients, individuals suffering from dementia, nursing home residents, and psychiatric inpatients (for a thorough review, see Stiles and McGarrahan[10]).

The correlation between the GDS and other screening measures for depression is an indicator of the scale's construct validity. The GDS was initially validated against the Hamilton Rating Scale for Depression[11] (HRS-D) and the Zung Self-Rating Depression Scale[12] (SDS), finding high correlations suggesting that the GDS measures similar constructs as the HRS-D and SDS. Other comparisons with the GDS have also been conducted, including the Beck Depression

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Inventory[13] (BDI) and the Center for Epidemiological Studies Depression Scale[14] (CES-D). These comparisons also yielded significant correlations, adding to evidence supporting the construct validity of the GDS[15–18]. Furthermore, the GDS has non-significant correlations with measures of cognition, adding to the empirical evidence that the GDS measures depression and not another construct[19–21].

Dimensionality

Factor studies on the 30 items of the GDS have yielded mixed results. Sheikh *et al*.[22] proposed a five-factor solution among community-dwelling older adults. Abraham and colleagues[23] proposed a six-factor solution among nursing home residents. These studies contrast the findings from Parmelee *et al*.[9] and Salamero and Marcos[24], which both found the GDS items to be highly intercorrelated and suggested the scale has only one factor. Based on these results, both advised the GDS should only be interpreted from a single total score.

ALTERNATE FORMS

Brief Forms

Several brief forms of the GDS have been designed for use in settings where time is limited for depression assessment and with frail individuals for whom fatigue and poor concentration are concerns. Sheikh and Yesavage[25] developed a 15-item version of the GDS, commonly referred to as the Short Form (GDS-SF), by taking the 15 items from the original scale that had the highest correlation with depressive symptoms in earlier studies. Findings from their validation study suggested both forms were highly correlated ($r = 0.84$) and effectively differentiated depressed from non-depressed individuals. A subsequent study reported cut-off scores for the GDS-15 as *normal* (0–4), *mild* (5–9) and *moderate to severe* (10–15)[26]. Older adults rated the GDS-15 as an acceptable measure that was not difficult or stressful to complete[27].

Evidence for the validity of the GDS-15 is mixed. Some studies suggest the GDS-15 is not a suitable substitute for the full scale GDS in community-dwelling older adults[26,28] or cognitively impaired individuals[29]. It does appear effective for screening depression in older adults who are cognitively intact and medically ill[29], have affective disorders[30], or who are seen in primary care clinics[27,31]. The GDS-15 was shown to consistently identify depressed individuals in a VA nursing home population[32]. Chiang and colleagues[33] suggest that the GDS-15 may be less effective as a screening tool, but that it could be most effectively used to detect changes in moderate levels of depression.

Hoyl and colleagues[34] developed a five-item GDS for use in a geriatric outpatient population by selecting items from the GDS-15 that had the highest correlation with a clinical diagnosis of depression. Using a score of 2 or greater to indicate possible depression, the GDS-5 had a sensitivity of 97%, specificity of 85%, and alpha coefficient of 0.80. The GDS-5 was found to be as effective as the GDS-15 in an Italian sample of cognitively intact older adults across three settings: a geriatric acute care ward, a geriatric outpatient clinic and a nursing home[35]. In addition, validity of the GDS-5 has been demonstrated for older sedentary adults.[36] Weeks and colleagues[37] compared two versions of four-item GDS measures and the GDS-5 to the GDS-15 in a sample of acute care patients. They found the GDS-5 showed the highest sensitivity (97%), but led to a high number of false positives. The researchers re-ordered the GDS-15 items into a two-tiered instrument, named the GDS-5/15, so that the full GDS-15 would only be administered to individuals who scored a 2 or greater on the initial GDS-5 items[37].

Many brief forms of the GDS have been compared to a single-item depression screen. For example, D'Ath *et al*.[27] created three versions of the GDS containing 10 items, 4 items, or 1 item ('Do you feel that your life is empty?'). While the 10-item form performed well using either 2/3 or 3/4 cut-off scores, the 4- and 1-item versions had low sensitivity and specificity. Hoyl *et al*.[34] found a single-item depression screen ('Do you often feel sad or depressed?') performed significantly worse than the 15- and 5-item GDS, with a sensitivity of 85% and specificity of 65%. Likewise, a comparison of different versions of the GDS in a Dutch population found the diagnostic value of 30-, 15-, 10- and 4-item scales did not differ significantly; however, the 1-item version performed no better than chance[38]. Almeida and Almeida[39] determined the 15- and 10-item scales were good screening instruments for depression in a Brazilian population, but cautioned against using 4- and 1-item forms because of low reliability and failure to show severity of depressive episodes.

Nursing Home Forms

A 12-item GDS was created for use with individuals living in residential care settings, including those with cognitive impairment (GDS-12R)[40]. During administration of the longer GDS in residential care facilities, interviewers found difficulties with a few of the items that appeared irrelevant or ambiguous to residents (e.g. 'Do you prefer staying in rather than going out and doing new things?'). Removal of these items increased internal reliability from 0.76 to 0.81, with no significant difference in internal reliability for those with cognitive impairment. A cut-off score of 4/5 maximized both sensitivity and specificity of the GDS-12R and was suggested for research purposes. A cut-off of 3/4 was suggested for clinical use[40].

Similarly, Jongenelis *et al*.[41] developed a version of the GDS that would be more user-friendly for nursing home residents. Clinical experts (a psychologist, a physician and a nurse) reviewed and rated the usefulness of the items of the GDS-15, eliminating seven items that were presumed to be offensive or confusing to nursing home residents. The eight-item instrument demonstrated high internal consistency (alpha coefficient of 0.80) with equal sensitivity (96.3%) and greater specificity than the GDS-15 (71.7% versus 63.3%) at a cut-off point of 2/3. They concluded that although the GDS was created for older adults, it was not necessarily designed for frail nursing home residents and alternate versions perform better with this specific population[41].

Collateral Forms

Nitcher *et al*.[42] created a 30-item Collateral Source Geriatric Depression Scale (CS-GDS) by simply changing the pronouns from *you* to *they* on the original GDS items. Patients with cognitive functioning ranging from normal to moderate dementia and an informant with extensive personal knowledge about the patient completed a self-report version of the GDS-30 and the CS-GDS respectively. Informants reported a higher frequency of symptomatic responses for all symptoms, but both versions were consistent with an independent diagnosis of depression. Correlations between the CS-GDS and the GDS varied by familial relation, ranging from 0.55 for sons to 0.32 for daughters-in-law. A cut-off score of 21 maximized sensitivity and specificity (both at 68%). In addition, the CS-GDS has been shown

to maintain adequate reliability and validity when administered via telephone, using a cut-off score of 19[43].

Brown and Schinka[44] developed a 15-item informant version of the GDS (GDSI-15) for use as an adjunctive measure to self-report versions of the GDS or as an independent measure of depression. Cognitively intact older adults and an informant completed a self-report version of the GDS-30 and the 30-item CS-GDS, respectively. Item characteristics for all 30 items of the CS-GDS were examined; the same items used in the original version of the GDS-15 were found to have the best scale characteristics for the shortened informant version. Consistent with findings from the CS-GDS, informant scores were significantly higher than patient scores and had a 0.55 correlation with the self-report GDS-15. A cut-off score of 5 for the GDSI-15 was found to be optimal[44].

USE WITH SPECIAL POPULATIONS

Long-Term Care

The GDS has been shown to be a reliable and valid instrument for identifying depressed nursing home residents[8,45,46]. Abraham *et al*.[23] demonstrated that the factor structure of the GDS represents six common facets of depression in nursing home residents: life dissatisfaction, dysphoria, hopelessness/decreased self-attitude, rumination/anxiety, social withdrawal/decreased motivation, and decreased cognition.

Compared to a visual analogue scale, which required participants to mark their level of depression on a line, the GDS was better able to predict ratings of depression by a psychologist, particularly with residents with better cognitive functioning[47]. These researchers slightly modified four items of the GDS to be tailored to nursing home residents. Heiser[48] found the GDS was better at detecting depression in nursing home residents than the Minimum Data Set.

Targeting the concern of nursing home residents being too frail to complete a multiple item scale, Jongenelis *et al*.[49] evaluated the diagnostic accuracy of the GDS (30-, 15-, 12-, 10-, 5-, 4- and 1-item versions) among nursing home residents. Scales with greater than or equal to four items were useful for screening depression, but scales with lower numbers of items had less specificity. That is, scales with 4 items were able to detect major depression, but 10 items were necessary to effectively detect milder depression.

In a similar study, researchers[50] examined various versions of the GDS (30-, 15- and 8-item) and compared them to the Montgomery Asberg Depression Rating Scale (MADRS)[51]. Using the same data set utilized in the study by Jongenelis *et al*.[41] mentioned previously, not surprisingly, the authors found a similar pattern of results from the various forms of the GDS. They found the GDS was preferable to the MADRS due to the ease of administration; however, the MADRS, a longer instrument, was superior to all GDS versions in detecting depression in nursing home residents.

Cognitive Impairment

Several studies suggest that the accuracy of the GDS decreases as the level of cognitive impairment increases[29,47,52–54]. The majority of these authors (with the exception of Burke *et al*.[52]) suggest that the GDS can be used with older adults with mild to moderate cognitive impairment. A more preferable type of screen may involve the reporting of a collateral source such as the Cornell Scale for Depression in Dementia[54] (CSDD) or the informant versions of the GDS. Some authors[54,55] propose shifting the cut-off score (between 4 and 6) when using the GDS with a cognitively impaired individual.

Primary Care

A large study[56] of older adult primary care patients found the GDS to be reliable and valid in this population. A systematic review[57] of nine studies of the GDS in primary care settings found high sensitivity (ranging from 79% to 100%) and adequate specificity (ranging from 67% to 80%). Bijl *et al*.[31] examined the cut-off score of 5 in primary care patients and reported adequate sensitivity (79%) and specificity (67%). These positive results suggest that use of the GDS provides reliable and accurate depression screening in primary care settings[58].

Oldest-Old Individuals

De Craen *et al*.[59] examined the sensitivity and specificity of the GDS-15 in adults aged 85 years and older. Results indicated a low cut-off point (2/3) had high sensitivity (100%) and adequate specificity (68%). Findings from another study with adults aged 85 and older demonstrated that the GDS was able to detect increases in depressive symptoms after negative life events such as the loss of a spouse[60]. This suggests that the GDS is an appropriate measure to use for assessing longitudinal changes in older adults. A comparison between the GDS-15 and the General Health Questionaire-12[61] (GHQ-12) in Chinese old-old adults found the GDS-15 had higher reliability and higher sensitivity[62].

Ethnic Groups

The GDS has been evaluated in several different ethnic groups both within and outside of the US, with mixed results. It has shown to be a satisfactory screening tool in Chinese[63], Portuguese[64], Iranian[65] and Japanese American older adults[66]. Results from a study comparing Korean and American older adults indicated the GDS-SF had good reliability with both groups, but the underlying factor structure differed[67]. Costa and colleagues[68] found that reliability was good for the GDS, but it did not perform better than the GHQ-12[61] and neither was an ideal screening tool for Brazilian older adults even with adjustment of cut-off scores.

SUMMARY

Use of the GDS for the screening and detection of depression among older adults is widespread. As with any psychological measure, test performance of the GDS varies depending upon population characteristics (e.g. individuals with different levels of cognitive functioning). Brief forms of the GDS, as well as versions designed for specific populations (e.g. residents in nursing homes), detect depressive symptoms as well as, if not better than, the original GDS. Further research is needed to explore the factor structure of the GDS. The GDS remains a popular and well-validated screening tool for diverse older adult clinical and research settings.

Dementia Care Mapping

Dawn Brooker

University of Worcester Association for Dementia Studies, Institute of Health and Society, University of Worcester, Worcester, UK

INTRODUCTION

Dementia Care Mapping (DCM)[1,2] is an observational tool that has been used in formal dementia care settings such as hospital wards, care homes and day care facilities since 1991. Its main uses are:

- at an individual clinical level to elucidate situations where an individual is displaying distress behaviours or to improve well-being;
- as an instrument of practice development for shifting the culture of care to one that is person-centred rather than task focused;
- as a tool in research to assess quality of care and quality of life.

DCM is grounded in the theoretical perspective of a person-centred approach to dementia care. Person-centred care values all people regardless of age and health status, is individualized, emphasizes the perspective of the person with dementia and stresses the importance of relationships[3]. DCM originated from the pioneering work of the late Professor Tom Kitwood in person-centred approaches to dementia care. In his final book[4] Kitwood described DCM as: 'a serious attempt to take the standpoint of the person with dementia, using a combination of empathy and observational skill' (p. 4).

THE DEVELOPMENT OF DCM

Tom Kitwood and his PhD student Kathy Bredin developed the original tool through ethological observations of many hours in nursing homes, hospital facilities, and day care facilities in the United Kingdom[1]. It was designed primarily as a tool to develop person-centred care practice over time with data being fed back to care teams who could then use it to improve their practice. The original development work is not available in the public domain[5].

DCM has been through a number of changes since its inception. From 1991 to 1997, the first publically available version, DCM 6th edition, was used. This was revised based on feedback from practitioners in the UK resulting in the 7th edition being launched in 1997. The unexpected death of Tom Kitwood in 1998 created a need to have more formalized structures around DCM. The role of strategic lead for DCM was created at the University of Bradford in 2001 which the author fulfilled until 2009. The formal network of DCM trainers and the DCM International Implementation Group had their inaugural meetings in 2001 and 2002 respectively. DCM underwent a further major revision 2002–2004 drawing on the international perspectives. In 2005 DCM 8 was launched. The revised tool (DCM 8) was validated against DCM 7th edition[6].

The DCM tool is only available through undertaking a registered courses delivered by licensed trainers using standardized training methods. Those undertaking the basic DCM training course (3–4 days duration) do not need any formal qualification although the complexity of the method requires reasonable numeracy and literacy skills. DCM is not aligned to a particular discipline. There are a number of different levels of training that have developed over the years to equip users of DCM at a variety of different levels.

DCM training has been available in the UK since 1991. The worldwide spread of DCM has been remarkable. Tom Kitwood taught the first DCM course outside the United Kingdom in the United States in 1998. In the same year, the materials were translated into German and training commenced there. Australia ran its first course in 2001. The Danish translation and the first course in Denmark took place in 2002. Training has been available in Switzerland with support from Germany since 2002. The materials were translated into Japanese and the first basic course took place in Japan in 2003. Translation into Korean occurred a couple of years later. Spanish and Catalan translations were completed in 2009. At the time of going into press the translations into Flemish, Dutch and Italian are being done. Strategic partnerships exist between the University of Bradford and organizations in all these countries to ensure that training in DCM adheres to international quality standards. At time of going into press there are approximately 8000 people trained at basic level worldwide.

The DCM International Implementation Group is an association of all those countries where DCM training is offered or who are preparing to offer training. Its purpose is to consider the training, care practice and research associated with DCM drawing on expertise from around the world and ensuring a common set of quality standards.

DCM has grown in popularity over the years. Many practitioners have used DCM in many different situations and continue to do so. This may be because DCM appears to provide a vehicle for those wishing to systematically move dementia care from primarily a custodial and task-focused model into one that focuses on the well-being of people living with dementia. There are very few other tools that purport to do this or that have been shown to be effective in this endeavour. Whether it has had a sustained impact on practice is difficult to assess. The investment of time and effort in undertaking training and sustaining mapping cycles can be a barrier in practice.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

There has been no survey of how many care providers actually use DCM in practice. A survey undertaken some years ago indicated that around 50% of people undertaking the training actually used mapping in practice although many more reported a beneficial impact on their own practice of undertaking the training[7].

THE DCM TOOL

During a DCM evaluation, an observer (mapper) tracks five people with dementia (participants) continuously over a representative time period. Observation takes place in communal areas of care facilities. Guidelines are provided during training about how to observe in a way that does not increase the ill-being of people with dementia. After each 5-minute period (a time frame) two types of codes are used to record what has happened to each individual. The behavioural category code (BCC) describes one of 23 different domains of participant behaviour that has occurred.

Based on behavioural indicators, a judgement is also made of the relative state of affect and engagement experienced by the person with dementia. This is called a mood/engagement value (ME value) and is rated on a scale ranging from −5 (extreme negative state) to +5 (extreme positive state. ME values are averaged over the mapping period to arrive at a well- and ill-being score (WIB score). This provides an index of relative well-being for a particular time period for an individual or a group. Being in a state of well-being is defined as experiencing a preponderance of positive over negative experiences and feelings over a period of time. Therefore, for a person with dementia, experiencing relative well-being would relate to experiencing more of the indicators of well-being over a period of time than the indicators of ill-being.

Personal detractions (PDs) and personal enhancers (PEs) are recorded whenever they occur. PDs are staff behaviours that have the potential to undermine the personhood of those with dementia. These are described and coded according to type and severity. PEs are staff behaviours that are thought to enhance personhood. These are described and coded according to type and the degree to which it is thought they enhance personhood.

From published papers on DCM[8] there is consistency of what is reported in DCM data. In long-term care facilities, behaviour codes indicating social interaction, passive watching, and eating and drinking appear as the most frequent codes almost without exception. Codes for walking and sleeping appear as the next most frequently cited. In facilities with lower well-being scores, withdrawn and repetitive behaviours are frequently seen. In facilities with higher well-being scores, creative activity, physical exercise and general leisure activities occur more frequently. Generally, a greater diversity of behaviour and higher well-being scores are reported in day-care facilities. These scores both increase generally during periods of therapeutic activity. Higher levels of personal detractions occur in those facilities with the lowest well-being scores.

LENGTH OF OBSERVATION PERIOD

Most of the published studies here have mapped continuously for 6 hours, although those using DCM for practice-development purposes mapped for longer[9–12]. It also is evident from practice that useful insights can be gained from mapping for just a couple of hours[13]. Mapping an individual at a particular time of day may throw light on the causes and triggers of distress behaviours. Length of maps will depend, in part, on the reason for mapping. Sometimes mapping is spread over a couple of days. This can have the advantage of sampling a greater amount of variety of staffing situations but some of the continuity may be lost at an individual participant level. For research purposes, a statistically significant correlation between the hour prior to lunch and a 6-hour map on all their key indicators at the group level has been described[14]. It is likely that there would be more variation for individual level data.

Maps above 4 hours' duration have been reported to correlate well with longer maps but that those below 4 hours do not[6]. When comparing maps over time it is important to try to map for the same time period to ensure that the same opportunities are available for activity on both occasions. Mapping over a meal time will increase levels of activity for example. So if on the first occasion of mapping, only one meal time is observed it is important to ensure only one meal time is observed on the second occasion.

WHAT DCM EVALUATES

The DCM tool provides in-depth detail about the following:

- variations in individual and group care facility levels of well-being and ill-being;
- how people with dementia spend their time and how this is linked to relative well- and ill-being; and
- staff behaviour that promotes personhood and staff behaviours that undermine personhood.

DCM tells us about the quality of care as it impacts on the quality of life of those living in dementia care settings. Within Kitwood's writing was the assumption that, for people with dementia, well-being is a direct result of the quality of relationships they enjoy with those around them. The interdependency of the quality of the care environment to the relative quality of life experienced by people with dementia is central to person-centred care practice. In placing DCM in the taxonomy of measures of quality of life and quality of care, DCM attempts to measure elements of both. In its BCCs and WIBs, DCM measures relative well-being, affect, engagement and occupation, which are important elements of quality of life. Through PDs and PEs, DCM records the quality of care practice as it promotes or undermines the personhood of those being mapped.

In terms of concurrent validity with other measures there is some evidence that DCM is related to indicators of quality of care[9,15] and with proxy quality-of-life measures[14,16]. With persons with more advanced dementia it is difficult to ascertain whether there is a correlation between DCM scores and direct quality-of-life interviews. One study[16] did not find a correlation on a subsample with participants with mild cognitive impairment. In a multi-method study[17] it was noted that during interviews, people with dementia rated their quality of life as better than their DCM scores would suggest.

DCM measures something similar to proxy measures and other observation measures. It is somewhat different from other quality-of-life and quality-of-care measures in that it attempts to measure elements of both. In training to use DCM, mappers are explicitly taught to increase their empathy for the viewpoint of the person with dementia and to use this during their coding decisions.

RELIABILITY OF DCM

In research papers it appears that a reasonable agreement between trained mappers can be achieved. Nineteen studies reported inter-rater

coding agreements ranging from 0.7 to 1.0, most reporting concordance coefficients of 0.8[8]. Mappers in routine practice are likely not to spend time ensuring that their inter-rater reliability is adequate. When many different mappers are engaged in mapping at different points in time, drifts in coding can have a significant impact on results[18] unless systematic checking is in place to prevent this. There are various ways in which reliability can be achieved in routine mapping[19].

Only one paper has reported on test–retest reliability on the same individuals a week apart[14]. There was satisfactory correlation between +3 and +5 ME values, overall WIB score and type of BCC. To date DCM data has only been published on DCM 7 data.

POPULATIONS THAT DCM IS USED WITH

DCM is used primarily with people with dementia living in long-term care settings. This covers a wide range of cognitive ability and dependence. There is evidence to suggest that level of dependency is correlated with DCM scores, specifically that low WIB scores are associated with high dependency levels[9,16,18]. However, this is not always the case[20,21]. The correlations between low WIB scores and high dependency may of course be related to a third factor of poorer quality of psychosocial care for people with dementia who have high dependency needs. In two studies where DCM was used in a systematic way to improve practice over time, the relationship between dependency and WIB scores disappeared as care quality improved[9,10]. DCM helps to focus care staff to consider the needs of those whose well-being is lowest, who are usually those with the greatest levels of dependency. Accordingly, DCM can help staff to refocus and adapt their care practices to better meet the needs of more dependent clients.

The evidence that dependency level skews DCM results is strong enough to suggest that a measure of dependency should be routinely taken alongside DCM evaluations so that the results can be scrutinized for this relationship.

Although DCM was originally developed in formal care services for people living with dementia, over the years it has also been used in services for people with learning disabilities[22] on general elderly care wards[23] and with people with Huntington's disease[24].

USING DCM TO IMPROVE THE QUALITY OF CARE

DCM lends itself well to improving well-being and quality of life for people with dementia at an individual care-plan level. The analysis of individual maps provides a lot of information about how to optimize an individual's well-being over the day. Small things that engender joy or distress, that are easy to miss as part of general care, become very clear in the process of mapping. This can be built upon to ensure that people have the opportunity to experience well-being more often.

At a group level, for example in the management of a hospital ward or nursing home, DCM can be used to improve the organization of care towards one that is person-centred rather than task-focused. An analysis of key events over the day – such as meal times or activity sessions or handovers – often reveals where changes can be made that will improve levels of well-being of the whole group of service users.

At a management level within care organizations, DCM data can help in decisions around skill mix, training needs and staff development. DCM sheds light on those skills that engender well-being. It can be useful in tailoring training and staff development programmes around specific examples from the lived experience within an organization.

An advantage of DCM is that it can be used over time to monitor change at all these levels, thus evaluating whether the changes have had an impact. DCM data can be analysed to monitor change over time at an individual resident level and at an organizational level. DCM data can be utilized to good effect in fulfilling a number of reporting requirements for commissioners and inspections.

USING DCM TO CHANGE THE CULTURE OF CARE

In 2001, an international 'think tank' of DCM practitioners came together to review their collective experience on DCM[25]. Their conclusions from practice were that DCM, used within an organizational framework that supported person-centred care, could improve levels of well-being, increase the diversity of occupation, and decrease the incidence of personal detractions. The published developmental evaluations although limited in number supports this assertion both for larger scale quality-assurance initiatives[9,10] and more in-depth developments in single establishments[12,26]. A recent Australian cluster-randomized control trial of DCM demonstrated that DCM improved levels of agitation and that the number of falls decreased in care homes that used DCM[27].

Using DCM to achieve culture change is not an easy or trivial process. It does not provide a quick fix solution. This fact needs to be engaged with by both staff and management teams prior to deciding to use DCM. DCM is unlikely to have a positive impact unless staff have the necessary knowledge and skills base to use the information it generates. Also, as DCM works through helping staff teams reflect on their practice to bring about quality improvements, mechanisms such as supervision, mentoring, governance and quality assurance groups need to be established at an organizational level for DCM to work effectively over a sustained period of time.

Bringing DCM into an organization as a driver for person-centred care practice is a major undertaking. It requires clear strategic and operational planning if there is to be a maximum return on investment. Many organizations spend over a year planning and ensuring they are prepared before embarking on their first DCM evaluation. The British Standards Institute have developed a Publically Accessible Specification[28] to provide health and social care organizations with comprehensive guidance to assist them in this process.

USING DCM IN RESEARCH

The University of Bradford maintains a DCM bibliographic database that contains all known publications on DCM (http://www.bradford.ac.uk/acad/health/dcm). It is updated by the Bradford Dementia Group with annual bibliographic searches on Medline, Cinahl, and Psychinfo using the terms 'DCM' and 'dementia care mapping' as well as personal correspondence from practitioners and researchers.

A review of the published literature on DCM[8] revealed a number of papers of variable quality dating back to 1995 that have used DCM in a research context. These were categorized into the following types:

1. Cross-sectional surveys: Ten papers reported DCM results across a number of different facilities, and the results either compared or pooled. An additional three papers used DCM to investigate the relationship between participants' characteristics and well-being and activity.

2. Evaluations of interventions: In a further ten papers DCM was used to evaluate the impact of various interventions including a number of non-pharmacological therapeutic interventions and a double-blind, placebo-controlled, neuroleptic discontinuation study[29].
3. Practice development evaluations: Six papers investigated the ability of DCM to develop practice over time by means of repeated evaluations.
4. Multi-method evaluations: Three articles reported using DCM as part of a multi-method evaluation of a single facility or service.

DCM was not designed to be a research tool. Careful consideration should be given in deciding whether DCM is fit for purpose given the specific topic under investigation. In terms of cross-sectional surveys, there are tools that may be more suited to this task that do not have the attendant time-consuming problems and specialist training associated with DCM.

DCM seems to be suited to smaller scale within-subjects or group comparison intervention evaluations, given that it appears to demonstrate discrimination on a variety of interventions. In multi-method qualitative designs, DCM appears to enrich the data derived from proxy and service-user interviews and focus groups. DCM provides an opportunity to represent a reflection on what could be the viewpoint of service users who are unable to participate fully in interviews.

What is clear is that BCCs do not measure real-time estimates of different types of behaviour[18]. Because of the rules of coding in DCM, it will underestimate the occurrence of socially passive and withdrawn behaviour compared with data collected with continuous time sampling. Researchers interested in looking at withdrawn and passive behaviour might be better advised to use another tool. It is worthy of note, however, that despite this, three studies[21,30,31] found DCM discriminated between groups on social withdrawal in their evaluations. There are a number of modifications to DCM that might prove useful when using DCM in research[32].

CONCLUSIONS

DCM has a long history and it has changed over time. It has been taken up by practitioners in many countries who wish to improve the quality of care for people with dementia. It can be used on an individual client level or to improve group care. It requires specialist training to use and it takes careful planning to ensure that it is used to good effect. It has been utilized as a research tool for a variety of purposes.

DCM's advantages are that it is standardized, quality controlled, international, responsive to change, multidisciplinary and has an increasing research base. Its disadvantages are that it is resource heavy in terms of its training and administration. DCM holds a unique position in relation to quality of life in dementia care, being both an evaluative instrument and a vehicle for practice development in person-centred dementia care.

INTRODUCTION AND OVERVIEW OF DEMENTIA STAGING

Dementia is a progressive pathological process extending over a period of many years. Clinicians and scientists have long endeavoured to describe the nature of dementia progression. Such descriptions have generally been encompassed within two broad categories: global staging and more specific staging, sometimes referred to as axial or multi-axial staging. A comparison of the major current dementia staging systems with the most widely used mental status assessment in Alzheimer's disease, the major cause of dementia, is shown in Figure 31.1.

This Figure illustrates some of the major potential advantages of staging. These advantages include: (i) staging can identify premorbid, but potentially manifest conditions which may be associated with the evolution of subsequent dementia, such as subjective cognitive impairment, a condition which is not differentiated with mental status or psychometric tests; (ii) staging can be very useful in identifying subtle predementia states, such as mild cognitive impairment (MCI), wherein mental status assessments and psychometric tests, while frequently altered, are generally within the normal range and, consequently, are not reliable markers[17–19]; and (iii) staging can track the latter 50% of the potential time course of dementias such as Alzheimer's disease (AD), when mental status assessments are virtually invariably at bottom (zero) scores[20]. Furthermore, apart from their utility in portions of dementia where mental status and psychometric assessments are out of range, or insensitive, there are clear data indicating that staging procedures can more accurately and sensitively identify the course of dementia in the portion of the condition which is conventionally charted with mental status assessments. This latter evidence comes from longitudinal investigation of the course of AD[9], pharmacological treatment investigation of AD[21–23], and study of independent psychometric assessments of AD[24]. For example, longitudinal study has demonstrated that the Functional Assessment Staging procedure (FAST)[5] and the Global Deterioration Scale (GDS)[3] accounted for more than twice the variance in the course of AD over a five-year mean interval, compared to the Mini-Mental State Examination (MMSE)[7,9]. When employed together, the GDS and the FAST staging procedures explained nearly three times the variance in the temporal course of AD compared to the MMSE (i.e. change in measure versus change in time), with the MMSE encompassing only 10% of temporal change variance and the GDS and FAST together encompassing 28% of the temporal change variance[9]. In pharmacological studies, staging procedures have frequently demonstrated sensitivity to effects of the interventions in pivotal studies where mental status assessment has not shown a significant effect. This superiority in the demonstration of pharmacological treatment efficacy for staging procedures over mental status assessment has been seen for both classes of currently approved pharmacotherapeutic agents; that is, for *N*-methyl-D-aspartate (NMDA) receptor antagonist treatment decreasing glutamate-induced excitotoxicity, and for cholinesterase inhibitor treatment enhancing cholinergic brain functioning. For example, a pivotal, multicentre trial associated with worldwide approvals of memantine treatment for AD found a robust statistically significant effect of the memantine, NMDA receptor antagonist treatment with the FAST staging procedure, but no significant effect was observed with the MMSE evaluation[21]. Similarly, in a pivotal study associated with worldwide approval of the cholinesterase inhibitor, rivastigmine, it was found that low dose treatment (1–4 mg/day) was associated with significant improvement on the GDS staging procedure, but not on the MMSE assessment[22]. Additionally, study of predominantly institutionalized persons with more advanced AD in the latter portion of the MMSE range (i.e. with MMSE scores of 10 or below), with specially designed psychometric procedures for advanced AD patients, have clearly shown that the FAST staging procedures can robustly track progressive change in these more advanced AD patients, in conjunction with special psychometric procedures, whereas the MMSE does not sensitively change in this more severe range[24]. Another potential advantage of staging procedures in comparison with mental status

[a] Stage range comparisons shown between the CDR and GDS/FAST stages are based upon published functioning and self-care descriptors.

[b] Numerical values represent time in years.

For GDS and FAST stage 1, the temporal values are subsequent to the onset of adult life.

For GDS and FAST stage 2, the temporal value is prior to onset of mild cognitive impairment symptoms.

For GDS and FAST stage 3 and above, the values are subsequent to the onset of mild cognitive impairment symptoms.

In all cases, the temporal values refer to the evolution of Alzheimer's disease pathology.

All temporal estimates are based upon the GDS and FAST scales and were initially published based upon clinical observations in Reisberg, *Geriatrics* 1986; **41**(4): 30–46[8]. These estimates have been supported by subsequent clinical and pathological cross-sectional and longitudinal investigations (e.g. Reisberg *et al.*, *Int Psychogeriatr* 1996; **8**: 291–311[9]; Bobinski *et al.*, *Dementia* 1995; **6**: 205–10[10]; Bobinski *et al.*, *J Neuropathol Exp Neurol* 1997; **56**: 414–20[11]; Kluger *et al.*, *J Geriatr Psychiatry Neurol* 1999; **12**: 168–79[12]; Prichep *et al.*, *Neurobiol Aging*, 2006; **27**: 471–81[13] ; Reisberg and Gauthier, *Int Psychogeriatr* 2008; **20**: 1–16[14]; Wegiel *et al.*, *Acta Neuropathol* 2008; **116**: 391–407[15]; Reisberg *et al.*, *Alzheimers Dement* 2010; **6**(1): 11–24[16]).

The spacing in the figure is approximately proportional to the temporal duration of the respective stages and substages, with the exception of GDS and FAST stage 1, for which the broken lines signify an abbreviated temporal duration spacing for this normal adult condition which lasts approximately 30 to 50 years.

[c] MMSE scores are approximate mean values from prior published studies.

[d] For typical adult psychometric tests.

Figure 31.1 Typical time course of normal brain ageing; mild cognitive impairment associated with Alzheimer's disease and the dementia of Alzheimer's disease. AD, Alzheimer's disease; CDR, Clinical Dementia Rating[1,2]; GDS, Global Deterioration Scale[3,4]; FAST, Functional Assessment Staging[5,6]; MMSE, Mini-Mental State Examination[7]; Mod AD, moderate Alzheimer's disease; Mod sev AD, moderately severe Alzheimer's disease. or psychometric assessment of AD and other dementias, is in identifying the management concomitants of severity assessments[25,26]. Staging procedures have also been successfully applied postmortem to retrospectively assess the diagnoses (i.e. AD or other non-AD dementia) of a diverse assortment of dementia-related cases available for 'brain banking', but on which no antemortem clinical data were available[27]. Similarly, postmortem retrospective staging procedures have been successful in establishing remarkably robust clinicopathological correlations in longitudinally studied AD cohorts[10,11,15,20].

GLOBAL STAGING

Efforts to globally stage progressive dementia can be traced back at least to the early nineteenth century when the English psychiatrist, James Prichard, described four stages in the progression of dementia: '(1) impairment of recent memory, (2) loss of reason, (3) incomprehension, (4) loss of instinctive action'[28,29]. More recently, the American Psychiatric Association's[30] Diagnostic and Statistical Manual of Mental Disorders, 3rd edition (DSM-III) recognized three broad stages in its definition of primary degenerative dementia[30]. Subsequently, in 1982, two more detailed global descriptions of the progression of dementia were published. One of these, the Clinical Dementia Rating (CDR) scale[1], describes five broad stages from normality to severe dementia. The other, the Global Deterioration Scale (GDS)[3], identifies seven clinically recognizable stages from normality to most severe dementia of the Alzheimer type. A recently published abridged version of the GDS is shown in Table 31.1[31].

Complete versions of the CDR and the GDS scales can be found in the literature (e.g. for the original CDR, references[1,32] and for the CDR 'current version', reference[2]; for the GDS, reference[3], and for the tabular format of the GDS, reference[4]). These two global staging instruments, the GDS and the CDR, are generally compatible except that the GDS is more detailed and specific and identifies two stages which the CDR staging does not.

One of these stages identified by the GDS staging procedure but not by the CDR is a stage in which subjective complaints of cognitive deficit occur in the absence of clinically identifiable symptoms (GDS stage 2). These subjective complaints are now recognized as occurring very commonly in older persons (e.g.[33–35]). Although this stage of subjective complaints continues to be identified only by the GDS staging system, studies have indicated that persons with these complaints are at increased risk for subsequent overt dementia (e.g.[12,16,36–38]). A distinct diagnostic terminology, namely, 'subjective cognitive impairment' (SCI), has recently been suggested for otherwise healthy older persons with these symptoms who are free of overtly manifest symptoms of mild cognitive impairment (MCI) or dementia[14,39]. A recent study, which is apparently the first to systematically examine the prognosis of GDS stage 2, SCI persons, in comparison with persons with no cognitive impairment (NCI, GDS stage 1), from the perspective of the subsequent development of MCI or dementia, has indicated the true morbidity associated with this SCI condition. Over a mean seven-year follow-up, the risk of subsequent decline to MCI or dementia was 4.5-times greater in persons with SCI (GDS stage 2) than in persons who are free of these subjective complaints, after controlling for differences in age and other demographic variables, as well as follow-up time[16]. Physiological differences between otherwise healthy older persons with these subjective complaints of cognitive impairment and similarly aged persons without these symptoms (i.e. between GDS stage 2 and GDS stage 1 subjects) have now been reported for brain metabolism and cortisol levels[40,41]. Longitudinal studies are also presently confirming[13,14] a previously estimated 15-year duration[8] for this GDS stage 2 condition, identifying subjective impairment only, in the evolution of brain ageing and AD pathology.

The GDS staging measure and associated assessments from the GDS staging system also identify a stage, GDS stage 3, for which the terminology mild cognitive impairment (MCI) was originally coined in 1988[42]. This GDS stage 3 is described, in part, as a stage in which: (i) the 'earliest clear-cut deficits' become manifest; (ii) 'objective evidence of memory deficit is obtained only with an intensive interview', and (iii) there is 'decreased performance in demanding employment and social settings'. Many of the early observations with respect to the nature of MCI were made using this GDS stage 3 definition (see[17] for a review), and the GDS 3 definition of MCI remains compatible

Table 31.1 Abridged global deterioration scale

Stage 1: NCI. No subjective memory deficit (no cognitive impairment); no problems with activities of daily living.

Stage 2: SCI. Subjective cognitive impairment (subjective memory and/or other cognitive complaints): observations, sometimes accompanied by complaints, of being forgetful, such as of difficulties with recall of names, and/or of misplacing objects.

Stage 3: MCI. Earliest subtle deficits (mild cognitive impairment): difficulties often noted at work; may have become lost; may have misplaced a valuable object.

Stage 4: Mild dementia. Clear deficits on clinical examination (moderate cognitive impairment): decreased knowledge of personal and/or current events; often difficulties with finances or shopping or meal preparation or travel.

Stage 5: Moderate dementia. Can no longer survive independently in the community without some assistance (moderately severe cognitive impairment): difficulty with recall of some important personal details (e.g. address, names of one or more important schools attended); may require cueing for activities for daily living.

Stage 6: Moderately severe dementia. Largely unable to verbalize recent events in their life (severe cognitive impairment): may forget name of spouse; incontinence develops as this stage progresses; requires increasing assistance with activities for daily living such as dressing and showering. Increased behavioural problems (e.g. agitation) or other personality problems are common.

Stage 7: Severe dementia. Few intelligible words or no verbal abilities (very severe cognitive impairment): the ability to walk is lost as this stage evolves. Later, basic capacities such as the ability to sit up independently, to smile, and to move and/or to hold up the head independently are progressively lost.

2009 abridged version. Original abridged version published in *Canadian Medical Association Journal* 2008; **179**(12): 1281. Modified from Reisberg B, Ferris SH, de Leon MJ *et al*. The global deterioration scale for assessment of primary degenerative dementia. *Am J Psychiatry* 1982; **139**: 1136–9.

with the current international consensus definition of MCI, published by Winblad *et al*. in 2004[19]. The CDR staging methodology identifies a CDR 0.5 stage originally termed 'questionable dementia', which is somewhat broader in scope than the MCI entity, and which encompasses some of early (mild) dementia, as well as the MCI clinical timeframe.

At the other end of the pathological spectrum, the CDR does not identify any stage beyond that in which dementia patients 'require much help with personal care' and are 'often incontinent'. In contrast, the GDS identifies a final seventh GDS stage in which patients are already incontinent and over the course of which language and motor capacities are progressively lost. Importantly, the CDR does not stage or substage the latter portion of the dementia of AD, representing nine or more years of potential life and continuing decline for these patients (see Figure 31.1). This absence of attention to the nature of severe dementia clinical changes in the CDR staging methodology may add to the neglect of persons with more advanced dementia and, in particular, the dementia of Alzheimer's disease. In marked contrast with the CDR, the GDS identifies two stages (GDS stages 6 and 7), corresponding to the CDR 3 stage range. Additionally, the other elements of the GDS staging system, described below, chart this latter portion of the dementia of AD in detail. For example, the FAST scale (described below) identifies eight substages corresponding to the CDR stage 3, 'severe dementia' range.

In addition to the range differences discussed above and differing staging numbers, the CDR scale and the GDS staging scale also have different procedures for scoring. The original CDR versions used a 'sum of boxes' procedure, with means of the sum of boxes in six CDR assessment categories, i.e. (1) Memory, (2) Orientation, (3) Judgement and Problem Solving, (4) Community Affairs, (5) Home and Hobbies, and (6) Personal Care. However, current scoring procedures for the CDR are much more complex and more weighted towards the memory category. The GDS staging procedure simply requires the choice of the most appropriate global stage, based upon cognition and functioning. GDS staging descriptors acknowledge common emotional concomitants of the stages; however these are not employed in the stage selection. The comparisons shown in Figure 31.1 between the CDR and the GDS/FAST staging categories and other assessment procedures are based upon the CDR functioning and self-care descriptions.

In summary, with respect to range, the GDS staging and associated measures from the GDS Staging System, are much more detailed at both ends of the pathological spectrum of brain ageing and progressive dementia than the CDR staging. As discussed, the GDS staging identifies an SCI stage prior to the development of mild cognitive impairment, which the CDR staging does not refer to. Also, the GDS staging procedures are more rigorous in the definition of MCI and the separation of MCI from early dementia. In the severe end of the dementia spectrum, the GDS staging and the associated GDS Staging System, described in greater detail in the next section, are much more detailed than the CDR.

Staging procedures have been shown to be valid and reliable methods for assessing the magnitude of pathology in AD and related dementing conditions. This validity and reliability is illustrated in this brief review for the GDS, the most detailed and explicit staging procedure.

The validity of the GDS has been demonstrated in several ways. Cross-sectional studies have confirmed the consistency of the ordinal sequence and the optimal weighting of the hierarchically sequenced items embodied in the GDS stages in ageing and progressive Alzheimer's disease (AD)[42–45]. Thus, the specific impairments characteristic of each stage almost always follow the impairments described for the previous stage. Also, the grouping of impairment characteristics within stages appears to be optimal.

For example, naturalistic study has supported the identification of staging phenomena, largely identical to the GDS stages, by independent layperson observers. In this study[44], a 30-item questionnaire derived from the GDS was completed by a relative or caregiver for each of 115 patients with varying degrees of dementia. Principal components analysis was used to combine the items into a single composite scale that more reliably represents distances between the 30 clinical manifestations along the continuum of cognitive decline. In the study it was found that 'the scale scores for the clinical manifestations were observed to cluster into relatively discrete groups, suggesting naturally occurring stages or phases. Objective cluster analysis methods further confirmed the presence of distinct transitions along the cognitive decline continuum.' It was concluded that the 'utility of empirically derived scale values in staging the course of primary degenerative dementia is suggested.'

The relationship between the GDS stages and mental status assessments, other dementia assessments, scores on cognitive tests and other objective tests and *in vivo* assessments of brain change in ageing and progressive dementia have been studied in considerable detail[3,42]. These studies have indicated significant correlations between all of these measures of dementia severity and the GDS stages. However, the strongest relationships have been observed between comprehensive dementia assessments such as the Mini-Mental State Examination (MMSE)[7] and the progression of dementia on the GDS[42]. The GDS also correlates well with independent physical markers of AD progression such as changes in neurological reflexes[46]. Thus the construct validity of the GDS has been well substantiated.

At least six separate studies have examined the reliability of the GDS[47–52]. Reliability coefficients have ranged from 0.82 to 0.97 in these studies using disparate procedures in diverse settings. These studies have indicated that the GDS is at least as reliable as any other instruments upon which clinicians rely, such as the MMSE. In a reliability study in a nursing home setting[51], the GDS was found to be somewhat more reliable than the MMSE. Importantly, GDS staging has also been shown to be a reliable procedure when assessed using a telephone format[52].

Global staging scales such as the GDS have certain important advantages in dementia assessment. First and foremost, these scales are strongly anchored to the clinical symptoms, behaviour and functional changes in progressive degenerative dementia, and particularly those of Alzheimer's disease. Consequently, they discourage misdiagnosis. Unlike many mental status and other dementia test instruments, global stages are relatively stable over time and relatively resistant to practice effects. Equally importantly, global staging instruments are minimally influenced by educational background and socioeconomic status, whereas mental status and similar assessments are strongly influenced by such factors. Also, as previously noted, global staging, and in particular the GDS, covers the entire range of pathology in central nervous system (CNS) ageing and progressive dementia, whereas, for example, mental status assessments and most psychometric tests entirely fail to distinguish GDS stages 1 and 2 (i.e. NCI and SCI). Occasionally, patients may display GDS stage 3 symptomatology (MCI) and still score a perfect 30 on the MMSE. Uncommonly, dementia patients may display GDS stage 4 symptomatology (mild dementia), and still score a perfect 30 on the MMSE. Much more commonly, patients may display the clear-cut dementia symptomatology characteristic of GDS stage 4 and achieve

MMSE scores which are near perfect or within the so-called 'normal' range. At the other end of the pathological spectrum, most patients at GDS stage 6 (moderately severe dementia) achieve only bottom scores on traditional psychometric tests. Over the entire course of the GDS 7 (severe dementia) stage, most patients attain only zero (bottom) scores on the MMSE. The GDS, however, describes a final seventh stage, over the course of which patients may survive for many years.

AXIAL AND MULTI-AXIAL STAGING

The observation that the progression of dementia pathology is accompanied by progressive changes in more specifically defined processes, termed 'axes' has resulted in efforts to stage dementia in terms of those processes. Generally, axial staging has attempted to exploit progressive changes in cognition or functioning, although attempts have also been made to hierarchically stage progressive mood and behavioural changes, progressive motoric changes and progressive neurological changes, as well as other observable concomitants of dementia. These efforts can be traced back more than 40 years to the work of de Ajuriaguerra and associates[53–55]: Swiss investigators who were strongly influenced by Piaget's investigations of the stages of normal infant and childhood development. More recently, Cole and co-workers in Canada employed this approach in their Hierarchic Dementia Scale[56–58]. A similar approach was pursued, apparently independently, by Gottfries and associates in Sweden[59].

The CDR staging has a 'sum of boxes' approach which employs a hierarchical, multi-axial-like procedure[60], or, more recently, a modified, multi-axial-like procedure[2]. Based upon the seven-stage GDS, Reisberg and associates also described axial and multi-axial concomitants of progressive dementia[61,62] in a measure termed the Brief Cognitive Rating Scale (BCRS). Each of the BCRS axes has been enumerated to be optimally concordant with the corresponding GDS stages. Ultimately, the functional component of these BCRS axes resulted in the most detailed hierarchical staging of progressive dementia proposed to date, a 16-stage and substage measure of progressive functional change. This latter assessment is termed Functional Assessment Staging or FAST[5] (Table 31.2).

Like the BCRS axes, the FAST has been enumerated to be optimally concordant, in dementia of the Alzheimer type, with the corresponding GDS stages, discussed above. The FAST can be used as an independent staging measure of the magnitude of dementia pathology, or as part of the GDS Staging System[45]. Advantages of the FAST staging procedure include the following: (i) the FAST is capable of describing the entire course of brain-ageing associated, cognition-based functional changes and subsequent dementia of the Alzheimer type, ordinally (i.e. hierarchically), in unprecedented detail; (ii) the scale can assist in differentiating dementia of the Alzheimer type from other dementia processes[8,65,66]; (iii) the scale can assist in identifying premature and potentially remediable functional changes in AD patients (e.g. premature loss of ambulation due, for example, to the side effects of medication)[8,65,66]; (iv) the scale permits the retrospective as well as prospective examination of the temporal course of AD[10,11]; and (v) the scale is the only current measure which permits the detailed staging of severe AD[20,23,24,43]. A strong relationship between this FAST procedure and comprehensive cognitive assessments such as the MMSE has long been noted[64,67]. However, because the MMSE and other cognitive modalities bottom out prior to the final five to eight FAST substages, complete concurrent validation and examination of the FAST had to await the development of cognitive measures useful in most severe dementia. Such measures were developed towards the end of the twentieth century and do, in fact, evidence strong relationships with the final FAST stages[24]. Subsequent work showed approximately equally strong relationships between this latter portion of the FAST and ostensibly cognition-independent neurological reflex changes[46], as well as hippocampal neuropathological changes in volume[10], cell number[11] and the percentage of remaining hippocampal neurons with neurofibrillary changes[11], with the advance of AD as per the FAST stages and substages (reviewed in[20]). Also, the second layer of the entrohinal cortex is believed to be a very early site of AD pathology. In this layer, a very robust relationship, across the FAST severity spectrum from FAST stage 3 to 7f, with the decrement in neuronal numbers has recently been reported ($r = 0.9$)[15]. The correlations between the advance of AD as measured with the FAST in the latter portion of the course of AD, generally after the MMSE bottom (zero) point, and cognitive, neurological reflex and neuropathological hippocampal measures are generally approximately 0.8–0.9. These diverse relationships are comparable to the correlation between the FAST and the MMSE in the MMSE-sensitive portion of the FAST staging assessment. Because of these properties and others, the FAST has proven to be of widespread utility. For example, in the United States, the FAST staging procedure has been utilized as the Medicare mandated 'gold standard' for hospice admission for more than a decade[68]. Importantly, because of the sensitivity of the FAST staging procedure to the course of AD, not only over the final seventh stage when the MMSE is zero, but also over the course of FAST stage 6, when patients still score on measures such as the MMSE, the FAST measure has shown a significant effect on the course of AD in a pivotal multicentre drug trial, associated with worldwide approvals for memantine as the first medication for advanced AD, whereas the MMSE was not sensitive to change in this study[21]. At the present time, the FAST has been used as an efficacy and/or severity assessment in all pivotal trials associated with United States and European Union approvals of medications for advanced AD (for a review, see[23]).

Apart from the utility of the FAST staging, other elements of the multi-axial BCRS staging procedures have also proven useful in AD assessment. On the BCRS, Axis I assesses concentration; Axis II, recent memory; Axis III, remote memory; Axis IV, orientation; and Axis V, functioning. Axis V of the BCRS was developed and expanded in the process of the creation of the FAST staging procedure. All of these elements of the BCRS, including the FAST, have been utilized as part of the syncretic NYU CIBIC-Plus assessment measure[69]. As part of the NYU CIBIC-Plus, these measures have been used as primary outcome measures in pivotal trials associated with regulatory body (e.g. FDA) approvals of two of the three medications currently approved and marketed for the treatment of AD in the United States (i.e. rivastigmine and memantine) (for a review, see[23]). At the other end of the brain-ageing and AD continuum, the BCRS Axes I to V have been found to add significantly to the GDS global assessment in predicting the risk of decline and the time to decline to MCI or dementia in ostensibly normal subjects with NCI or SCI (GDS stages 1 and 2)[16].

SUMMARY

Behaviourally based brain-ageing and progressive dementia staging procedures can be useful and, frequently, superior to other assessment modalities in identifying potential treatments for AD and related

Table 31.2 Functional Assessment Staging (FAST) and time course of functional loss in normal brain ageing and Alzheimer's disease

FAST stage	*Clinical characteristics*	*Clinical diagnosis*	*Estimated duration in AD*[a]	*Mean MMSE*[b]
1	No decrement	Normal adult		29–30
2	Subjective deficit in word finding or recalling location of objects	Subjective cognitive impairment	15 years	29
3	Deficits noted in demanding employment settings	Mild cognitive impairment	7 years	24–27
4	Requires assistance in complex tasks, e.g. handling finances, planning dinner party	Mild AD	2 years	19–20
5	Requires assistance in choosing proper attire	Moderate AD	18 months	15
6a	Requires assistance in dressing	Moderately severe AD	5 months	9
b	Requires assistance in bathing properly		5 months	8
c	Requires assistance with mechanics of toileting (such as flushing, wiping)		5 months	5
d	Urinary incontinence		4 months	3
e	Faecal incontinence		10 months	1
7a	Speech ability limited to about a half-dozen words	Severe AD	12 months	0
b	Intelligible vocabulary limited to a single word		18 months	0
c	Ambulatory ability lost		12 months	0
d	Ability to sit up lost		12 months	0
e	Ability to smile lost		18 months	0
f	Ability to hold up or move head independently lost		12 months or longer

[a] In subjects without other complicating illnesses who survive and progress to the subsequent deterioration stage[9–16].
[b] MMSE = Mini-Mental State Examination score (Folstein *et al*., 1975[7]). Estimates based in part on published data summarized in Reisberg *et al*., 1989[63] and in Reisberg *et al*., 1992[64]. It should be noted that the educational level of the subjects in these studies is high (mean ~15.5 years ± ~ 3 years, of formal education). The influence of these educational levels on the mean MMSE scores should be given consideration.

dementias[70–72], as well as in assessing the course and the management needs of the dementia patient, and also in the diagnosis and differential diagnosis of dementing disorders. In providing an overview of the course of dementias such as AD, from the initial to final clinical symptoms, staging is uniquely useful. Staging is also singularly useful in assessment at various specific points in the evolution of dementing processes. Very importantly, staging can uniquely relate to management needs and the general management import of dementing processes.

ACKNOWLEDGEMENT

This work was supported in part by US DHHS grants AG03051 and AG08051 from the National Institute on Aging of the US National Institutes of Health; by grants 90AZ2791, 90AM2552 and 90AR2160 from the US Department of Health and Human Services Administration on Aging; by grant NCRRM01 RR00096 from the General Clinical Research Center Program and by Clinical and Translational Science Institute grant 1UL1RR029893 from the National Center for Disease Research Resources of the US National Institutes of Health; by the Zachary and Elizabeth M. Fisher Center for Alzheimer's Research Foundation; by a grant from Mr. William Silberstein; by the Leonard Litwin Fund for Alzheimer's Disease Research; by the Woodbourne Foundation; and by the Hagedorn Fund.

The Clinical Dementia Rating

Rawan Tarawneh, B. Joy Snider, Mary Coats and John C. Morris

Washington University in St. Louis, St. Louis, MO, USA

INTRODUCTION

The Clinical Dementia Rating (CDR) is an instrument used to assess the presence and severity of dementia of the Alzheimer type (DAT); it may be applicable to other dementias as well. The CDR was developed at Washington University School of Medicine in 1982 and revised in 1993 to improve the distinction between different severity levels.

Determination of the CDR is based on separate semi-structured interviews with the patient and an appropriate informant, such as spouse or adult child, to provide information regarding the patient's current level of cognitive function and daily activity in comparison with previously attained abilities.

DEVELOPMENT OF THE CDR

Measuring dementia severity is useful for research as well as for clinical decision making. Accurate staging of dementia is particularly important in clinical trials, both to select appropriate participants with similar levels of disease severity and to monitor disease progression[1]. The importance of a standardized approach to dementia staging in clinical trials is highlighted by the US Food and Drug Administration's Guidelines for the Clinical Evaluation of Anti-Dementia Drugs: 'the stage and severity of the dementia affecting each subject participating in a clinical trial must be assessed and recorded systematically in a manner that will be readily understood by other workers in the field'[2].

Prior to the introduction of the CDR, most attempts at the clinical staging of dementia were based on psychometric tests and behavioural rating scales. Some early instruments included the Dementia Scale (DS) of Blessed, the Global Deterioration Scale (GDS), the 29-item Blessed Information and Memory Scale (BIMC), and the Short Blessed Test, an abbreviated 6-item version of the BIMC.

The CDR is a 'global' scale that assesses impairment in cognitive ability, including the impact of cognitive changes on everyday functioning; it was designed to be performed independently of psychometric test results. The CDR assesses intra-individual change from the individual's prior cognitive and functional ability. Psychometric testing typically compares individual performance to reference group norms. By comparing functional and cognitive changes to the premorbid (predementia) level of function for that individual, the CDR minimizes effects of confounding factors such as age, educational level and ethnicity (i.e. the individual serves as his or her own control).

The CDR has been validated in several neuropathological studies of Alzheimer's disease[3]. It has demonstrated strong correlations with other behavioural and functional tests, as well as strong inter-rater correlations, attesting to its validity and reliability. While it may not be suitable for every situation, the CDR has become internationally recognized as a highly reliable diagnostic and severity-ranking scale for dementia, has been cited in over 1000 references (http:/apps.isiknowledge.com) and translated into 60 different languages and dialects (http://alzheimer.wustl.edu-/cdr/PDFs/translation/). Although primarily developed to assess DAT, the addition of language and behaviour domains in the Uniform Data Set version of the CDR (UDS) has allowed its use in the evaluation of other causes of dementia[4].

Online training in the use of the CDR is available at http://alzheimer.wustl.edu/cdr/Application/Step1.htm or by writing to the authors.

OVERVIEW OF THE CDR

The CDR is performed in two components: a semi-structured interview with a collateral source that provides information on the individual's premorbid level of function and any changes that have occurred, and an interview with the individual that includes some objective testing. It is determined by rating cognitive, behavioural and functional changes resulting from cognitive loss in each of six categories: Memory, Orientation, Judgement and problem solving, Community affairs, Home and hobbies, and Personal care (Table 32.1). Each category is scored independently on a 5-point scale of impairment (0 = no impairment, 0.5 = questionable or very mild, 1 = mild, 2 = moderate and 3 = severe impairment); one category, Personal care, does not have a 0.5 impairment level. The CDR scoring table includes descriptive 'anchors' that guide the rater in determining individual domain ratings based on both collateral source report and patient performance. The clinician uses his or her judgement to determine each rating, scoring each as independently as possible. With CDR training, clinicians can successfully distinguish between physical and cognitive causes of functional impairment and assign a CDR that accurately reflects dementia severity even in the presence of impaired physical performance[6].

The global CDR is determined by applying a scoring algorithm (www.biosat.wustl.edu/~adrc/cdrpgm/index.html), where global

Table 32.1 The clinical dementia rating scale

	None 0	*Questionable 0.5*	*Mild 1*	*Moderate 2*	*Severe 3*
Memory	No memory loss or slight Inconsistent forgetfulness	Consistent slight forgetfulness; partial recollection of events; 'benign' forgetfulness	Moderate memory loss: more marked for recent events; defect interferes with everyday activity	Severe memory loss, only highly learned material retrained: new material rapidly lost	Severe memory loss only fragments remain
Orientation	Fully oriented	Fully oriented but with slight difficulty with time relationships	Moderate difficulty with time relationships; oriented for place at examination; may have geographic disorientation elsewhere	Severe difficulty with time relationships; usually disoriented to time, often to place	Oriented to person only
Judgement and problem solving	Solves everyday problems and handles business and financial affairs well; judgement good in relation to past performance	Slight impairment in solving problems, similarities and differences	Moderate difficulty in handling problems, similarities and differences; social judgement usually maintained	Severely impaired in handling problems, similarities and differences; social judgement usually impaired	Unable to make judgements or solve problems
Community affairs	Independent function as usual in job, shopping, volunteer and social groups	Slight impairment in these activities	Unable to function independently at these activities though may still be engaged in some; appears normal to casual inspection	No pretence of independent function home; appears well enough to be taken to functions outside the family home	Appears too ill to be taken to functions outside the family home
Home and hobbies	Life at home, hobbies and intellectual interests well maintained	Life at home, hobbies and intellectual interests slightly impaired	Mild but definite impairment of functions at home; more difficult chores, and complicated hobbies and interests abandoned	Only simple chores preserved; very restricted interests, poorly maintained	No significant function in the home
Personal care	Fully capable of self-care		Needs prompting	Requires assistance in dressing, hygiene and keeping of personal effects	Requires much help with personal care; frequent incontinence

Score only as decline from previous usual level due to cognitive loss, not impairment due to other factors.
Source: Morris, J.C. (1993) The Clinical Dementia Rating (CDR): current version and scoring rules. *Neurology*, **43**, 2412–4.

CDR 0 = no dementia and CDR = 0.5, 1, 2 and 3 for very mild, mild, moderate and severe dementia. The CDR-sum of boxes (CDR-SB) is obtained by summing the scores in the individual categories, so CDR-SB ranges from 0 to 18 ('best' to 'worst' performance)[7]. The CDR-SB offers some advantages: it does not require an algorithm to calculate and can be treated as interval data in statistical analysis whereas the global CDR represents ordinal data. More importantly, the CDR-SB offers a wider range of values and increased precision for tracking changes across time. For example, mild DAT (global CDR 1) spans CDR-SB scores from 3.5 to 10, whereas moderate DAT (global CDR 2) spans 8–15.

CHARACTERISTICS

The CDR has two important properties of a global staging measure: hierarchy and concordance[8]. Hierarchy means that dementia severity

is proportional to the CDR score (e.g. global CDR 3 is more severe than global CDR 2). The CDR captures different disease patterns and can identify subgroups of patients through concordance, another important property. In individuals with DAT, most of the six domains are expected to be reasonably concordant with the memory score (e.g. in global CDR 0.5 most domains would have scores of either 0.5 or 0 or 1). Disconcordance between different cognitive domains (e.g. a mix of 0, 2 and 3s) is suggestive of a non-Alzheimer's cause of dementia.

The CDR has demonstrated excellent 'face validity' in that it assesses the influence of cognitive loss on the ability to conduct everyday activities. It provides a standardized and meaningful way to describe clinically relevant changes to patients and their families[8].

The CDR has demonstrated its validity in multiple longitudinal studies with neuropathological confirmation of Alzheimer's disease; both the CDR and CDR-SB have been shown to correlate with the densities of neurofibrillary tangles and senile plaques, particularly in the neocortex[3]. Since the inception and revision of the CDR, the diagnosis of dementia has evolved, with increasing interest in and recognition of milder stages of dementia. The CDR has demonstrated a high degree of sensitivity (91%) in distinguishing individuals with even the mildest stages of dementia from normal individuals in longitudinal studies with neuropathological confirmation of Alzheimer's disease[9].

When administered in a standardized fashion, the CDR has excellent reliability. Inter-rater reliability of the CDR in several single and multicentre clinical trials including both physicians and non-physicians is 80% or greater for overall CDR, and $\geq$80% for almost all of the individual boxes[10,11].

The stability of the CDR over time was investigated in a 30-year longitudinal study of 1768 patients 63–83 years of age and with CDRs 0, 0.5 or 1 at Washington University[13]. Over time, the participant sample became older, more highly educated, more ethnically diverse, more likely to be female and more likely to have non-Alzheimer's disease dementias. There was a high turnover in the individual clinicians. Despite these changes, the psychometric test scores of individuals with similar CDR ratings did not change significantly over the 30-year period.

DIAGNOSIS AND DETECTION OF EARLY STAGES OF DEMENTIA

In its original form, CDR 0.5 denoted a heterogeneous group with questionable dementia. However, there is a growing body of evidence that many in the CDR 0.5 group are very similar to those with mild DAT in cognitive, behavioural, psychometric performance, longitudinal progression, as well as in neuroimaging and CSF biomarker characteristics.

By relying on intra-individual cognitive decline rather than inter-individual comparison of psychometric performances with arbitrary cut-points for impairment, CDR 0.5 allows the identification of individuals with cognitive impairment that may be too mild to fulfil criteria for mild cognitive impairment. Longitudinal studies have consistently demonstrated that the CDR 0.5 designation, when impairment is believed clinically to be caused by DAT, is followed by progressive cognitive and functional decline over time and by the histopathological changes of Alzheimer's disease at autopsy even when the CDR 0.5 diagnosis is 'pre-mild cognitive impairment'[9].

CDR 0.5 is now considered to characterize 'very mild' rather than 'questionable' dementia. We attempt to diagnose the aetiology of dementia even when the degree of impairment is very mild (CDR 0.5).

ADAPTATIONS OF THE CDR

The CDR has been adapted to other clinical settings such as nursing homes and chronic care facilities (CDR-CC). A more abbreviated form of the CDR has been included into the Diagnostic and Statistical Manual for the identification of dementia.

The CDR interview can take 45–60 minutes and may be impractical for some clinical and research settings. A software system for administration and automatic scoring of the CDR using a hand-held device platform was recently developed. The platform includes specific algorithms for each scoring domain and the global CDR. The platform increases ease of data collection and management and is transferable to other platforms, allowing its use in both research and clinical settings. The Palm-based CDR has excellent validity, reliability and high correlation with the traditional CDR and is accurate for distinguishing CDR 0 and 0.5, which is probably the most challenging distinction in practice[14].

A brief informant questionnaire, referred to as 'AD8', has been developed in another attempt to avoid the time limitations of the CDR. The AD8 scores responses to eight questions. It offers a practical screening tool for the presence of dementia, with high sensitivity, specificity and face validity. However, in contrast to the CDR, it cannot be used as a staging tool for dementia[15].

POTENTIAL LIMITATIONS OF THE CDR

The CDR is not without limitations, including reliance on clinical judgement and the availability of an observant collateral source, and the length of time required for administration. Although the semi-structured interview format is flexible and can be adapted to different cultures and socioeconomic groups, social, cultural and educational factors may influence some domains of the scale. Therefore, additional validation studies will be needed to establish the validity and reliability of the CDR in ethnic subpopulations[16].

GMS-HAS-AGECAT Package and the Global Mental Health Assessment Tool (GMHAT): Epidemiology and Closing the Treatment Gap

John R. M. Copeland

Division of Psychiatry, University of Liverpool, UK

For epidemiological and other studies of mental illness and morbidity in older age it is important to ensure as far as possible that the differences in the levels of cases of illness found between geographical areas and between studies at different points in time are not due to methodological differences and, in particular, the way the diagnoses themselves are made. To overcome this problem, standardized interviews were introduced. The GMS-HAS-AGECAT Package consists of a series of interviews designed to be given to a person for assessing the dementias and depression, with optional sections for minor mental illness. The Geriatric Mental State (GMS) was derived originally from the Present State Examination and the Mental Status Schedule (see the GMS Resource Centre at www.liv.ac.uk/gms). Substantial modifications and additions were incorporated to make it more applicable to older populations and to increase emphasis on organic states. The Package now provides, in addition to the GMS, which is an interview with the subject, the History and Aetiology Schedule (HAS) for an informant, which allows the assessment of onset and course of illness, past history, family history and certain risk factors for dementia, depression and other mental illness.

Standardization of diagnosis is achieved by the Automated Geriatric Examination for Computer Assisted Taxonomy (AGECAT) computer-assisted differential diagnosis based on an extensive decision tree method. The system aggregates the data into scores and allots each subject to levels of 'diagnostic confidence' on each of eight diagnostic syndrome clusters: organic, schizophrenia/paranoid, mania, depression (psychotic and neurotic type) (levels 0–5), obsessional, hypochondriacal, phobic and anxiety neurosis (levels 0–4). Level 3 and above are what would usually be recognized by psychiatrists as cases of illness. The computer then compares these levels with one another to derive a final diagnosis and flags cases where the decision has been difficult. The validity of the AGECAT diagnosis has been assessed against psychiatrists' diagnoses on the same patients. The range of kappa values for the agreement between AGECAT and psychiatrists' diagnoses for organic states is 0.80–0.88 and for depressive states 0.76–0.80. Outcome studies are now providing additional validation. After three years of follow-up, over 83% of AGECAT cases of organic disorder identified in the community study were either dead or still dementing. One third of depressed cases were also depressed three years later. Postmortem studies have provided some validation of the dementia diagnosis[1].

In the second stage AGECAT uses the data from the HAS to take the diagnosis to a further stage, dividing organic states into acute or chronic, and the latter into the different types of dementia using a standardized form of the Hachinski Ischaemia Score. It also identifies bereavements and flags co-existent immobility, pain, lifelong intellectual function and physical illness.

The GMS can be used by trained lay workers and provides a diagnosis by AGECAT. When used in epidemiological studies it is possible to derive prevalence figures for the full range of psychiatric morbidity using a one-stage design. The measures are therefore economical as well as reliable and valid. The Package does not rely on special psychological tests as these are not applicable across cultures or socioeconomic groups or with populations of varying literacy. The interviews have also been transferred for presentation on laptop computer, which improves accuracy and communication, avoids delays and costs in inputting data, and provides rapid access to results and easy quality control of interviewing techniques.

These measures have been used in a number of projects, including the Medical Research Council (UK) ALPHA study of the incidence of the dementias (Liverpool, UK) and the multicentre MRC Cognitive Function and Ageing Study of six centres in the UK, the EURODEP EC-funded Concerted Action across nine European centres, the ongoing ASIADEP studies in five Asian centres, and the 10/66 Dementia Research Group (www.alz.co.uk), a collective of dementia researchers from the developing world examining the validity of dementia diagnosis in 27 centres in Latin America, Africa, India and South Asia, China and Southeast Asia, as well as forming part of the minimum dataset required by the EURODEM (EC Concerted Action on Epidemiology and Prevention of Dementia). The GMS has been translated and used in 40 different languages. The HAS has been shortened and modified to provide for the criteria of Lewy body dementia, and other recognized dementia classifications[2].

Of particular interest has been the question of how accurately the GMS Package diagnosed dementia among those persons with little or no education, an environment for which it was not initially developed. Findings now suggest that the GMS does tend to over-identify

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

organic disorder in low education groups free of dementia. However, overall the GMS appears to have performed well, and with some minor modifications when used in conjunction with the Community Screening Instrument for Dementia (CSI-D) has made an important contribution to one-stage dementia diagnosis for use in the developing world. Ongoing studies have continued to address these issues[3].

A recent development has been aimed at developing a clinical tool for areas of the world where there are no or very few psychiatrists or psychiatrically trained nurses. The Global Mental Health Assessment Tool (GMHAT[4]; see www.gmhat.org) has been developed in two versions. The first is for use as a diagnostic tool in primary care for the identification and treatment of mental illness in both young adult and older populations. Taking only 15 minutes on average and only requiring brief training in its use at high school educational level, it can be employed much as a blood test or an X-ray but much more cheaply and quickly. The second or full version, for secondary care where there is no psychiatrist, is designed to be given by a psychiatric nurse trained briefly in the method. The extensive computerized diagnostic algorithms based on the AGECAT system have been much extended to include mental illnesses encountered in younger age groups as well as those in older people (All-AGECAT) and more extended treatment options. Preliminary trials have begun in the UK, the Netherlands, Ireland, India and Africa. Closing the treatment gap particularly in low and middle income countries is now of growing concern. Achieving a reliable diagnosis and instituting treatment is the vital rate-limiting step on the road to recovery and return to work. In many parts of the world older people need to continue to work to support themselves and their families, especially in countries ravaged by HIV AIDS.

Assessing Life Skills

Colin Depp, Veronica Cardenas, Ashley Cain and Thomas L. Patterson

Department of Psychiatry, University of California – San Diego, USA

INTRODUCTION

Particularly among older adults with mental illnesses, functional impairments play a critical role in clinical decisions, whether in determining a patient's ability to maintain residence in the community or gauging how well interventions aid patients in fulfilling life roles. The goal of mental health interventions is to restore functioning as much as possible, ideally to the individual's premorbid level of functioning, and so it follows that the measurement of functional abilities is of paramount clinical importance. By virtually any measure, the functional impact of psychiatric illness is immense and typically lifelong. Among people with schizophrenia, about two-thirds are unable to perform social roles and fewer than one-third are ever employed[1]. According to the World Health Organization (WHO), depression is among the commonest causes of days of disability, among all diseases, in the developed world[2]. Dementia due to Alzheimer's disease, which is now the sixth-leading cause of death, is also a leading cause of nursing-home placement in older adults[3]. In addition to the personal losses associated with functional impairment, disability associated with late-life mental illness imposes substantial monetary costs on society, such as wages lost by sufferers and their caregivers, the expense of services that compensate for functional deficits and other supportive costs.

Historically, much of the focus in psychiatry has been on quantifying and treating the symptoms of mental illness, with relatively less methodological rigour on the conceptualization and measurement of everyday functioning and skills for daily life. However, recent years have seen a rapid increase in the sophistication of approaches to measure the capacity to perform activities of daily living and in the quantification of 'real-world' outcomes that patients and providers care about. In this chapter, we will review the domains of interest and approaches to assessing daily living skills in older people with psychiatric disorders, provide a model linking the factors that contribute to functional disability and review the measurement modalities and the instruments available to measure functional outcomes in geriatric psychiatric patients.

CONSIDERATIONS IN MEASURING FUNCTIONING

Functional abilities encompass a number of life domains and there is no definitive subset of abilities under the umbrella of functional status nor a 'gold standard' defining functional independence or dependence. As a result, dozens of measures of functioning exist that cover different life domains, with varying theoretical bases and psychometric properties. Recent initiatives, such as the Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS)[4] (sponsored by the National Institute of Mental Health) have attempted to rectify the heterogeneity of functional measurement approaches by validating and recommending a core set of functional assessments. Other NIH initiatives, such as the Patient Reported Outcomes Measurement Information System (PROMIS)[5], are also underway to provide a standard 'toolbox' with which researchers and clinicians can select standardized population-normed instruments to measure functioning with self-report measures.

While the process of identifying a 'core' set of functional measures is ongoing, several important dimensions must be considered in any approach. The conceptualization of functional impairments generally separates what an individual *can* do (capacity) from what an individual *does* do (actual performance). Functional capacity refers to the ability of an individual to perform a task under optimal conditions and that performance can be measured with the observational or performance-based approaches described in the latter portion of this chapter. Actual performance may be discrepant from functional capacity, as real-world performance is affected by motivation, opportunities and environmental barriers.

In addition to the distinction between capacity and actual performance, the functional consequences of an illness can be judged in a number of ways. Functional status can be assessed relative to age-adjusted norms, premorbid ability or a criterion devised by an external entity (e.g. some government agency standard). The normative basis for assessing functioning is important when interpreting scores from instruments that are generic (e.g. the Medical Outcomes Study – Short Form) and meant to be applicable to the broad population. Alternatively, functioning measures can be disease-specific, such as those focusing on severe mental illnesses (e.g. the Independent Living Skills Survey). Although these latter measures may not provide an estimate of functioning relative to healthy older adults, the items may have a lower 'floor' and thus can guide rehabilitation targets in functionally impaired people.

Another way in which functioning can be classified, typically in population-based studies, are preference-weighted approaches. These approaches use population data on preferences for states of health to create indices of disability adjusted life years (DALYs) or quality adjusted life years (QALYs), which can be compared across illnesses or treatments. For example, the Quality of Well-Being Scale uses a preference-weighted approach. Previous use of this instrument

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

estimates that the 'well years' lost to schizophrenia among middle-aged and older adults are slightly more than that experienced by ambulatory individuals with AIDS[6].

Yet another distinction in assessing functioning involves the source of the information. Not surprisingly, ratings of functioning provided by patients, their family members and their clinicians often show inconsistencies – for example, patients with depression may overestimate their impairment, while patients with diminished insight due to dementia may believe they are fully capable when they are not. Family and clinician judgements of functioning may depend upon the degree to which they are familiar with the individual's functioning in the community. Some indicators of functioning, such as employment status or medication adherence, may be dependent on contextual factors such as availability of social support. Furthermore, daily living skills must be assumed to fluctuate within the individual, based both on the context and on the course of the psychiatric illness and its treatment, such that any point-in-time assessment of functioning may be biased by state-level factors (e.g. mood state, fatigue).

Taking all these considerations together, it is clear that attaining reliable and accurate representations of an individual's level of functioning presents a challenge for clinicians and researchers. The best approach typically utilizes multiple measures of functioning (e.g. performance-based, subjective ratings) in different contexts (e.g. at home and in the clinic).

WHAT ARE THE SKILLS OF DAILY LIVING?

There is no single definition of daily life skills, but the primary functional categories include activities of daily living, social role functioning, decision-making capacity and recovery. The activities of daily living (ADLs) were defined in the 1960s and a decade later they were differentiated from instrumental activities of daily living (IADLs). ADLs include toileting, dressing, transferring and other activities basic to maintaining residence in the community. IADLs are more cognitively complex and involve fine motor movements, including managing medications, using the telephone, arranging transportation, managing money and preparing meals. In the general population, impairment in ADLs and IADLs increases with age, although the overall prevalence of ADL impairment in older people seems to have declined over the past several decades[7]. Change in ADLs often corresponds to change in disease status and not infrequently triggers placement in a care facility. Typically, ADLs and IADLs are rated by an observer or clinician, but self-perceived impairment in functional tasks is also frequently evaluated. Measures of perceived ability to complete functional tasks are embedded in subjective questionnaires (e.g. 'Are you impaired in your ability to walk one mile?') as well as whether a disease impacts functioning (e.g. 'Has your mental health interfered with your social activities?'). Finally, a number of approaches to the measurement of general physical function are used to assess physical fitness in older adults (e.g. grip strength, sit to stand tests), but because these are not specifically tied to daily life skills, we will not describe them here. Interested readers are referred to an excellent review on these physical functioning instruments[8].

Social functioning is another key domain in functional assessment. Actual performance can be measured in regard to an individual's roles in the workplace, in close relationships and in leisure activities. In geriatric populations, particularly after retirement, social roles may be less culturally prescribed than among younger adults, which makes determining the extent of social impairment more challenging. Particularly in schizophrenia as opposed to mood disorders or dementia, social skills may be measured in standardized role-play tasks. These simulate conversations in which the participant's performance is graded. The use of performance-based measures of social functioning is generally restricted to research.

Another context of functional status that clinicians are frequently asked to evaluate in older adults with mental health problems is decision-making capacity, particularly with regard to medical or other major life decisions. The assessment of capacity to make decisions should be specific to the context. For example, it cannot be assumed that impairment in the handling of personal finances signifies impairment in the making of medical decisions, such as the refusal of treatment. Assessing decisional capacity typically includes four components: understanding, appreciation, reasoning and expressing a choice. Understanding describes the extent to which the individual comprehends what is at stake, i.e. probable outcomes, risks and benefits. Appreciation measures how well the individual can relate the decision to his or her own situation, while reasoning measures the quality of the mental process by which the individual arrives at that decision. Finally, expressing a choice concerns whether the individual is capable and/or willing to express a decision. Research in older patients with schizophrenia or bipolar disorder using standardized measures of decisional capacity has indicated that cognitive impairments are the single greatest predictor of impairment in decisional capacity, over and above psychotic or affective symptoms. However, the manner in which the information is conveyed to the patient, particularly whether it is repeated, appears to make a significant difference in whether capacity is achieved. It cannot be assumed that the presence of a psychiatric disorder translates to a lack of capacity.

Finally, recent years have seen an emergence of a more patient-centred concept of functioning that is termed 'recovery'. The precise definition of this term is debated, but a consensus panel formed by the US Substance Abuse and Mental Health Services Administration (SAMHSA) provided the following: 'Mental Health recovery is a journey of healing and transformation enabling a person with a mental health problem to live a meaningful life in a community of his or her choice while striving to achieve his or her full potential'[9]. Although recovery shares a focus with the above domains on functional outcomes, greater emphasis is placed on the patient's sense of self-efficacy and meaning. The measurement of recovery is thus more idiographic than that of the domains just described. How the construction of recovery changes, if at all, across the lifespan of people with mental illnesses has received little research.

WHAT ARE THE INFLUENCES ON DAILY LIVING SKILLS?

Many factors influence functioning and daily living skills, including illness, cultural issues, environmental contexts and age-related changes. In this section, we review the impact of these factors and provide an integrative model that combines them.

Emerging evidence in a variety of psychiatric disorders suggests that cognitive impairments are the greatest contributors to diminished functional status[10,11]. On average, the relative influence of cognitive impairments on functioning probably increases over the course of a long-term illness. This is in part due to declines in the acuity of psychopathological symptoms for people with early-onset mental illnesses[12] and also because cognitive impairments beyond those associated with normal ageing may cross thresholds to create functional impairment. A number of studies have examined the relative

impact of cognition on functioning in older patients with mental illness and the general conclusion is that cognitive impairments supersede psychopathologic symptoms in their associations with functional deficits of older adults with schizophrenia, bipolar disorder and depression[13]. Among cognitive abilities, impairment in executive functioning, which includes planning, task switching and other higher order mental abilities, appears to be most influential on functional status. Recent research has suggested that even among older patients with depression or bipolar disorder, both cognitive impairments and functional problems appear to persist between mood episodes.

However, concurrent symptoms do appear to produce disability, particularly in subjective functioning. In addition to cognitive impairments, among older patients with schizophrenia, negative symptoms appear to be more closely associated with functional impairment than are positive symptoms. In mixed-age patients with bipolar disorder, depressive symptoms appear to be more disabling on average than manic symptoms, in part because they are, on average, more frequent and intractable. Another general trend among older adults with severe mental illnesses is that earlier age of onset is associated with greater functional impairment, likely because functional problems have had a longer time to accrue and because patients have a comparatively shorter time in which to establish life roles free of illness. Medical co-morbidities and substance abuse also appear to produce added functional impairment.

Another strong determinant of functional status and one frequently overlooked in assessment, is the patient's environment. The concept of person–environment fit[14] posits that functioning is a product of individual abilities and environmental supports. In this model, the physical and social environment may support or detract from autonomous function. For example, the elimination of high curbs can enable individuals in wheelchairs to function at a level similar to those who are not wheelchair-bound. By contrast, chaotic or novel environments may overwhelm cognitive resources and exacerbate functional deficits in vulnerable older people. Some recently developed interventions for schizophrenia[15] and for dementia[16] emphasize environmental supports to compensate for cognitive deficits and maintain functioning.

Finally, sociocultural influences affect functioning in geriatric patients with psychiatric disorders. Culturally based expectations regarding functioning and mental illness can influence the kinds of daily tasks an older adult can accomplish. For example, older immigrants may have a language barrier or lack the means to acquire resources needed to improve functioning. Moreover, culturally diverse older adults may be accustomed to carrying out daily activities following a different set of steps or using different means from those of the dominant culture. For example, a person may not know how to refill medication by way of telephone as is often done in the United States. The person may also come from a culture with clearly defined gender roles that impede the learning of such tasks as cooking, cleaning or driving a vehicle. Culturally held beliefs about the elderly can also influence daily functioning. For example, family members may feel obligated to do things for ageing relatives to ease their burden, ensure their safety, or to express culturally appropriate reverence. This sense of duty may intensify when a psychiatric illness is involved.

INTEGRATING THE CONTRIBUTORS TO FUNCTIONAL DISABILITY: A MODEL

A number of disablement models have been developed over the past three decades. Most recently, the WHO developed what it termed a revised working disability model. This model clarified certain constructs and operationalized functioning across three levels[17–20]: the body; the person as a whole; and the person in social contexts. While this model is useful, it lacks specificity and fails to consider a host of other factors which may influence functional capacity, such as cognitive deficits, earlier age of onset of illness, the environment in which a person lives and co-morbidities such as substance abuse.

The following conceptual model of functional capacity (see Figure 34.1), which incorporates many of the issues mentioned above, elaborates on the WHO model. Hypothetical paths between concepts are indicated by arrows. An important feature of this model is the role of mediation – i.e. causal links are implied between illness features and disability. Among older adults with

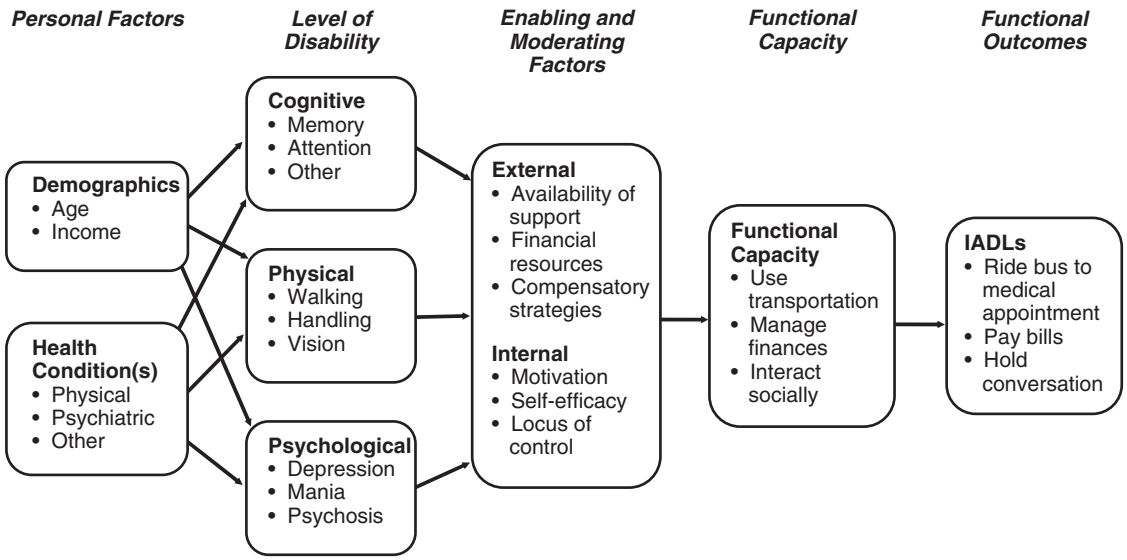

Figure 34.1 Model of functional capacity

schizophrenia, recent evidence shows that the pathway between cognitive abilities and functioning may be mediated by functional capacity. Bowie *et al*.[10] examined the relationships between functional capacity data, scores on the UCSD Performance-Based Skills Assessment (UPSA), case-manager ratings of real-world functioning (covering interpersonal skills, work skills and community activities), neuropsychological test scores and symptom levels, and they constructed a path model showing that neuropsychological performance predicted functional capacity, which in turn predicted all three domains of real-world functioning. Psychiatric symptoms, specifically depression, predicted interpersonal and work skills, while negative symptoms affected interpersonal skills independently of other predictors. However, while real-world adaptive life skills were predicted by neuropsychological performance, symptoms and functional capacity, neuropsychological performance contributed little to the prediction of real-world performance after accounting for functional capacity. This study illustrates how specific paths in our proposed model can be validated with data and the model provides a heuristic by which to organize assessment data in gauging individual functioning.

DESCRIPTIONS OF SPECIFIC MEASURES OF FUNCTIONING

As described in the introduction, many measures of functioning exist with different psychometric properties, formats and content. In considering which measure to use, it is important to recognize that all have limitations in terms of completeness, ceiling and floor effects, sensitivity to change and applicability across multiple patient groups (e.g. inpatients vs. outpatients). Measures for assessing functioning fall into four broad categories: self-reports, informant reports, clinician ratings and observational measures. Below and in Table 34.1 we have selected from among the best validated of these measures and describe the instruments in detail.

Table 34.1 An overview of specific functional instruments

Measure	*Time to administer*	*Domains assessed*	*Type of administration*	*Validity, relationship to real-world outcomes*
UPSA	30 minutes	Functional capacity: household chores, communication, finance, transportation and planning recreational activities	Performance-based	Predictive of one's ability to live independently in the community
UPSA-Brief	10–15 minutes	Functional capacity: finances and communication	Performance-based	Highly correlated with full UPSA
SSPA	20 minutes	Social skills	Performance-based	Excellent inter-rater reliability, good test–retest reliability; scores correlate with health-related QWB and observed performance on activities of daily living
MMAA	15 minutes	Medication management ability	Performance-based	Significantly related to prescription refill records, performance-based measures of everyday functioning and self-reported quality of life
ILSS-SR	20–30 minutes	Functional living skills (see text for full list)	Self-report	Marginal to good internal consistency, stability and inter-rater reliability; good ability to predict employability
GAF	5–15 minutes	Functional impairment secondary to mental illness	Clinician-rated	Good reliability and a valid measure of psychiatric disturbance in severely mentally ill
SF-36	5–10 minutes	Mental and physical health-related quality of life	Self-report	Good internal reliability and construct validity
QWB-SA	15 minutes	Quality adjusted life years Health-related quality of life	Self-report	Results comparable to interviewer-administered version
SAFE		Adaptive functioning; social-interpersonal, instrumental and life skills functioning	Observational	Good convergent, discriminant and predictive validity
MOSES		Levels of functioning in self-care, levels of organization, depressed and anxious mood, irritability and behavioural withdrawal	Observational	Satisfactory validity against other established measures (Zung depression, Robertson short mental status, Kingston dementia, PAMIE scales)

SELF-REPORT

Generic Measures

SF-36

The Medical Outcomes Study (MOS) 36-item short-form Health Survey (SF-36) is a self-report measure that covers eight different domains: physical functioning, role limitations due to physical health problems, bodily pain, general health perceptions, vitality, social functioning, role limitations due to emotional problems and mental health. These eight subscales are combined to produce two summary scores: the physical and the mental composite score[21]. An even shorter 12-item (SF-12) scale has been developed that can be completed in one or two minutes[22].

QWB

The Quality of Well-Being (QWB) is a preference-based questionnaire that measures health-related quality of life. The original version was administered by an interviewer, but a self-administered version (QWB-SA) was subsequently developed to avoid some of the difficulties associated with interviewer administration. The QWB-SA consists of five sections totalling 56 items that assess acute or chronic symptoms, self-care, mobility, physical functioning and performance of everyday activities. Participants are asked to think about the past three days and indicate if they experienced the symptom or problem on the previous day, two days ago, three days ago, or some combination thereof. The QWB-SA takes approximately 15 minutes to complete[23].

Disease-Specific Measures

ILSS

The Independent Living Skills Survey (ILSS) tests basic functioning in patients with severe and persistent mental illness. There are two versions: informant-rated (ILSS-I) and self-report (ILSS-SR). The ILSS-I consists of 103 items that assess 12 areas of basic community living skills. The ILSS-SR has 70 items that cover 10 different domains: personal hygiene, appearance and care of clothing, care of personal possessions and living space, food preparation, care of personal health and safety, money management, transportation, leisure and recreational activities, job seeking and job maintenance. Participants are asked to indicate by a 'yes' or 'no' response whether they had performed a specific task in the past month. The ILSS-SR takes approximately 20 to 30 minutes to complete[24].

INFORMANT RATINGS

ADL

Some patients, such as in Alzheimer's disease, may not be able to complete a self-report measure. In such cases, an informant provides information on life skills. Typically, the informant is a spouse, an adult child, or a caregiver who spends at least two days a week in direct contact with the patient. The Katz activities of daily living (ADL) index is one of the more widely used informant-rated measures. Caregivers rate the patient's level of dependence on others in six different areas: bathing, dressing, toileting, transferring, continence and feeding. A zero score indicates complete independence, while a three is complete dependence. Slightly more sensitive than the Katz is the Barthel index, which uses 10 different categories. In addition to the six categories used in the Katz, the Barthel index divides toileting into bladder and bowel control and adds walking, stair climbing and grooming. Higher scores are assigned to those with higher levels of independent functioning, for a possible total of 100 points[26].

IADL

The Instrumental Activities of Daily Living Scale (IADL) covers the more complex instrumental activities that are needed to live independently. The IADL evaluates ability to use a telephone, shop, prepare food, keep house, do laundry, use transportation, take medication and manage finances. Typically, women are scored on all eight domains, while for men, food preparation, housekeeping and laundering are sometimes excluded[27].

RIL

Another example of an informant-completed measure is the Record of Independent Living (RIL). The informant rates the patient on the categories of activities, communication and behaviour. Ratings for activities range from 0 (no change when compared to previous competence) to 4 (patient no longer performs this activity) with allowances for 'don't know' or 'not applicable.' Similarly, ratings for communication range from 0 (no difficulty) to 4 (no longer performs this function). The behaviour section consists of a checklist on which the informant indicates whether specific problem behaviours were present before the illness and whether they are currently present[28].

CLINICIAN-RATED

GAF

The Global Assessment of Functioning (GAF) describes a person's overall psychological, social and occupational functioning. It is used as Axis V in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition and consists of 10 'ranges of function' that total 10 points each, for an overall possible score of 100. A perfect score indicates superior functioning, while a score of less than 10 indicates 'persistent danger of severely hurting self or others, or inability to maintain minimal personal hygiene, or serious suicidal act with clear expectation of death'. The GAF co-mingles functional impairment and psychiatric symptoms and so it is not a 'pure' measure of functioning as is the ILSS[25].

OBSERVATION

SAFE

The Social Adaptive Functioning Evaluation (SAFE) was developed for a geriatric psychiatric inpatient population to evaluate social-interpersonal, instrumental and life-skills functioning. This 17-item scale is scored using observation, caregiver contact and interaction with the subject. These items assess self-care, social competence and adjustment and miscellaneous skills such as impulse control and cooperativeness. Items are rated on a 5-point scale with higher scores reflecting greater impairment. This scale is useful because the patient can be rated regardless of their cooperation or responses[29].

MOSES

The Multidimensional Observation Scale of Elderly Subjects (MOSES) is an observation-based measure that can be completed by nurses or staff at residential facilities. It consists of 40 items that measure five different areas of functioning related to life in a residential facility: self-care, levels of organization, depressed and anxious mood, irritability and behavioural withdrawal. There is also a briefer 24-item version[30–32].

PERFORMANCE-BASED MEASURES

UPSA

The UCSD Performance-Based Skills Assessment (UPSA) uses role-play tasks to examine five areas of everyday functioning including household chores, communication, finance, transportation and planning recreational activities. Patients are asked to plan a trip to the beach, write a cheque, read a bus route map, complete a shopping list and call a doctor to reschedule an appointment. It typically takes about 30 minutes to administer and includes several props such as grocery items, maps and a telephone. The UPSA has shown excellent reliability as well as strong convergent validity and good criterion validity with real-world outcome measures[33]. Also available is the UPSA-Brief, which includes only the communication and finances sections of the original UPSA. The UPSA-Brief and UPSA show high levels of convergence in predicting real-world functional outcomes.

MMAA

The Medication Management Ability Assessment (MMAA) also uses role-playing tasks, specifically focused on assessing a patient's ability to manage a moderately complex prescription medication regimen similar to one an older adult might typically encounter. The interviewer shows the patient four standard prescription pill bottles with mock labels and filled with differently coloured dried beans. The labels read: Parlenol: Take 2 tablets twice a day with food; BRB: Take 1 tablet 3 times per day; Cyclomeovan: Take 2 tablets three times a day on an empty stomach (i.e. at least 1 hour before or 2 hours after a meal); and Linophen: Take 2 tablets 4 times a day. The interviewer then removes the bottles and an hour later the interviewer asks the participant to 'walk' verbally through his or her day, handing the interviewer the appropriate type and number of pills at the appropriate times. Scores are based on the total number of correct responses for a possible total of 25 points. The number of pills over and under the prescribed amount is also scored. The MMAA has excellent test–retest reliability and good construct validity, with scores significantly correlated with two other performance-based measures of functionality[34].

SSPA

The Social Skills Performance Assessment (SSPA) is designed to measure everyday social skills. This performance-based measure consists of two role-playing tasks, each lasting three minutes. In the first task, the interviewer plays a new neighbour and the participant's goal is to initiate an acquaintance with the new neighbour in a 'friendly and informative manner'. In the second task, the participant plays a tenant who must contact his or her landlord (played by the interviewer) to discuss a leak that needs to be repaired immediately. Each scenario is scored from 1 (low) to 5 (high) on various factors including: interest/disinterest, fluency, clarity, focus, affect, grooming, social appropriateness, overall conversation, negotiation ability, submission/persistence and overall argument. The entire measure takes about 20 minutes to administer[35].

SUMMARY

We have described a general approach to assessing life skills in older people with psychiatric disorders, an integrative model linking the determinants of functioning with each other and specific instruments that cover multiple modalities. The best approach to measuring functioning integrates multiple assessments modalities in different contexts and uses both subjective and objective data obtained from the patient, family or other proxy informants and direct observation. The use of instruments validated in geriatric populations, such as the ones we have described, will increase the reliability and interpretability of assessment. As the focus of psychiatric care shifts from symptoms to broader functional outcomes and recovery, expanding the evidence base for functional assessments will become all the more important.

Quality of Life Measures in Old Age

Juanita Hoe, Martin Orrell and Gill Livingston

Department of Mental Health Sciences, University College London, UK

INTRODUCTION

The maintenance of physical and cognitive functioning and the avoidance of disease are associated with well-being and quality of life (QoL) in old age, as poor health can lead to loss of control, autonomy and independence[1,2]. Traditionally, outcomes of treatment have been evaluated in terms of mortality or symptoms, but a more important outcome measure may be the patient's perspective, as symptoms may improve in one area while overall quality of life decreases because of the negative effects of treatment[3]. The emergence of QoL as a fundamental measure for evaluating and monitoring health outcomes in old age is attributed to the ethical and economic concerns associated with the ageing population and the concomitant increase in chronic illness and disability. Birren and Dieckmann[4] identify three main areas of concern associated with this increase: (i) the impact on health service resources and the potential financial burden anticipated; (ii) the intrusive use of medical technologies; and (iii) the QoL for people in institutions. In chronic illness, people can suffer from both the disability and the treatment[5]. Moreover, treatment can often result in limited gains in terms of survival, or absence of cure, which changes the balance as to acceptable side effects. Aggressive interventions may have therapeutic benefits that are overshadowed by the negative effects, thus leading to reduced QoL overall. Any detrimental impact on QoL needs to be weighed against the advantages offered through treatment[6]. It is the individual's perception that predicts whether they seek help, accept treatment or regard themselves to be well and recovered, and therefore, should be part of any outcome measures[7]. Thus, subjective health measures can be used to help provide a fuller picture of the individual's health state.

THE MEANING OF QoL

The term quality of life is used frequently in everyday life, with most people assuming they know what it means without considering how to define or measure it. In terms of health, QoL has become a popular, broadly used expression that is frequently taken for granted without the meaning being clear. There is debate about the true definition and meaning of QoL, particularly whether ratings should be objective or subjective, what criteria should be used and what is actually being measured, 'the quality of an individual's life, state of life, or the meaning of life in general'[8]. QoL is argued to be less related to basic needs than to individual expectations and experiences of life, which include individual perceptions of well-being, happiness, goodness and satisfaction with various aspects of their lives and environment[9–11]. What is apparent is that QoL is a multidimensional concept 'just as is life itself'[12]. A wide range of domains is suggested for inclusion as QoL indicators, including physical and mental health, intellectual and emotional function, social and role function, activities of daily living, economic aspects, and job and life satisfaction[13–15]. The expression QoL may also overlap with the terms 'health status' and 'functional status', and have been considered interchangeable[16]. Perceptions of well-being may, however, be influenced by psychological factors unrelated to health or function[17].

DEFINITIONS AND CONCEPTUALIZATIONS OF QoL

There are several meanings of the term QoL, which remains a vague, elusive concept for which there is no single widely accepted definition. The definitions provided are broad and varied; indeed, there may be as many QoL definitions as there are people[18]. QoL is viewed as 'a concept which incorporates all aspects of an individual's existence'[19] and as 'an abstraction which integrates and summarizes all those features of our lives that we find more or less desirable and satisfying'[20]. The inclusion of the terms life satisfaction, morale and happiness are debated but may be considered to be transient states which should be distinguished from QoL as they differ in their degree of subjectivity[21]. Alternatively, life satisfaction, self-esteem and physical health are argued to be key dimensions of QoL[22]. Lawton[23] defines QoL as 'the multidimensional evaluation, by both intrapersonal and social-normative criteria, of the person–environment system of an individual in time past, current and anticipated' and hypothesizes four dimensions of QoL: behavioural competence, perceived QoL, objective environment, and psychological well-being. Each sector is intrinsic and considered core to the concept of QoL and also interlinked. Fundamentally, QoL is perceived as being continuous and dynamic in nature and may be evaluated negatively or positively depending on the individual's own internal perceptions and response to their environment.

HEALTH-RELATED QoL

Within the context of health, QoL is defined as a reflection of patients' perception and response to their health status and to other non-medical aspects that have an impact on patients' lives, and within health-related quality of life (HRQoL) this includes physical,

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

psychological and social perspectives[24,25]. This definition is in keeping with that given by the World Health Organization Quality of Life Group (WHOQOL), as 'the individuals' perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns'[26]. This broad description encompasses the complex nature of the person's physical, psychological and social well-being in relation to their environment. The recognition of cultural factors is particularly important when considering the QoL of the ageing population and especially those people with dementia. Memory impairment is not regarded as so important in all cultures[27]. Similarly, functional disability may seem less important in cultural contexts where independence and autonomy in activities of daily living are a less central part of the older person's role[28]. Older people are frequently marginalized as society holds a negative view of their QoL, and health and social research tends to focus on decline and disability[29]. There are, however, both positive and negative elements that impact on an older person's QoL, and Hughes[30] identifies the key domains that should be evaluated when measuring older people's QoL. These include physical environment, social environment, socioeconomic, cultural and health status, personality and personal autonomy factors.

MEASURING QoL IN HEALTH

Lerner[31] argues that 'health is more than just a biomedical phenomenon; it involves a social human-being functioning in a social environment with social roles they need to fulfil'. The use of QoL as an outcome measure focuses the impact of the patient's condition and treatment on their emotional and physical functioning and lifestyle[3]. Hence, health-related QoL has become important in measuring the impact of chronic disease[16]. This is of particular significance as patients with the same clinical symptoms often differ in their evaluation of what the illness means to their life. The term 'disability paradox' is used to describe how patients with significant health and functional problems frequently have high QoL scores despite their health status[32]. QoL measures can be used to evaluate human and financial costs-benefits of interventions and care provided through assessing change in physical, functional, mental and social health[33].

Calman[34] suggests that people perceive QoL in relationship to their past experiences, current lifestyle, hopes and ambitions for the future. QoL measures the gap between the individual's present experience and their expectations for the future. QoL can therefore be improved by narrowing this gap, either by improving experience or lowering expectations[34]. Importantly, the model recognizes the highly individual nature of QoL and the influence of culture and past experience[35]. Carr *et al*.[36] further propose a model of the relation between expectations and experience and identify three areas of difficulty in measuring QoL: people have different expectations; people are at different stages of their illness when QoL is measured; and expectations may change over time. By providing health education, information and increasing awareness of risks, patients are helped to adapt to their disability through changing their health expectations. The impact of the disability on their QoL may thus be reduced[36].

SUBJECTIVE AND OBJECTIVE DIMENSIONS OF QoL

Testa and Simonson[33] recommend that measures of QoL should cover the objective and subjective components important to the relevant patient group that may be affected positively or negatively

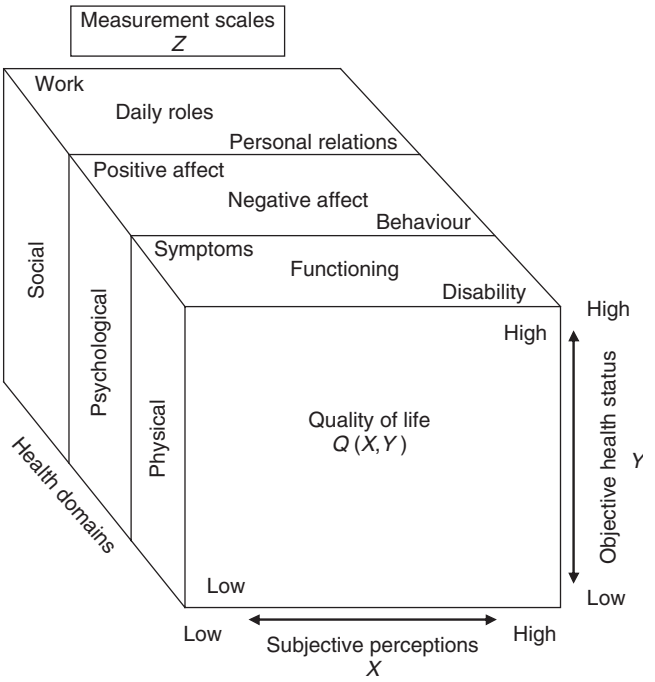

Figure 35.1 Conceptual scheme of the domains and variables involved in a QoL assessment

by interventions. Objective factors are primarily needs based and incorporate basic needs that determine people's well-being in society, such as environment and material resources, including levels of income, crime, pollution, transport, housing type, access to amenities and employment[2,37]. Subjective factors include life satisfaction and psychological well-being, morale, individual fulfilment, happiness and self-esteem, and are expressed in terms of satisfaction, values and perceptions of individual life circumstances[1]. While health status is defined through the objective components, QoL is determined through subjective perception and expectations (Figure 35.1)[33]. The subjective perceptions thus translate that objective assessment into the actual QoL experienced.[33] Nevertheless, Bowling[3] cautions that subjective measures are not designed to be used as substitutes for traditional measures of clinical endpoints but to complement existing measures and provide a fuller picture of health state.

Variation among QoL scales is often due to the different emphasis placed on objective and subjective dimensions, which domains are covered and the question format rather than differences in how QoL is defined[33]. The overall satisfaction an individual has with life is argued to be the most important domain of QoL[2,38]. This means the importance of the individual's personal sense of satisfaction with various areas of life is recognized; these include physical comfort, emotional well-being and interpersonal connections[38].

VALIDITY AND RELIABILITY

QoL scales should be able to demonstrate validity but this is complicated as there is no measure of criterion validity: no scale can provide a full picture of people's life quality or be relevant to all

individuals[33,39,40]. Content validity includes evaluation in terms of the applicability of the questionnaire and its comprehensiveness, as well as its clarity, simplicity and likelihood of bias[41]. Scales should also have predictive validity, sensitivity and be responsive to change in QoL, particularly for clinically important changes[3,33,42,43]. This ensures the areas relevant to the patient's QoL are measured and that scales are responsive to the different stages of the disease and interventions or treatment given. Orley *et al.*[44] argue that QoL is influenced by a broad range of facets and is therefore unlikely to alter markedly from day to day. Fallowfield[45] recommends that QoL measures should discriminate between patient groups and identify those patients experiencing good QoL and those who are not. In addition, QoL measures used in clinical practice must be appropriate and acceptable for their intended use and the results meaningful and amenable to clinical interpretation[43].

GENERIC VERSUS DISEASE-SPECIFIC MEASURES OF QoL

Generic as opposed to disease-specific instruments offer broader measures of health status and are useful for making comparisons with other conditions, while disease-specific instruments are used for assessing disease-related attributes when greater sensitivity to specific aspects of the clinical condition is required[3,33]. Generic measures include single indicators, health profiles and utility measures. Health profiles attempt to measure all aspects of health-related QoL potentially affected by a condition or its treatment. Thus generic instruments tend to be lengthy to ensure sensitivity and adequate psychometric properties[3]. They can be applied irrespective of the underlying condition but may be unresponsive to changes in specific conditions. Disease-specific instruments aim to have greater discrimination between severity levels of a particular disease and thus have increased sensitivity to clinical outcomes[44]. They are more concise and should be able to reflect clinically significant change in health status or disease severity. Therefore in order to detect significant clinical changes, generic measures may need to be supplemented with disease-specific measures[16], particularly for evaluating therapeutic interventions within clinical trials[33]. The use of disease-specific measures may, however, be limited as their narrow focus may not assess the impact of disease or interventions upon wider aspects of life, which could disadvantage arguments for additional resources[24,46].

Essentially the use of both generic and disease-specific measures is recommended to ensure assessment of both disease-specific and wider aspects of life and to detect positive or negative impacts of interventions[3,16,24].

METHODS OF QoL MEASUREMENT

Self-Assessment Scales

The use of visual analogue scales is a common method for measuring subjective experiences such as QoL[47]. They are, however, time consuming to complete and may not be relevant to the experience being considered[45]. Self-reports are obtained using standardized measures that have response formats with closed questions in a categorical dichotomous format (e.g. yes/no) or sequences of categorized responses (e.g. strongly agree, agree, disagree, strongly disagree). Standardized measures have fixed questions and a range of answers; Carr and Higginson[32] caution that these may not measure patients' QoL unless scores are weighted for the individual patient. Individual weightings are important for obtaining a true assessment of QoL and being responsive to change. Scores may be calculated for each domain separately or combined to provide a composite or index score of overall life satisfaction. The disadvantage of scales that are calculated to produce an overall score is that the total may result from several combinations of responses, thus leading to a loss of information about the individual components of the scale[48]. Muldoon *et al.*[17] and Lawton[49] both argue that the use of a composite score fails to recognize QoL measures as being multidimensional and that it is illogical to aggregate scores that combine appraisals of objective measures of behaviour, function and subjective well-being; and there is a need to evaluate individual domains separately within research and clinical practice[12,30,49]. Alternatively, Gill and Feinstein[25] advocate the use of a global rating through aggregating the scores of individual QoL domains as this explains QoL more comprehensively, and they encourage more explicit criteria or weighting of the different components that construct QoL. Furthermore global ratings have been considered more acceptable for use in clinical trials as change in QoL could be more easily distinguished.

Direct Observation

Where self-ratings of QoL are difficult to elicit, such as in dementia, observational ratings may be of more benefit[50–52]. Observational methods are undertaken either through direct observation of the person with dementia, which records the frequency at which certain behaviours present, or by applying attribute ratings of observed affect states over time. Direct observation is time consuming and costly but, it has been argued, provides the most objective method of rating QoL in dementia as the subjective component is removed[49,53]. Observation requires a degree of interpretation by the rater and training to reduce any influence on the behaviour observed. In addition, multiple observations of the same individual are needed to achieve a consistent result and cannot be limited to the 'working day' of the observer[54]. Observational tools have, however, been devised that can be used to reliably measure health-related QoL and well-being in people with dementia[55,56], with Dementia Care Mapping[56] being increasingly used to assess the well-being of people with dementia in care settings. Well-being scores were found to be closely associated with QoL[57].

Proxy Ratings

Proxy ratings involve a judgement of the person's QoL being made by another person to whom they are known and may be provided by a paid or family caregiver. Proxy reports may be the only source of information available, particularly for those people with the most severe levels of cognitive impairment[58]. Proxy ratings have been shown to be a reliable and valid indicator of patient QoL[59,60]. Nevertheless, proxies impose their own judgement, and in dementia these are thought to be influenced by feelings of caregiver burden and depression as well as by how the person with dementia is feeling[59,61]. Moreover, QoL is consistently rated lower by caregivers than by patients with mild to moderate dementia[62–66]. While proxy ratings may be considered necessary where cognitive impairment exists, the inclusion of the individual's own rating of QoL is the preferred method for assessment, as QoL ultimately reflects the experience of the person with the disease[67,68].

Utility Assessments (Cost-Effectiveness)

Utility measures of QoL originate from economic and decision theory and are devised to reflect the health status and value of that health status to a patient[16], to assess cost-effectiveness in health care. When applying utility measures, values are placed on different health states, and the preference of a particular health outcome is determined through calculating a single summary score[3]. A common utility measure is quality adjusted life years (QALY), which are used as indicators of health gain for health service resource allocation. QALYs integrate two concepts, life expectancy and life quality, that offer a mathematical outcome for rationing the allocation of health service resources[8]. Although offering a utilitarian argument for determining the greatest health gain for the greatest number, QALYs are criticized as being ageist and for focusing on cure rather than care and their use marginalizes the most disabled, elderly and chronically ill[48]. Older people have a shorter life expectancy in comparison to younger people. A further criticism of using QALYs is that the 'disability paradox', where QoL scores do not appear commensurate with the patient's health status, prevents direct comparisons of different patient groups for allocating resources[43]. There are, however, other measures of cost-effectiveness that consider the cost per unit of health gain and do not involve years. Cost-utility ratios are being calculated in some trials in dementia using utility scores computed from the EQ-5D and societal weights. The National Institute for Health and Clinical Excellence (NICE) now uses cost-effectiveness in consideration of all interventions in the UK[69].

MEASURING QoL IN OLDER AGE

Early studies identify retirement, bereavement, loneliness and isolation as important influences on older people's lives[70], whereas, more recent studies found that older people define good QoL as family, social contacts, health, mobility/ability, material circumstances, activities, happiness, youthfulness and living environment[71]. Hyde *et al.*[72] argue that the improved health and financial status of older people means the lives of older people have changed over recent decades, with increased healthy life expectancy and access to personal incomes, such as private pensions, share dividends and rent. The QoL of people entering old age who are younger, healthier and wealthier will differ from those much older people who are more likely to experience chronic and degenerative ill health or require palliative care. Not all older people can be assumed to suffer poor QoL and while health status is an essential component of QoL, it cannot be used as a proxy for QoL in older age[72]. Individual perceptions are therefore essential in assessing health-related QoL in people of all age groups. Magaziner[73] reported that a fifth of older adults living in the community and half of those living in institutions are reluctant or unable to be interviewed. In contrast, Livingston *et al.*[74] administered the Index of Health-Related Quality of Life (IHQL)[75]

Table 35.1 Generic quality of life instruments for use with older people

QoL measure	*Target population*	*Respondent*	*Item no.*	*Domains*	*Single score*	*Time taken*
EQ-5D EuroQol Group[96]	General	Self-report	5	Mobility Self-care Usual activities Pain/discomfort Anxiety/depression	Yes	5 mins

DEMQOL Smith *et al*.[99]	Mild/moderate dementia MMSE $\geq$ 10	Self-report	28	Health Well-being Cognitive functioning Social relationships Self-concept	Yes	Not specified

to a community sample of 782 older people aged 65 years and older. Their study found that three quarters of the respondents were able to complete the IHQL and the other measures used; interestingly, this included those people with dementia. Those experiencing somatic symptoms or subjective memory impairment were less likely to complete the questionnaires. They found that the scale was not valid in older people. Pettit *et al*.[76] administered the 12-item Health Status Questionnaire (HSQ-12)[77] or the 12-item Short Form Health Survey (SF-12)[78] to a community sample of 1 085 older people over 65 years of age. They found that both Health-Related QoL measures were acceptable and valid for use within this population. Completion rates were lower in those people with dementia and the SF-12 was found not to distinguish between people with and without dementia. It is clear, therefore, that most older people and those experiencing dementia are able to complete instruments assessing their own QoL.

MEASURING QoL IN MENTAL ILLNESS

Orley *et al*.[44] discuss the use of QoL measures in psychiatric patients and consider how QoL ratings may be affected by the impact of the disorder through disturbed affect or thinking and through institutionalization. While psychiatric symptoms such as depression may affect a person's QoL, they do not distort it or make their perceptions invalid. In addition, while institutionalization may mean psychiatric patients perceive a good QoL due to lowered expectations, their assessments are still valid. Proxy ratings for patients with cognitive impairment may be useful for planning and evaluating care, but they should not be taken as a measure of perceived QoL[44].

MEASURING QoL IN DEMENTIA

The nature of dementia, which affects cognition and communication, means assessing QoL in dementia offers a unique challenge. The progression of dementia is non-linear; dementia has multiple causes and outcomes and is a complex disorder when compared with other health states[46]. Difficulties are routinely assumed in people with dementia providing subjective assessments of their QoL or care, owing to limitations with comprehension and reliability[79]. Providing an answer does not mean that the question is necessarily understood, and QoL may also be perceived differently as the disease progresses[80]. However, it is logical to assume that people with dementia will have likes and dislikes[55]. Even in the most severe dementia it is possible to display preferences and aversions through emotional expression. Lawton[49] reasons that although subjective measures demand a degree of cognitive skill, people with dementia can provide reliable assessments of their mood and QoL. The patient's subjective ratings of QoL are suggested as the gold standard for measuring QoL.

Several studies have now shown that QoL can be reliably measured in people with mild, moderate and severe dementia using self-rating QoL scales[51,61,81,82]. However, there are differences in QoL ratings as given by caregiver proxies and those given by the person with dementia[62,83–86]. Clinicians should be aware that proxy ratings do

not necessarily replicate the QoL views of the person with dementia, and should not be substituted for self-ratings.

Few studies have employed QoL as an outcome measure for interventions in dementia and at present the evidence is not consistent, possibly due to the variety of measures used. Studies have indicated both an increase and a decrease in QoL as dementia advances[65,87,88]. Some studies that have identified cognition and dementia severity as a predictor of QoL in dementia[59,89] were based on caregiver proxy ratings of the person, although more recent studies found caregiver proxy ratings of QoL were strongly associated with depression, disability, and neuropsychiatric symptoms of the person with dementia[64,83,84,90,91]. Depressive symptoms have most consistently been identified as a predictor of lower QoL in dementia[59,62–64,66,81–84]. A review of recent studies of QoL in dementia found that depression was most strongly associated with lower QoL in dementia, but found no consistent association between lower QoL and sociodemographic factors or a decline in cognition and functional ability[92].

Health Questionnaire

English version for the UK
(validated for Ireland)

By placing a tick in one box in each group below, please indicate which statements best describe your own health state today.

Mobility
- I have no problems in walking about ❑
- I have some problems in walking about ❑
- I am confined to bed ❑

Self-Care
- I have no problems with self-care ❑
- I have some problems washing or dressing myself ❑
- I am unable to wash or dress myself ❑

Usual Activities (*e.g. work, study, housework, family or leisure activities)*
- I have no problems with performing my usual activities ❑
- I have some problems with performing my usual activities ❑
- I am unable to perform my usual activities ❑

Pain/Discomfort
- I have no pain or discomfort ❑
- I have moderate pain or discomfort ❑
- I have extreme pain or discomfort ❑

Anxiety/Depression
- I am not anxious or depressed ❑
- I am moderately anxious or depressed ❑
- I am extremely anxious or depressed ❑

CHOOSING A QoL MEASURE

There are a broad range of QoL scales that may be used for people with psychiatric disorder[3,93] and for older people[42,94]. The evidence for the validity, reliability and acceptability of generic QoL scales with older people is mixed, although their use is encouraged within research and clinical practice to promote evidence-based health care[1,42,74,94,95]. Table 35.1 gives some examples of generic scales[72,77,78,96] that have been used in studies involving older people with mental health needs[76,97,98]. Haywood *et al.*'s[42,94] review of QoL measures in old age found the SF-36 showed the best reliability and recommended its use where a comprehensive assessment of health is required in older people. Alternatively, the EQ-5D[96] (Figure 35.2) is recommended where a briefer assessment is needed and significant changes in health are anticipated[42,94].

Table 35.2 gives examples of disease-specific QoL scales in dementia[51,61,88,99,100]. Each of the disease-specific QoL scales has been included in previous literature reviews examining the validity and reliability of QoL scales in dementia and their use is supported[68,80,101–105]. The QOL-AD[61] (Figure 35.3) is the preferred measure of choice, as it is brief and has demonstrated sensitivity to psychosocial interventions[101]. However, none of the reviews conclusively identifies a QoL scale for use with people with dementia, and Schölzel-Dorenbos *et al.*[102] state that no QoL scale can be used across all stages of dementia.

Overall, QoL measures should be brief, easy to use, valid and reliable, sensitive to change and useful for both clinical and research settings. In dementia these should where possible include both patient and proxy ratings. It is also possible to generate QALYs from the scores of some QoL scales such as the SF-12, EQ-5D and DEMQOL, to provide an economic evaluation.

CONCLUSION

Within health, HRQoL provides a global measure of well-being in patients and is an appropriate outcome measure for the assessment of disease impact and interventions provided to older people. Moreover, in chronic and disabling disorders where symptomatic and functional recovery is unrealistic, improving quality of life is a particularly worthwhile outcome. QoL is now an established outcome measure for older people and should be routinely included within studies evaluating the effectiveness of care and treatment. Further evidence is needed to show how interventions influence QoL provided to older people with mental health needs. The research undertaken in recent years has established the validity and reliability of a number of QoL measures for use with older people, particularly within dementia. Where possible the individual's perceptions should be sought in preference to the views of others, and this may offer a challenge to health professionals working with older people experiencing increasing physical and mental frailty.

Delirium

Barbara Kamholz

Department of Psychiatry, Duke University, USA

INTRODUCTION

Delirium is prevalent, dangerous and costly. It is caused by medical or surgical problems and medication burdens that are beyond the physiological tolerance of the patient. Delirium costs between $38 and $152 bn per year[1]. In ICUs, episodes of delirium average 39% higher ICU costs and 31% higher hospital costs[2]. Long considered a reversible epiphenomenon of hospital care, delirium is an independent risk factor for death and dementia[3] and it contributes heavily to lengths of stay, in-hospital complications, and new institutionalization. Deliriums that are more severe or persistent have even more dire outcomes[2]: 22–76% of hospitalized inpatients with delirium die[4]. Delirium occurs in 15–60% of nursing home patients, 14–56% of inpatients and up to 60–80% of ICU patients[5]. Yet delirium can be prevented or mitigated in health care settings that understand it, diagnose it and implement interdisciplinary programmes across the health care spectrum to address it, and there is considerable economic potential in doing so. Progress in the field has been seriously hampered by difficulties with diagnosis; up to 95% of cases are missed[6].

PRESENTATIONS, PHENOMENOLOGY AND IDENTIFICATION OF DELIRIUM

Delirium is misdiagnosed in all settings, including emergency rooms, hospitals, and long term and palliative care settings. The clinical presentation of delirium remains a 'black box'; as of this time we have no explanations for the variations in behavioural, affective, sensory and motor signs of delirium. These signs can change within seconds or hours, and most likely reflect the complex underlying pathophysiologies. The DSM IV-TR diagnostic criteria are shown in Table 36.1[7].

Many rating scales have been developed to assist with the diagnosis, the most widely used including the CAM[8] and CAM-ICU[9]. Inattention and the broad fluctuations of symptoms are characteristics not found in other psychiatric illnesses. At the same time, they are the most difficult to measure and identify. Attention is a complex phenomenon that involves distractibility, vigilance and concentration, and is our most basic interface with the environment. Unless patients are grossly agitated and irrational, the clinical expression of inattention can be very subtle. It is easily mistaken for the withdrawal and lack of environmental engagement found in depression. Fluctuations, unless they are marked, are often written off as fatigue, uncooperativeness, withdrawal, differing responses to different health practitioners, or reactions to procedures. Given changeovers of physicians and nurses in busy hospitals, such indefinite characteristics go largely unrecognized unless staff nursing notes are carefully mined for evidence of these subtle changes. Nurses are the first to recognize early symptoms of delirium, although they do not reliably diagnose it as such, and are a rich source of descriptive information that can greatly assist with diagnosis[10].

Broadly accepted subcategories include 'active', 'mixed', and 'quiet' delirium. These subcategories may have implications for prognosis or pathophysiology. Significant investigation of these subtypes has been done, although these have not yet provided clear implications for causality, prognosis or intervention. Active delirium is defined as a state marked by agitation, physically aggressive and often violent activity, hyperattentiveness (the inability to suppress responses to the environment or to internal states) and emotional lability. In this condition, deficits in focused attention and fluctuations of presentation are easily identified. Quiet delirium is defined as a state marked by withdrawal, lack of involvement in or communication with the environment, bland or flat affect, and a depressed level of consciousness short of frank stupor. These symptoms reflect an inability to attend appropriately and in sequential fashion to the demands of the environment. Mixed deliriums are considered to be a combination of the two. The prevalence of these subtypes is variably reported but averages 25% for quiet delirium, 45% for mixed delirium, and 30% for active delirium. All subtypes of delirium can present with motor symptoms (dysarthria, difficulty swallowing, gait disturbances), affective symptoms (dysphoria, lability, anxiety), sensory difficulties that are associated with incorrect cerebral processing of sensory data (clinically expressed as difficulties with hearing, appreciation of pain), and illusory phenomena, aphasia (partial or global) and impaired cognitive function (dysexecutive function, disorientation, nonsensical speech). Any of these symptoms may fluctuate, even within seconds. The appreciation and reporting of pain by the delirious patient is particularly problematic, as untreated pain can worsen delirium, yet overtreatment with narcotic agents can have the same result. Psychotic-like symptoms such as disorganized speech and visual hallucinations may also be associated, although the hallucinations in delirium are more illusory than hallucinatory. They commonly involve nonsensical images such as 'clowns on bicycles' or 'tires in the ceiling'. The differentiation of delirium from prominent psychotic illnesses, including schizophrenia, schizoaffective disorder and bipolar disorder, can be problematic. Pre-existing psychiatric diagnoses are a principal cause of poor identification of

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

Table 36.1 DSM-IV-TR diagnostic criteria for delirium

A. Disturbance of consciousness (i.e. reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
B. A change in cognition (e.g. memory deficit, disorientation, language disturbance) or
C. Development of a perceptual disturbance that is not better accounted for by a pre-existing, established, or evolving dementia.
D. Disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
E. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition.

delirium, as the patients' symptoms are often attributed to them[11]. In these cases, reliance on clues from the patient's clinical history is critical. Quietly delirious patients are frequently misidentified as depressed. Farrell and Ganzini[12] found that 42% of patients referred to psychiatry consultation services for depression were actually delirious. However, an additional finding was that 60% of patients with delirium have symptoms of dysphoria, and 52% have passive or active thoughts of suicide. Acutely 'suicidal' patients suffering with prolonged hospitalizations and multiple medical problems are prototypically confusing. In such cases, the burden of risk and need for immediate medical intervention rest with delirium rather than depression.

A further consideration is that symptoms of delirium present along a spectrum. Evidence for the existence of subsyndromal delirium has been presented by Levkoff *et al*., among others[13]. Marcantonio *et al*. found that patients with subsyndromal delirium had worse outcomes than patients with diagnosable mild delirium[14].

The recognition of delirium remains one of the most prominent problems in the field. The term 'recognition' includes not just diagnosis of the medical condition of delirium, but also the recognition that it is a severe illness that cannot be assumed to resolve on its own with few sequelae. Recent appreciation of this has led to skyrocketing numbers of publications in the field in recent years[15].

THE ETIOLOGY OF DELIRIUM

Population at Risk

A multitude of risk factors have been identified in treatment studies of delirium, often with little overlap. However, most would agree that age, cognitive impairment, medication and medical burden define the characteristics of the population at highest risk[2]. Efforts to advance the field by seeking universal 'causes' of delirium have therefore been very frustrating. It is easiest to conceptualize the aetiology of delirium from the perspective of the syndrome of frailty. Frailty has many definitions, but on a physiological level its most commonly accepted conceptualization is sarcopaenia, or progressive deterioration of skeletal muscle[16]. It is usually found in patients who are older, cognitively impaired and medically ill, and in fact the majority of patients who develop delirium are frail. Some investigators provide a broader view of the components of frailty by including socioeconomic stressors, psychiatric disorders, medication and home environment as well as medical vulnerabilities, which reference the broad network of resources that frail geriatric patients require to avoid catastrophic illness[17]. The increased vulnerability of frail patients to the catastrophic decline represented by delirium is related to their limited physiological reserve. With ageing, there is diminution of redundant systems such as neurons and neuronal circuits in the brain and excess metabolic capacity in the liver and kidney. Patients with the least reserve are more susceptible to any stressor, however small, than healthier individuals, in a striking resemblance to chemical equations far from equilibrium. The implication is that the patient's underlying vulnerability and disequilibrated status (as opposed to any specific 'last minute' precipitating causes), are the most important predictors of delirium in an individual person. It is then easy to conclude that the prominent precipitating causes of delirium are the most common complications, including iatrogenic ones, found in hospitalized patients. A short list includes hyponatraemia, acute blood loss, pain, acute renal failure, fractures, acute infections (urinary tract or pulmonary), the use of longer term indwelling bladder catheters, dehydration, decubiti, malnutrition and the use of psychotropic medications[2].

Pathophysiology of Delirium

Historically, multiple interacting theories have been proposed to explain the pathophysiology of delirium. Any given delirium may have an unknown number of associated clinical conditions (baseline and precipitating factors), and they do not necessarily occur in the same combinations. It is only when the patient has recovered that there is any clinical certainty that the basic physiological process(es) have been fully addressed. However, many deliriums do not fully resolve. It is also not necessarily the case that two patients who appear to have equal degrees of baseline and precipitating stressors will both become delirious. This lack of reproducibility has wreaked havoc with our investigations of pathophysiology. We are left with broad-based geriatric clinical intervention methods that are helpful but quite non-specific, and this may account for some of our difficulty in making progress in the field.

At a cellular or molecular level, the most compelling evidence indicates that excess dopamine and/or insufficient acetylcholine in the brain could best explain the cascade of metabolic and behavioural complications of delirium. Each has complex and interactive impacts on cellular function within the CNS[18]. Impairments in neuronal membrane function appear to underlie much of the pathophysiology of delirium. Neuroimaging has recently been incorporated to evaluate structural and functional processes in the brain during delirium, although the findings are diverse enough that consistent trends have so far been elusive. Yokota and colleagues, using xenon enhanced CT, found that patients with delirium experienced a 42% reduction in overall cerebral blood flow compared to baseline; after recovery from delirium, the findings normalized[19]. Such findings may explain the multisystem deficits observed, which include cognitive, affective, sensory and motor function. There is not enough evidence at this time to determine whether structural correlates precede or follow delirium.

Major areas of exploration

Inflammation Inflammatory processes such as urinary tract infection, osteomyelitis and pneumonia, are highly associated with delirium. With ageing there is an elevated inflammatory profile[20]. Activated glial cells transmit peripheral inflammatory cytokine

responses to the CNS. This is associated with decreased synaptic plasticity, a necessity for the modulation of behaviour, learning and cognition[20]. Inflammatory states as well as hypoxia and hypoglycaemia are associated with impaired mitochondrial function; this might support a hypothesis that disturbed function of endothelial cells could alter the blood–brain barrier. Release of the inflammatory cytokines TNF-alpha and interleukin-1 generates adhesion molecules that disrupt cerebral vasculature, further impacting the integrity of the blood–brain barrier[20].

Extracellular glutamate in normal brain is quickly metabolized. However, in the presence of impaired mitochondrial function, hypoglycaemia hypoxia, and glucose, excess extracellular glutamate results in increases in cellular influx of Ca^{++}. This in turn leads to stimulation of NMDA receptors, which are excitotoxic[2]. Intracellular Ca^{++} appears to be the main trigger of a series of reactions, including mitochondrial injury and activation of catabolic enzymes that lead to cellular dysfunction and potentially death. During states of cerebral ischaemia, further cellular risk is posed by efflux of dopamine. Use of barbiturates, isoflurane and etomidate, common agents associated with anaesthesia, may mitigate these responses[2,21]. Few, if any, studies have linked the risk of delirium to the use of anaesthetic agents.

The acetylcholine hypothesis

Another principal theory involves decreases in the availability to brain cells of adequate amounts of acetylcholine (ACH). ACH is a fundamentally important neurotransmitter in areas serving attention and memory. Among multiple reports, surgical ICU patients with delirium had higher serum anticholinergic levels. A dose-related relationship was identified by Flacker *et al*.[22], who also identified higher levels of endogenous anticholinergic substances. A number of studies, although not all, have associated anticholinergic medications with delirium.

Impact of excessive dopamine

Another important hypothesis relates to increased extracellular dopamine. The influx of calcium into cells that occurs during hypoxic conditions in brain stimulates the activity of tyrosine hydroxylase. This results in increased production of dopamine, with resulting disruption of ATP production. Decreases in the production of ATP and the increase in toxic metabolites of dopamine then inhibit cathechol *O*-methyltransferase, the main extracellular deactivator of dopamine. These processes collectively result in increased dopamine levels in brain, up to a factor of 500× during episodes of striatal ischaemia[5]. Further, dopaminergic neurons themselves are known to be highly susceptible to oxidative stress, which may result in massive releases of dopamine into the extracellular space[5]. Agents that increase available dopamine in the brain, such as stimulants, have also been associated with delirium. D2 blockers such as haloperidol are widely known to improve behaviour in patients with delirium, and possibly the syndrome itself.

Other neurotransmitters

The kinetics of neurotransmitters other than acetylcholine and dopamine are also highly sensitive to conditions of hypoxia and hypoglycaemia, as above. Disorders of release, synthesis and degradation of gamma-aminobutyric acid (GABA), serotonin (either in excess or insufficiency), as well as norepinephrine and glutamate, have been linked in various work to delirium[5]. Cerebral oxidative metabolism, as well as cardiovascular and respiratory reserves that support it, decrease with ageing[2].

Glycemic control

Decreased availability of inhibitory neurotransmitters, deposition of neutrophils and mitochondrial damage are associated with poor glycaemic control. Improved glucose control with insulin (specifically) improves the CNS outcomes of critically ill patients[21].

Molecular genetics

Efforts to link the presence of the *APOE4* variant of this gene, which has been well established in association with Alzheimer's disease, have resulted in mixed findings[2]. It has been associated with increased duration of delirium in ICUs. Polymorphisms in DRD3 and the dopamine transporter SLC6A3 are the most commonly polymorphisms associated with delirium tremens[20].

THE IMPACT OF FOCUSED INTERVENTION TRIALS ON RECOGNITION AND MANAGEMENT

A number of intervention programmes have been employed to address the severe long-term outcomes of delirium, which include death, dementia, increased lengths of stay, decreased function, rehospitalization and new institutional placement. These programmes have been studied in hospitalized patients; there are no published trials among outpatients. A number of these trials have found that they are not helpful for the primary outcome of a decrease in incidence[23,24]. Other studies have demonstrated decreases in severity and duration of symptoms of delirium in hospital, both of which have been significantly associated with worsened outcomes. Unfortunately the impact of these interventions on longer term outcomes has been mixed and overall disappointing[25]. In some cases this may be due to the limited time the patient is exposed to the intervention, e.g. when hospitalized as part of a pre-established protocol[14]. In light of this, most studies conclude that prevention of delirium is the primary clinical goal. In a prominent study published in 1999[26], a complex intervention that involved a significant amount of volunteer work as well as a very high level of nursing care was shown to significantly reduce length of stay, number of episodes and, finally, the incidence of delirium. This may have been due to the highly refined identification of risk factors in this population; Inouye distinguished baseline risk factors for delirium from risk factors for triggering of a new episode. Going forward, this two-phased risk assessment method has helped reshape our conceptualization of treatments for delirium by focusing on modifiable, new onset, precipitating risk factors. This innovation has improved our ability to intervene effectively in cases of delirium.

Marcantonio performed a highly organized and comprehensive geriatric medicine programme that also demonstrated a decreased incidence of delirium in post-hip fracture patients[14]. The work of both Inouye and Marcantonio, that has primarily focused on providing basic, but comprehensive care, has demonstrated that the interventions needed in delirium are most often not arcane or difficult to employ, and are largely inexpensive. These interventions highlight an effective level of geriatric care that could be attained in any institution.

DEMENTIA AND DELIRIUM

Delirium is often confused with dementia. A critical part of the diagnosis of delirium involves identifying that the mental status presented

by a patient is not the patient's baseline level of cognition and that a relatively rapid change has taken place. Delirium is an acute, catastrophic response to an inciting medical event. The evolution of dementia is significantly more gradual in most cases. Where there is doubt, it is safest to address the clinical situation as a delirium so that any precipitating causes are addressed as soon as possible. The differentiation of these two clinical problems is complex because the precipitating cause(s) of the delirium may not easily be temporally connected with the onset of the syndrome of delirium itself. Patients with delirium superimposed on dementia had more than twice the risk of mortality at 12 months than patients with delirium alone, dementia alone or patients with neither[27]. Assisted living facility residents classically have high rates of dementia and the relative risk of discharge of such patients back to institutional settings after an episode of delirium was 9.1[1]. There may be priming of the immune system as well. Patients with dementia are increasingly understood to have chronic inflammatory processes within the CNS. Acute systemic inflammatory processes that precipitate delirium may have been 'primed' by the underlying inflammatory process[20].

TREATMENT APPROACHES TO DELIRIUM

Priorities of treatment include addressing acute medical contributors to the syndrome as well as stabilizing patient behaviour sufficient to enable the treatment of underlying medical causes. The primary task of clinicians is to identify and address modifiable conditions. In this way the impact of relatively unmodifiable conditions (such as stroke, myocardial infarction end stage renal function etc.) can be minimized. Our effectiveness at treating delirium depends on the extent to which we can provide skilled and sophisticated nursing care that allows time for the multiple interventions required by elderly patients. Avoidance of iatrogenesis that can prolong the delirium is an essential part of this effort. Factors contributing to increased risks of delirium in hospital include the increased pace of health care settings, rapid and increasingly unstable discharges and remarkably limited amounts of time spent with patients. Housestaff may have as little as 3.5 minutes per day per patient[4]. Skilled nursing care alone could provide many of the most effective strategies for minimizing delirium, including mobilization, improvement of cognitive stimulation and minimization of the need for restraints. Up to 50% of cases of delirium can be prevented[4].

Pharmacological Approaches to Behavioural Stabilization

The use of restraints can worsen delirium, as can the overuse of certain medications. Use of benzodiazepines, while standard for obligate alcohol detoxification regimens and for sedation in ICUs, has nonetheless been found in most studies to carry a high risk of inducing or significantly worsening delirium[2]. There are few double-blinded, placebo-controlled, randomized trials of neuroleptics for behavioural management in delirium. Of all these agents, haloperidol remains the most studied. Haloperidol can be effective in low dosages, starting with 0.25 mg po or IM bid, and increasing to the 2–3 mg per day range only in severe cases. Risperidone in doses ranging from 0.5 to 4.0 mg daily and olanzapine in doses of 2.5–11.6 mg daily have been efficacious for the behavioural treatment of delirium with fewer extrapyramidal effects than haloperidol[2]. In addition, case reports or case series regarding quetiapine, aripiprazole and ziprasidone have been published with no randomized, double-blinded, placebo-controlled studies yet reported. There are very few such medication trials in the field.

Environmental Management for Behavioural Stabilization

Patients with delirium are unable to manage their environment, make appropriate decisions or care for their basic needs, and they cannot problem solve. Therefore, the environment has to adapt to them. Most studies agree that decreasing the complexity of the environment by limiting rotation of personnel caring for the patient, minimizing room changes, providing rest and quiet at night time, feeding the patient, providing a calming 'interpreter' such as a 'sitter' or family member to reorient and guide the patient, limiting distractions (loud conversation, beepers, overhead speakers, televisions, crowded areas), providing hearing aids and glasses, and providing clear-cut and step-by-step instructions are critical. Mobilizing the patient will minimize recovery time, and also may have modulatory impacts on recovering muscle after a critical illness[28]. Patients must be kept safe by limiting dangerous objects in their reach, avoiding falls and using assistive devices to limit the possibility of their pulling at lines or touching wounds. Complex protocols exist for the design of the treating environments that are beyond the scope of this chapter[14].

Treating the Causes

Acute medical conditions

The basic principle of treatment of delirium is to aggressively seek and treat the reversible causes of delirium and to mitigate those that have little room for modulation. Emphasis should be placed on illnesses that result in poor cerebral oxygen availability or that are associated with significant metabolic impairments. Elimination of infectious or inflammatory sources, addressing orthopaedic injuries and removal of offending medications are also essential (see below). Given that most cases of delirium occur in the most vulnerable patients, correcting the most common metabolic and infectious factors, such as serum bun, creatinine, sodium and calcium, and treatment of urinary tract infections and pneumonia are remarkably effective interventions. Identification of metabolic trends by graphing laboratory values can be very helpful to determine original causes as well as indicators of further decline or recovery. Head imaging is not helpful in the absence of focal findings[29].

Removal of offending medications

Removing offending medications, including opiates, anticholinergics, benzodiazepines and dopaminergics, is extremely important. Medications that alter the dopamine/acetylcholine balance within the CNS are a primary focus. A significant number of deliriogenic medications are found in commonly used medications, including digoxin, penicillin, amantadine, quinolone antibiotics, furosemide, nifedipine and warfarin. Further treatment of this topic is beyond the scope of this publication[2].

Pharmacological Approaches

Historically, medications have been used to address behavioural problems, but recent evidence indicates that there may be some gains in disease modification.

Neuroleptics

Recent work (see 'Pathophysiology of Delirium', above) suggests that the use of dopamine blockade is useful for disease modification. Agents that block dopamine have the potential to inhibit many neurotoxic events that occur in the presence of delirium, especially during conditions of hypoxia. Recent studies have focused on the usefulness of prophylactic antipsychotic use to diminish the incidence, severity or persistence of delirium. Kalisvaart was able to demonstrate decreased severity and persistence of delirium, although not incidence, among postoperative hip fracture patients by providing perioperative haloperidol use at 1.5 mg/day preoperatively and 3 days postoperatively. This was the first major study to demonstrate that pharmacological approaches could be used for disease modification[30]. In another randomized, placebo-controlled, double-blinded study of cardiac surgery patients, the incidence of delirium was quite significantly decreased when compared with placebo, even with a single dose of risperidone at 1 mg postoperatively[31]. The use of neuroleptics as preventative or mitigating agents in delirium is not widespread at this time.

Cholinesterase inhibitors

The use of cholinesterase inhibitors has been trialled in delirium. In a randomized, placebo-controlled, double-blinded study by Liptzin *et al*., the use was not found to have a significant impact on the incidence of delirium among young, relatively healthy patients undergoing elective hip fracture[32]. In a small retrospective study, a population of dementia patients chronically maintained on rivastigmine had significantly less incidence of delirium than a comparable, non-chronically medicated group[33].

Dexemedetomidine

The use of psychopharmacological agents to treat agitation in the ICU has been largely limited to propofol, which is an alcohol that is associated with hypotension and hyperlipidaemia, or to midazolam, which can suppress ventilatory effort and cause hypotension. Both have GABAergic effects that can worsen delirium. Fentanyl, an opiate IV for pain control and sedation, is also frequently utilized, either alone or in combination with propofol or midazolam, with attendant risks of dopaminergic/anticholinergic impacts. Dexemedetomidine, a very selective alpha-2 adrenergic agonist, has analgesic, sympatholytic, sedative and anxiolytic properties. It has increasingly been trialled as an alternative to the older protocols. In a randomized controlled trial of dexemedetomidine versus lorazepam in the ICU setting, while not significant, there was a dramatic difference in post-ICU mortality at 28 days and one year[34].

Delirium is a critical illness that occurs primarily in elderly and frail individuals. Modulation of this very significant problem, however, is increasingly within our reach.

The Nosology of Dementia

Kenneth Rockwood

Division of Geriatric Medicine, Dalhousie University, Halifax, NS, Canada

INTRODUCTION

Nosology is the classification of disease. How the syndrome of dementia has been classified has changed over the years. Recognizing that textbooks are commonly consulted because readers want pragmatic answers to questions, and that understanding nuances first requires understanding the basic facts, this chapter will begin with the current classification of dementia. A second section will provide some historical context. The third section will suggest some areas that remain to be understood or at least, settled on. The focus will be on understanding the basis for the definition of the syndrome of dementia, which historically has been rooted in the diagnosis of Alzheimer's disease. Separate chapters for many of the other dementing disorders will deal with these in separate detail; here we focus on diagnostic criteria for Alzheimer's disease, and how these have influenced the way in which dementia is understood.

CURRENT NOSOLOGY OF DEMENTIA

At present, three references – DSM-IV-TR[1], ICD-10[2] and the NINCDS-ADRDA[3] criteria – provide authoritative approaches to the nosology of dementia. Each is rooted in the formulation codified in an influential textbook by Lishman[4], which proposed that dementia was a global cognitive impairment (memory plus other cognitive features) that was sufficiently severe to interfere with social or occupational function. The newly developed 10/66 criteria, discussed below, have drawn attention to difficulties in the operationalization of the idea that the cognitive impairment must be severe enough to interfere with function, and it may be that their approach will become increasingly influential[5]. Similarly, although largely technically infeasible in the low- and middle-income countries being studied by the 10/66 group, another influential proposal suggests that clinical features beyond demonstrable memory impairment count for little, compared with biomarkers[6]. How these newer trends will play out is not clear.

As a syndrome, dementia must be differentiated from other syndromes in which cognition is (or can be) impaired, including delirium, depression and age-associated cognitive decline. This last is variably conceptualized. Each of the syndromes in which cognition is impaired, but which the cognitive impairment does not meet criteria for dementia, forms part of what has been referred to as 'cognitive impairment, no dementia' (CIND). The prevalence of the heterogeneous group of disorders that is CIND is estimated to be about twice that of the prevalence of dementia[7].

DSM-IV-TR

The Text Revision of the Fourth Edition of the Diagnostic and Statistical Manual of the American Psychiatric Association (DSM-IV-TR) was published in 2000[1]. As with DSM-IV, it gives a general (syndromic) definition of dementia, but the actual dementia diagnostic codes are presented by subtype, based on presumed aetiology. These include Alzheimer's disease, vascular dementia, and separate categories for dementia due to HIV disease, head trauma, Parkinson's disease, Huntington's disease, Pick's disease, Creutzfeldt–Jakob disease, other general medical conditions, substance-induced persisting dementia, dementia of multiple aetiologies, delirium and dementia not otherwise specified.

Within the classification of other general medical conditions are listed a variety of other problems. Some, such as structural brain lesions, including subdural haematomas, and brain tumours, are not infrequently encountered, as are dementia due to multiple sclerosis or to systemic lupus erythematosis. Others are less common, such as dementia due to endocrine disorders (e.g. hypothyroidism or hyperparathyroidism) and CNS infection (neurosyphillis, cryptococcus). Still others are often obscure disorders, such as Kuf's disease and adrenoleukodystrophy.

Note, too, that dementia due to Lewy bodies can be classified in DSM-IV-TR as due to 'other general medical conditions' (or as Parkinson's disease dementia; DSM-IV-TR is in this way up to date in noting controversy over whether Lewy body dementia and Parkinson's disease dementia are aspects of the same disorder, or usefully separable)[8–10]. Frontotemporal dementia, a broader classification than the not unproblematic Pick's disease, can also be recorded under dementia to other general medical conditions.

Although dementia is diagnosed by aetiology, the syndromic aspects said to be 'essential' are repeated for each type. In the criteria for 'Dementia of the Alzheimer's Type' (Table 37.1) these are items A, B, C and E. Item D is adapted to be more disease-specific for each separate dementia classification. Note that DSM-IV-TR maintains the development of DSM-IV in that memory impairment is not further delineated, whereas in DSM-IIIR, impairment had to be demonstrated in both so-called short- and long-term memory.

ICD-10

Chapter V of the 10th revision of the International Classification of Diseases (ICD-10) is the World Health Organization's codification of

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Table 37.1 DSM-IV-TR diagnostic criteria for dementia of the Alzheimer's type

A. The development of multiple cognitive deficits manifested by both (1) memory impairment (impaired ability to learn new information or to recall previously learned information) (2) one (or more) of the following cognitive disturbances:
   (a) aphasia (language disturbance)
   (b) apraxia (impaired ability to carry out motor activities despite intact motor function)
   (c) agnosia (failure to recognize or identify objects despite intact sensory function)
   (d) disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
B. The cognitive deficits in Criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
C. The course is characterized by gradual onset and continuing cognitive decline.
D. The cognitive deficits in Criteria A1 and A2 are not due to any of the following:
   (1) other central nervous system conditions that cause progressive deficits in memory and cognition (e.g., cerebrovascular disease, Parkinson's disease, Huntington's disease, subdural hematoma, normal-pressure hydrocephalus, brain tumor)
   (2) systemic conditions that are known to cause dementia (e.g. hypothyroidism, vitamin B or folic acid deficiency, niacin deficiency, hypercalcemia, neurosyphilis, HIV infection)
   (3) substance-induced conditions
E. The deficits do not occur exclusively during the course of a delirium.
F. The disturbance is not better accounted for by another Axis I disorder (e.g. Major Depressive Episode, Schizophrenia).

Additional coding, based on presence or absence of a clinically significant behavioral disturbance:

294.10 Without Behavioral Disturbance: if the cognitive disturbance is not accompanied by any clinically significant behavioral disturbance.

294.11 With Behavioral Disturbance: if the cognitive disturbance is accompanied by a clinically significant behavioral disturbance. (e.g. wandering, agitation)

Specification of subtype:

With Early Onset: if onset is at age 65 years or below

With Late Onset: if onset is after age 65 years

Source: DSM-IV-TR: Text Revision of the fourth edition of the Diagnostic and Statistical Manual of the American Psychiatric Association.

diagnoses in relation to 'mental and behavioural disorders'. Dementia is included as a so-called 'organic' mental disorder (Table 37.2). The ICD-10 manual states that 'Dementia (F00-F03) is a syndrome due to disease of the brain, usually of a chronic or progressive nature, in which there is disturbance of multiple higher cortical functions, including memory, thinking, orientation, comprehension, calculation, learning capacity, language, and judgment. Consciousness is not clouded. The impairments of cognitive function are commonly accompanied, and occasionally preceded, by deterioration in emotional control, social behaviour, or motivation' (Table 37.2). Its emphasis on impaired behaviour is noteworthy, although in practice this might not be operationalized as distinct from the impaired 'social functioning' seen with DSM. Like DSM-IV-TR, the ICD-10 classifies dementia into an early onset, before age 65 years, and a late onset, after age 65 years. ICD-10 suggests that the early-onset form should have a more rapid onset and progression than the late-onset form. In general, however, in both DSM-IV and ICD-10, the validity of subgroups of dementia has often been found lacking, at least as employed in routine clinical use[11].

The differences in how dementia is operationalized are not inconsequential. Even the minor differences between standard criteria can importantly influence prevalence rates[12,13], especially at very late ages[14]. In general, ICD-10 has been reported to be less sensitive than earlier versions of the DSM criteria, although that is not always the case[15,16].

Table 37.2 ICD-10 criteria for dementia. Definition of dementia in the ICD-10 (adapted)

G1 There is evidence of each of the following:
   (1) A decline in memory (at least) sufficient to interfere with everyday activities, though not so severe as to be incompatible with independent living
   (2) A decline in other cognitive abilities characterized by deterioration in judgement and thinking, such as planning and organizing, and in the general processing of information (at least) sufficient to cause impaired performance in daily living, but not to a degree that makes the individual dependent on others

G2 Awareness of the environment (i.e. absence of clouding of consciousness)

G3 There is a decline in emotional control or motivation, or a change in social behaviour manifest as at least one of emotional liability, irritability, apathy or coarsening of social behaviour

G4 The symptoms in criterion GI should have been present for at least 6 months

NINCDS-ADRDA

Even though the diagnostic classification proposed in this 1984 report focuses on Alzheimer's disease, the consensus diagnostic criteria proposed by the National Institute of Neurological and Communicative Disorders and Stroke, and the Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) has served for many years as the standard for a diagnosis of Alzheimer's disease, and its definition of dementia was also normative[3]. It still heavily influences how research on dementia is conducted, especially as it makes up the usual inclusion criteria for drug trials on Alzheimer's disease (Table 37.3). The original criteria have been adapted somewhat – dementia can be diagnosed with the aid of cognitive screening instruments other than

Table 37.3 NINCDS/ADRDA criteria for Alzheimer's disease

Criteria for clinical diagnosis of Probable AD include:
Dementia established by clinical exam and documented by MMSE or Blessed Dementia scale, confirmed by further neuropsychological tests.
Deficits in two or more areas of cognition.
Progressive worsening of memory and other cognitive functions.
No disturbance of consciousness.
Onset between the ages of 40 and 90.
Absence of systemic diseases or other brain diseases that could explain the cognitive changes.
The diagnosis of Probable AD is supported by:
Progressive deterioration of specific cognitive functions such as language, motor skills, and perception (aphasia, apraxia, agnosia, respectively).
Impaired activities of daily living.
Positive family history, particularly if documented neuropathologically.
Lab results: Normal lumbar puncture, EEG, and evidence of cerebral atrophy on CT or MRI.
Clinical features consistent with diagnosis of Probable AD, after exclusion of other causes of dementia:
Plateaus in clinical course.
Associated symptoms: depression, insomnia, incontinence, delusions, illusions, hallucinations, catastrophic verbal, emotional, or physical outbursts, sexual disorders, and weight loss.
Other neurological abnormalities in some patients, especially with more advanced disease and including motor signs such as increased motor tone, myoclonus, or gait disorder.
Seizures in advanced disease.
CT normal for age.
Features that make the diagnosis of Probable AD unlikely or uncertain:
Sudden apoplectic onset.
Focal neurological findings such as hemiparesis, sensory loss, visual field deficits, and incoordination early in the course of the illness.
Seizures or gait disturbances at the onset or very early in the course of the illness.
Clinical diagnosis of Possible AD.
May be made on the basis of the dementia syndrome, in the absence of other neurologic, psychiatric, or systemic disorders sufficient to cause dementia, and in the presence of variations in the onset, in the presentation, or in the clinical course.
May be made in the presence of a second systematic or brain disorder sufficient to produce dementia, which is not considered to be the cause of the dementia.
Should be used in research studies when a single, gradually progressive severe cognitive deficit is identified in the absence of other identifiable cause.

the Mini Mental State Examination (MMSE)[17] or Blessed Dementia Rating Scales[18], and neuropsychological confirmation is not always required. But the key points of a probable cause being the case for a clinical diagnosis, neuropathology providing the definition reference, and the diagnosis being only possible when other disorders are present operate still, even though each is far from an indubitable proposition[19]. Over the years, many proposals have been made for how Alzheimer's disease might be subtyped other than by age at onset. For example, rapidity of progression, focality of onset, presence of additional features such as early extrapyramidal signs each has had adherents, but none has made their way into standard criteria[19].

SOME HISTORICAL CONTEXT FOR THE CURRENT CLASSIFICATION

Dementia as a clinical syndrome has for a long time been distinguished from changes that are often seen as people age – especially problems with memory. Even in the last 30 years, however, there have been major changes in how dementia is conceptualized, and to a large extent these are reflected in ICD-10 and DSM-IV-TR. In the early years of the modern era, much effort was put into making clear that dementia was distinct from normal ageing. Even so, ICD-10 still has a conceptually ancient hold-over in the diagnostic code (Code R54) of 'senility without mention of psychoses', found in a chapter entitled 'The development of more clinically meaningful outcome measures and laboratory findings, not elsewhere classified'. This code can still appear in certain administrative tabulations, and has the advantage of also being in ICD-9, so that under those circumstances it can allow for the evaluation of trends. Still, the 'senility' diagnosis generally represents an outmoded, obsolete and offensive understanding of dementia – as somehow 'normal' ageing – that has no place in modern care.

Early in the modern era – roughly from the late 1950s, and especially following a series of articles in the mid-to-late 1960s by Martin Roth and colleagues[20–24], a lot of work was put into distinguishing between the neurodegenerative and vascular causes of dementia. They sought to repudiate the view that 'senility' was due to 'hardening of the arteries' and made the case that the changes in cognitive performance in elderly people was a result of plaques and tangles – Alzheimer's disease – or stroke – 'multi-infarct dementia'. While this was true, we have come to understand that the wall between the two is porous – that vascular risk factors are also a risk for Alzheimer's disease, and that the two commonly occur – even in the original series of cases from Newcastle[25] – and can act synergistically (although this last point is disputed)[26–29].

The early descriptions were correct in emphasizing how dementia affected the personality of an individual, through the undoing

of what later would be called executive function. For example, a 1971 description of the clinical symptomatology of dementia warned against putting too much emphasis on 'impaired memory and orientation' as an 'undue emphasis on these features may ... obfuscate the richness of the clinical symptomatology. ... an early and frequent complaint is that the patient is "not himself", meaning that the patient and his companions have noted the onset of illness in terms of changes in function that are quite specific to that particular person, whether described in terms of alteration of drive, mood, enthusiasm, capacity to give and receive affection, creativity or other features'[30]. As later – and comparatively recent – calls for an appreciation of the importance of executive function in dementia have made clear[31,32], these descriptions were largely lost soon thereafter. Instead, the view that Alzheimer's disease was predominantly a disorder of memory, that temporal and parietal involvement was early, that frontal lobe involvement was late, and that the standardization offered by psychometric testing would trump the subjectivity of clinical judgement each contributed to the systematic lack of attention to 'what makes a patient him[her]self'.

Another point seen in earlier iterations of dementia criteria that is less commonly emphasized now is that a diagnosis of dementia should only be made in patients in whom consciousness was 'clear'. This was meant to be another way of saying that consciousness should not be clouded, which in DSM-III was seen as a major distinguishing feature of delirium. (In DSM-IV-TR, delirium is again conceptualized as a disorder of consciousness; the only reference that it be clear, however, is the description of 'reduced clarity of awareness of the environment'.) With the recognition of the importance of alterations in levels of consciousness as a hallmark of Lewy body dementia, however[10], this particular requirement has been dropped. Instead, the criteria make reference to the cognitive disorder not being better accounted for by delirium.

FUTURE CHALLENGES IN DEMENTIA NOSOLOGY

The exciting pace of development in the study of dementia means that the field has to look anew at received wisdom. A large number of developments are likely to impact on what will be controversial about the nosology of dementia when the next edition of this textbook appears. Here, a few are sketched out in the barest detail. Even so, they give some hint as to why this most staid of topics is likely to have interest for some time yet.

'Alzheimerization' of Dementia Criteria

Current dementia criteria are, as we have seen, largely modelled on the dementia characteristically seen in Alzheimer's disease. This is a problem for dementias in which memory impairment is not the chief early manifestation. The two most commonly occurring examples are frontotemporal dementia and vascular dementia, especially the so-called 'subcortical' variant[33]. In either, affective and behavioural disturbances can predominate early. The consequences of this problem are many. In the case of vascular dementia, Hachinski has long drawn attention to the opportunities missed in dementia prevention[34] and in understanding the impact of vascular disease on brain function by underestimating its burden in the wait for memory to become impaired. In consequence, he has proposed the concept of vascular cognitive impairment[35]. Over time, this has had great influence[36], but has yet to be reflected in the standard criteria, including in the NINDS-AIREN criteria for vascular dementia[37].

The presentation (and evaluation) of impaired judgement in someone whose memory is reasonably intact can be problematic, especially where social conduct violates legal norms (e.g. theft, sexual impropriety). In some cases, it is clear that a reliable clinical diagnosis of dementia can be made due to other characteristic features in the patient's cognitive profile and how that impacts on function, even if memory is relatively intact. Even so, depending on the literalness of local prosecutors, the understanding that the criteria in real life often are only approximate can be a tricky business. (In such cases, where it is necessary to show that the criteria need not always be applied strictly, I have found it useful to cite Aristotle – who hedged that in biology rules apply 'always or for the most part'[38]. If that seems a bit obscure, it is always possible to resort to the usual disclaimer for hair loss products: 'Your results may vary'.)

Notwithstanding the incompleteness of the criteria, there are other circumstances of late-onset aberrant behaviour, coupled with some evidence of executive dysfunction, in which only the passage of time and progression of the illness to include other dementia features makes the diagnosis clear.

Cognitive Disturbances with Many Causes

Dementia occurs largely in older people who are more likely to have things wrong with them. In consequence, in clinical practice it is common to encounter patients with many things wrong that might contribute to cognitive impairment. For this reason, dementia diagnostic criteria need to give particular attention to how such problems are to be conceptualized and identified. This is relevant in three situations. 'Mixed dementia' refers to co-existing illnesses and especially to the combination of infarction (or, more controversially, ischaemia) with Alzheimer's disease. As noted, given that vascular risk factors are also risks for Alzheimer's disease, not unexpectedly the two often conclude and can be the most common form of dementia encountered[26–29,39]. In the ICD-10, NINCDS-ADRDA and NINDS-AIREN criteria, the result is a 'possible' diagnosis – e.g. 'possible Alzheimer's disease, with vascular component'. By contrast, DSM-IV-TR allows for 'Dementia due to multiple etiologies'. (From a coding standpoint, multiple codes are allowed – i.e. each of the codes for the given causes is recorded.)

A similar situation occurs when delirium complicates dementia. Again, this is a common situation, as each is a risk for the other[40]. In addition, delirium which does not resolve is a risk for dementia, and results in an indeterminate period (of between 3–6 months) when features of both may be present[41]. The multiple coding approach and the use of codes for delirium-complicating dementia seen in DSM-IV are considered a good way to handle the common co-occurrence of these syndromes, resulting in a proposal that ICD-11 should follow the lead of the DSM[40,42]. The parallel is also seen when depression complicates dementia[43].

Lessons from the 10/66 Experience

The 10/66 Dementia Research group is a collective of dementia researchers worldwide, who are carrying out population-based studies of dementia[44–46]. The title refers to the fact that two-thirds of people with dementia live in low- and middle-income countries and that 10% (or less) of population research is conducted there. An early and important finding of the 10/66 was how poorly standard dementia criteria applied in many parts of the world. In consequence, the 10/66 group developed its own. These criteria differ from the

standard criteria chiefly in how they operationalized the impact of cognitive impairment on function (relying less on informant reports of decline) and in the use of detailed procedures for operationalization, which were cross-culturally validated. These criteria yielded results that were both more consistent across sites and strikingly higher than those using DSM-IV dementia criteria (e.g. 10/66 criteria suggested prevalence of 5.6–11.7% by country, compared with 0.4–6.4%)[5]. These last results raised the question of whether the criteria were too sensitive, and thereby not specific enough, or whether 10/66 'pathologizes' mild decline that can be accommodated within many cultures in which less cognitive demand is placed on elders. These questions remain to be resolved.

Alzheimer's Disease without Dementia

At a different spectrum from those who look to diagnose dementia in low- and middle-income countries are groups who are aiming to develop preventive treatment for dementia, or at least ones which could be implemented as early in the disease course as possible[6]. For such groups, the interest is on how to couple the earliest manifestations of dementia with biological markers of the disease. Drawing on a body of work about very early[47] and prodromal Alzheimer's disease, and on the apparent promise of biomarkers, a consortium has proposed that biomarkers, coupled with a memory complaint, should form the basis for a diagnosis of Alzheimer's disease. The clear intent is to provide a test base of people who are at high risk for the development of 'full-blown' Alzheimer's disease, and to see if new interventions might prevent that outcome. How such a proposal will affect more widespread diagnosis of dementia is uncertain. Whether 'prevented Alzheimer's disease' will look like 'no (or mild) cognitive impairment' is also uncertain, but the parallel case might exist now for successfully treated Alzheimer's disease (below).

Executive Dysfunction

As noted, it had been the case that, central to a clinical diagnosis of dementia, was the loss of aspects of an individual's character which made them essentially themselves. This notion largely was lost for a period, before being rediscovered, under the guise of executive function. While the emphasis on executive function is welcome, it is not at all clear that the usual remedy (to employ measures of 'frontal lobe tests') addresses the clinical phenomenon sufficiently well. A cultural bias is at work in rejecting the characterization of an individual's complaints – what makes dementia a problem for them – as too subjective an evaluation process, and instead substituting finger-tapping or clock-drawing tasks as preferable alternatives. Future criteria will need to examine how they view the notion of subjectivity or objectivity. In this, they might be helped by consultation with philosophers who understand the distinctions that are at play here.

Successful Treatment of Dementia

Even though no current treatment cures Alzheimer's disease, many people can be treated successfully, to the extent of having important overall improvement on global clinical measures[48]. Evaluations of the notes from patient interviews in which clinicians rated patients as showing overall improvement have shown that typically in such cases some symptoms improve, most are stabilized and some worsen[49,50]. In short, successful treatment can result not in cure, but in a new state. This state has yet to be operationalized in any terms that could inform criteria. Even so, it offers a way to retrieve some of the lesson taught by Wells (i.e. the warning that too much emphasis on easily testable cognitive elements might obscure the richness of the clinical symptomology). The approach to this problem that I have used with colleagues is known as goal attainment scaling[51], about which independent reviews suggest it has promise, but needs additional work, chiefly replication and some standardization[52,53]. Whether the results of partially treated (or partially prevented) Alzheimer's disease will be stable enough and common enough to warrant special categorization is a development to be evaluated with some interest.

SUMMARY

The nosology of the dementia syndrome is likely to continue to evolve, reflecting developments in how and where dementia is studied. Important challenges to our understanding of dementia reflect continuing development of our knowledge of these dread illnesses.

Epidemiology of Dementia

Mary Ganguli

University of Pittsburgh School of Medicine and Graduate School of Public Health, WPIC, Pittsburgh, PA, USA

Epidemiology has traditionally been the study of the distribution and determinants of disease in the population. Its principles and approaches are also used to study normal variation, for example changes related to normal ageing in the population at large. Epidemiology helps clinicians by acquainting us with the proportions of given populations that are affected by the conditions we diagnose and treat; the frequency with which different conditions, changes and outcomes occur; and the factors that raise and lower the probability of these conditions occurring. Importantly, epidemiology also completes the clinical picture of disease, demonstrating that patients who seek our services for a given condition are not typical of all individuals in the community with that condition. For example, individuals with dementia who present to a psychiatric clinic may have different characteristics (insight, symptoms, severity, duration, support) than those who are seen in neurological or general practice settings, or who do not seek clinical services at all. As of this writing, efforts are under way to revise the current clinical diagnostic criteria for dementia and its subtypes, including Alzheimer's disease, in the World Health Organization's International Classification of Disease[1] and the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders[2]. More than in previous editions, attention is being paid to epidemiological data that bear on diagnosis: for example, the heterogeneity of dementia and cognitive impairment, and the predictive validity of various diagnostic criteria in population settings.

BASIC DEFINITIONS

Prevalence is a cross-sectional snapshot of the disease burden of the population. It is the proportion of individuals in a defined population who have the disease or condition at a given time (point prevalence) or defined period (period prevalence), regardless of how long these individuals have had the condition.

Incidence is the rate at which new disease occurs in the population. It is the proportion of individuals previously free of disease who develop the disease during a defined period (e.g. one year, or 1 000 person-years), within a defined population.

Overall prevalence and incidence estimates (e.g. for everyone aged 65 years and older) are less useful than age-specific estimates, that is, within defined age groups, such as those aged 65–74, 75–84 and 85+ years.

Prevalence is the product of incidence rate and duration of survival with disease. Thus, high prevalence can be the result of high incidence, long duration, or both. Two groups can have the same dementia incidence, with prevalence being higher in the group in which people with dementia live longer.

GLOBAL AGEING, DEMOGRAPHIC TRANSITION, DEVELOPED VS. DEVELOPING COUNTRIES

The world's population is ageing, as improving living standards have increased life expectancy across the globe. The most affluent countries have the longest average life expectancy, and the greatest proportions of older adults. However, population ageing is occurring faster in the low- and middle-income ('developing') countries than in the wealthier ('developed') countries. It is determined by both birth rates and death rates. Populations with high fertility tend to have low proportions of older people, and vice versa. The 'demographic transition' is the process in which, over time, a high-fertility-high-mortality population becomes a low-fertility-low-mortality population, and its average age increases. As people live longer, the public health concern becomes whether their years of extended life are characterized by relative health and independence or by ill-health, disability and dependence on others. Thus, we measure not only overall life expectancy but healthy life expectancy and disability rates.

In affluent countries, disability rates appear to be decreasing as the population ages. In low- and middle-income countries, it seems likely that disability rates will climb as people live longer with chronic disease. The least affluent countries are the least prepared to deal with the challenges of population ageing, given the rapidity with which the demographic transition is occurring in their societies. However, one factor in their favour is the elderly support ratio, which is the number of elderly people for every 100 younger adults in a given population, with younger individuals assumed to be directly or indirectly supporting older ones. This ratio is increasing rapidly in the affluent countries, with greater numbers of older individuals needing support from a shrinking number of younger persons. In the less affluent countries, this ratio is expected to change quite slowly[3].

Dementia is a major cause of functional disability, dependence and mortality in the elderly. It therefore reduces both overall life expectancy and active (disability-free) life expectancy, although the extent to which it does so might vary across populations. Dementia is also responsible for increasing use and cost of health services,

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

particularly long-term-institutional care, in countries where such institutions are available and culturally acceptable. The cost to a given society of caring for its members with dementia depends on its age structure, the numbers and proportions of affected individuals, their length of survival and degree of dependency, the availability of appropriate goods and services, and who bears the costs of these items. These direct costs, as well as indirect costs (e.g. loss of income by the patient and family caregiver) will vary according to the affluence and age structure of a given society.

SYNDROMAL DEFINITION OF DEMENTIA: DSM, ICD, EVOLVING CRITERIA; 'CASENESS'

At the time of this writing, the most widely employed diagnostic criteria for dementia at the syndrome level are those of the Tenth Revision of the International Classification of Diseases (ICD-10)[1] and the Fourth Edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)[2]. Over the years, studies in different countries have used different versions of these criteria. Variations in definitions and criteria can potentially raise and lower estimates of prevalence and incidence across studies and populations. One study demonstrated that the proportion of individuals classified as having dementia varied from 3% using the ICD-10 criteria to 29% using the DSM-III criteria, within the same population[4].

According to current definitions, dementia is a syndrome of acquired, chronic cognitive impairment, occurring in clear consciousness, sufficient to interfere with social and occupational functioning, and characterized by impairment in at least two cognitive domains. For the past few decades, the definition has further required that memory be one of the impaired domains[2], but this requirement may not persist in future revisions of diagnostic criteria. For example, it may be possible that an individual with significant impairments in executive and language functioning can be diagnosed as having dementia, even without memory impairment.

Further, there is currently no standard diagnostic entity reflecting a minor level of cognitive decline that is not accompanied by functional impairment, thus falling short of the threshold for being called dementia. This situation too may change as knowledge evolves and preclinical detection of dementing illnesses becomes a possibility. Besides the functional dimension of the diagnosis, the standard neuropsychological criteria for dementia typically require test performance in two cognitive domains to be at least two standard deviations below the mean for the individual's peer group, as defined by age, education, linguistic/ethnic group and sometimes gender. However, appropriate norms are not always available. Thus, the issue of 'caseness', or what makes an individual a true case, has yet to be universally defined, and will become harder as the demand increases for earlier detection of the dementia syndrome.

DEMENTIA SUBTYPES AND THE ROLE OF CO-MORBIDITY

Alzheimer's disease (AD) is a primary neurodegenerative disease which appears to be the single most common cause of the dementia syndrome in older adults, in most populations which have been studied worldwide. The next single most frequent cause of dementia is cerebrovascular disease; either cortical infarcts or white matter disease, or both, can lead to significant cognitive impairment and decline. Diagnostic criteria for vascular dementia and cognitive impairment have varied as to whether the mere presence of cerebrovascular disease with dementia is sufficient, or whether evidence from neuroimaging is also required, for the diagnosis[2,5]. However, mixed Alzheimer's and vascular pathology is more common than pure vascular disease or pure degenerative disease, as borne out by the few community studies that have been able to conduct autopsies[6]. Although prominent in specialty clinical settings, dementias related to other primary brain disorders such as frontotemporal lobar degeneration, Lewy body disease and Parkinson's disease appear relatively infrequent in the community at large; population-based estimates are scarce. Opinion is moving towards accepting co-morbidity and multiple causes in a given individual with dementia, rather than selecting one subtype over another in the presence of mixed aetiology.

PREVALENCE AND INCIDENCE OF THE DEMENTIAS

The overall prevalence of dementia, based on many studies in affluent countries worldwide, is in the range of 5–10% of individuals aged 65 years and older. One meta-analysis showed a doubling of dementia prevalence with every 5-year increase in age; for AD the doubling occurred with every 4.5 years and for vascular dementia every 5.3 years[7]. Population studies typically do not employ neuroimaging or neuropathology for diagnosis, but rather use operationalized standard clinical diagnostic criteria. In these studies, AD appears to account for two-thirds to three-quarters of observed cases. Previous reports of vascular dementia being more prevalent than degenerative dementia in some Asian populations may have been the result of varying diagnostic criteria. However, prevalence has not been established for the newer, broader entity called vascular cognitive impairment (VCI) which encompasses all levels of cognitive decline from mild deficits to dementia. The prevalence of dementia of Parkinson's disease has been estimated at about 0.5% of the population aged 65 years and older[8].

Although incidence rates vary, one meta-analysis showed rates of AD ranging from 0.33% per year for those aged 65–74 to 8.68% for those aged 95+ years[9]. Evidence is inconclusive as to whether incidence continues to increase after age 90. In a study including MRI scans for the diagnosis, the age-adjusted incidence rate for AD was 19.2, and for vascular dementia 14.6, per 1000 person-years[10]. While many studies have shown higher dementia prevalence among women, many incidence studies have not shown a gender difference. If incidence is indeed the same in men and women, gender difference in prevalence may be due to longer survival in women. There are few population-based data on early-onset dementias.

Based on a handful of studies from Asia, Africa, Central and South America, and Eastern Europe, prevalence in low- and middle-income countries is much lower than in the affluent countries. It is, however, increasing as their populations age, and seems to be divided between Alzheimer's and vascular subtypes as in the rest of the world[11]. The prevalence difference is not solely a function of life expectancy. Opinion is divided as to how much of the discrepancy is due to misclassification, given the difficulties in measurement discussed earlier, and how much reflects true differences in disease occurrence. However, all studies report an exponential increase in both prevalence and incidence with age. With the rapid population ageing of the less affluent countries, among which India and China have very large populations, even a lower proportion affected by dementia will reflect a larger number of individual cases in these countries than in the wealthier countries[12].

NORMAL VS. ABNORMAL COGNITIVE AGEING

To differentiate early dementia from the cognitive changes of normal ageing can be challenging in clinical practice, and is no easier at the population level. The majority of older adults experience some slowing of information processing as part of normal ageing. Memory, visuospatial ability and executive functioning/reasoning also are likely to decline with normal ageing. In contrast, verbal/language abilities tend to remain more stable.

Terms such as age-associated memory impairment and age-related cognitive decline have been used to characterize the cognitive changes of normal ageing. Terms including mild cognitive impairment (MCI)[13] and cognitive impairment, no dementia (CIND)[14] are used to describe states intermediate between normal cognitive ageing and dementia, where individuals experience or exhibit cognitive deficits greater than expected for age, without fulfilling diagnostic criteria for dementia. The prevalence of this variably defined intermediate state in the elderly population is entirely dependent on the definition, and has been shown to vary from 3 to 20% as a function of the criteria employed[15]. The key element is mild cognitive decline with little or no functional change. This state frequently but not inevitably progresses to dementia. The rate of progression to dementia is reported as 12–15% per year in patients actively seeking care for memory problems in specialized settings like memory disorders clinics. The rate is lower in the community at large, when MCI is systematically detected by standardized assessment. In fact, MCI in the community appears to be an unstable and heterogeneous state with many individuals remaining stable or even reverting to normal over time. This discrepancy is inadequately understood, but suggests that it is premature to assume that MCI uniformly represents preclinical dementia. Outside specialty clinical settings, other conditions (e.g. anticholinergic medication effects, depression, heart failure) may contribute substantially to the observed impairments. It is likely that the criteria will undergo further refinement to enhance their predictive validity, possibly by including reliable biomarkers of underlying disease.

It must be firmly recognized that no test of cognitive function is entirely free of the effects of culture and education. Individuals of greater age and lesser education will typically perform worse on most neuropsychological tests than younger and better-educated persons. If not carefully accounted for, these factors can lead to misclassification error in epidemiological studies, potentially inflating prevalence estimates of cognitive impairment and dementia in populations with low literacy and education.

CROSS-CULTURAL ISSUES IN DIAGNOSIS AND EPIDEMIOLOGY

With some caveats, the process and functional consequences of brain ageing are assumed to be fairly similar in all populations, while their personal and social impact may not be the same across societies and cultures. Thus, the clinical thresholds may be different, or the same underlying disease biology may cross the clinical threshold to different extents in different populations. This variation can give rise to varying estimates of prevalence and incidence. Such estimates are also influenced by variation in life expectancy, the presence of co-morbid medical conditions, and local norms and expectations. In many cultures, cognitive impairment is considered an inevitable consequence of ageing, and expectations of the elderly are tailored accordingly. It may be the norm for younger family members to assume most of the older adult's previous responsibilities other than basic self-care. Consider the examples of two older men with AD, one living in a large extended-family setting on a farm, and the other living alone in an urban apartment. Compared to the latter, the former may have to suffer a greater degree of cognitive impairment, and reach a more advanced stage of dementia, before he experiences interference with his own social and occupational functioning or the family reports a problem, resulting in a later diagnosis of dementia. Meanwhile, the second man's environment requires him to independently use household appliances, and manage his own meals, finances and transportation; a lesser degree of cognitive impairment would interfere with his daily functioning and lead to an earlier diagnosis of dementia. Measurements and diagnostic criteria developed in one setting or country may therefore not be entirely appropriate in another; cross-cultural validation is of critical importance as disease concepts and criteria are translated and applied internationally.

RISK AND PROTECTIVE FACTORS AND THE MEANING OF 'RISK'

Going beyond measures of disease distribution (prevalence and incidence), epidemiology also plays a major role in identifying disease determinants (risk and protective factors). As the term 'risk' is most commonly used in epidemiology, it refers to the probability of developing future disease. Thus, ideally, inferences about risk factors should be drawn from prospective studies and not cross-sectional or retrospective studies. Within any population, there are individuals who currently have disease, while the remainder are currently free of disease. A true risk factor is one associated with a significantly higher probability of future disease developing in currently disease-free individuals. The subgroup possessing this risk factor has a higher incidence rate of the disease than the subgroup without that risk factor. Similarly, protective factors are those associated with a lower probability and incidence rate of future disease. It is extremely important to recognize that an identified risk factor may not be the direct cause of the disease. It may be within the causal pathway, or might play a mediating or moderating role between a causal factor and the disease, or may be a surrogate for a causal factor. Further, a risk factor is not necessarily modifiable or preventable. Note that while some studies have singled out risk and protective factors for Alzheimer's disease, many have examined all dementias together, and, other than their genetics, little is known of risk factors for early-onset dementias.

For overall late-onset dementia, which is mostly Alzheimer's or vascular, the strongest known risk factor is greater *age*, as demonstrated by incidence rates increasing with age. Based on similar incidence rates in men and women, at least up until age 90, female *gender* may not be a true risk factor as previously supposed. Several studies have indicated that *lesser education* increases the risk of dementia; the underlying mechanism is not known. Possibilities include education being a reflection of, or a promoter of, greater cognitive 'reserve' capacity that allows the brain to resist or compensate longer for the increasing pathology within it. Alternatively, education could be a surrogate for lifelong socioeconomic status and its consequences, including nutrition and health care; or a confounding variable in the diagnosis of dementia based on cognitive test performance.

A positive *family history of dementia* in a first-degree relative increases the risk of dementia, suggesting a hereditary component. The genetics of AD have been studied the most extensively. While many genes have been reported to play a role in AD, there is, thus far,

conclusive evidence for only three deterministic genes and one susceptibility gene. Mutations of the ***APP*** (amyloid precursor protein) gene on chromosome 21, ***PS-1*** (presenilin 1) gene on chromosome 14, and the ***PS-2*** (presenilin 2) gene on chromosome 1 are all associated with early-onset familial AD. Relevant to the *APP* gene, *Down syndrome*, caused by trisomy of chromosome 21, is a well-established risk factor for AD. The one susceptibility gene consistently associated with sporadic cases and late-onset cases is the polymorphic ***APOE*** (apolipoprotein E) gene, on chromosome 19, also associated with cholesterol elevation. The *E*4* allele of this gene is associated with higher risk and/or earlier onset of Alzheimer's disease in a dose-related fashion, with homozygosity conferring higher risk than heterozygosity. In epidemiological studies, the *APOE*4* genotype is associated with a two- to three-fold elevation of probability of AD. The exceptions are African populations, where the *APOE*4* allele is of high frequency but appears not to increase AD risk, and African American populations, where risk elevation is present but lower. This paradox has been attributed to competing risk of vascular disease. Unlike the mutations, the *APOE*4* genotype only increases susceptibility and does not guarantee that the disease will occur. A comprehensive review of the genetics of AD and other dementias is beyond the scope of this chapter.

There is growing evidence that a host of *cardiovascular risk factors*, including but not limited to *hypertension, hypercholesterolaemia, diabetes mellitus and obesity*, all increase the risk of not only overall dementia and vascular dementia but also of AD. One explanation is that these factors operate primarily by causing cerebrovascular disease, which interacts with degenerative pathology, leading to earlier onset of the dementia syndrome. Another is that they directly influence neurodegeneration, for example by influencing the metabolism or accumulation of amyloid protein in the brain. From the epidemiological perspective, the most striking finding from long-term prospective studies is that dementia risk is elevated by hypertension, elevated serum cholesterol and obesity that are present in middle age, but in not old age. In fact, the onset of dementia in later life is preceded by a period of low blood pressure and cholesterol. These findings suggest, first, that the brain pathology that causes dementia develops over many decades and, second, that it is not only the presence or absence of a given factor but the timing and duration of exposure to the factor that influence the risk of dementia.

Other reported risk factors from the epidemiological literature are based on less consistent evidence. They include, for example, history of *head trauma* with loss of consciousness, possibly acting synergistically with the *APOE*4* genotype, *thyroid* abnormalities, and exposure to certain general *anaesthetic agents*.

Potential protective factors include the rare ***APOE*2*** genotype, intake of diets rich in *antioxidants*, exposure to the lipid-lowering drugs HMG Co-A reductase inhibitors ('statins'), exposure to non-steroidal anti-inflammatory drugs (*NSAIDs*), exposure to *oestrogen* supplements, *physical exercise* and *cognitive exercise*. It is difficult to draw firm conclusions about many of these factors because, although they show negative associations in observational studies, intervention studies using them have not revealed benefits in preventing or delaying the onset of dementia. Some observational data suggest that oestrogen supplements taken for several years, starting at menopause, may reduce incidence of Alzheimer's disease at least a decade later. However, clinical trials of oestrogen supplements taken in later life have not shown a protective effect against dementia and in fact suggested an increased risk. As noted earlier, the timing and duration of exposure to risk and protective factors may be critical.

Two examples will be discussed to further illustrate the complexity of putative risk relationships.

Cigarette smoking has been shown in cross-sectional as well as some prospective epidemiological studies of older adults to be associated with a lower probability of Alzheimer's dementia. Short-term trials of transdermal nicotine patches have been inconclusive.

It is certainly plausible that the nicotine use can have cholinergic effects that promote cognitive performance. However, it is also likely that the apparent protective effect is an artefact reflecting survival bias. Smokers who survive into old age without succumbing to heart and lung disease or cancer might be an unusually hardy group with enhanced capacity to resist many diseases including AD; those who died before they could develop dementia cannot participate in these studies.

Depression: in case-control studies, individuals with AD are more likely than healthy controls to have had previous histories of major depression. Older adults with major depression have cognitive deficits which resolve only partially when the depression remits. Major depression in younger adults has been found to be associated with atrophy of the hippocampal cortex, which has been attributed to prolonged hypercortisolaemia caused by depression[16]. The hippocampus and medial temporal lobe are the areas typically affected by AD pathology. An autopsy study of patients with AD showed that those who had suffered major depression earlier in life had greater density of degenerative pathology in their hippocampi than those with no previous history of depression[17]. However, one prospective population study was able to divide elderly participants without dementia into one subgroup which developed dementia over the next several years and another subgroup that remained dementia free. Depressive symptoms at the beginning of the study did not predict rate of cognitive decline in either group; subsequent cognitive decline was primarily explained by the incipient dementia[18]. A potential unifying hypotheses is that depression earlier in life may increase the brain's vulnerability to dementia, while late-onset depression may be merely an early manifestation of the dementing disorder.

BEHAVIOURAL AND PSYCHOLOGICAL SYMPTOMS OF DEMENTIA

Although cognitive impairment is the clinical hallmark of the dementias, Alzheimer's original case report was based on a woman who was brought for care primarily because of her behavioural and psychological disturbances[19]. These are still the symptoms that frequently bring patients with dementia into the mental health care system, but they have not been the focus of much epidemiological work. At least two major population-based studies have shown that the majority of patients with dementia have one or more neuropsychiatric symptoms which add considerably to personal distress and caregiver strain. Irritability and depressed mood are somewhat more common in earlier

and milder stages of disease, while wandering, apathy and delusions are more common in more advanced disease[20,21].

STUDY METHODS

For a comprehensive review, readers are directed to any standard epidemiology textbook. A few critical points follow. Different inferences should be drawn from different types of studies: for example, observational vs. experimental; cross-sectional vs. longitudinal; clinical case-control vs. population based. The source of the study sample, its size, and its potential for bias should be taken into account when interpreting the results and generalizing beyond that sample. Statistical significance indicates that the result is unlikely to have occurred by chance, but does not mean that the effect was large in size or that it was clinically significant. Screening tools should be selected after consideration of both sensitivity and specificity, which are usually enhanced at the expense of each other. The same tool, with no change in sensitivity or specificity, can have different predictive value in different populations, depending in part on how prevalent the disease of interest is in a given population.

Brain imaging and other biomarker-based approaches to diagnosis are gaining ground in clinical research as well as clinical practice, especially in the more affluent countries. To a lesser extent, epidemiological studies are incorporating these methods to determine their utility and validity for diagnosis at the population level, and to examine the distribution of these markers in individuals outside the specialty clinical setting. Very few epidemiological studies include *autopsy* data. They have shown the remarkable heterogeneity of neuropathology among individuals with dementia in the community, and also the extent of pathology that exists in relatively old individuals who were cognitively intact until the time of death[6].

FUTURE DIRECTIONS

Future research in the epidemiology of dementia faces both opportunities and challenges. The distribution of dementia and milder forms of cognitive impairment must be understood in a variety of populations, some of which have never been studied. As new tests and biomarkers are developed in specialized research settings, their validity must be ascertained in the community before they are recommended for widespread clinical use. Such research will contribute substantially to improved diagnosis and even preclinical detection of disease. Future studies will also focus on normal ageing, establishing norms for a wide range of populations to help distinguish healthy from pathological ageing. Longer-term population studies must track dementia incidence rates over time, to determine whether or not successive generations are following the same trends as life expectancy increases. They must also examine potential relationships of incidence to the different lifetime exposures in different generations. There is a growing call for 'life-course epidemiology'; that is, studies that start following cohorts of people when they are young or middle aged[22]. These studies will minimize survival bias and allow risk and protective factors to be studied early enough, and for long enough, to shed light on their long-term relationship with the dementias of later life. Such data will provide greatly improved information regarding potentially modifiable risk factors, and provide the basis for strategies to prevent dementia, or at least reduce its incidence, in future generations.

INTRODUCTION

The rise in numbers of older people and the changing proportion of old to young people has been predicted for some time. It has become clear that the potential impact of this ageing phenomenon would have a major impact on population health profiles. Its potential impact on social and economic aspects of the more affluent countries highlights ageing as a sufficiently important issue in resource allocation. Discussion between the UK Department of Health, UK Medical Research Council (MRC), and experts from the scientific and medical communities late last century resulted in the decision that brain changes, most particularly cognitive decline, dementia and their relation to disability were key topics requiring investigation at the population level. This prompted a decision to invest in research into this area and a working group was convened, which included those with epidemiological and biostatistical expertise relevant to such investigation. Out of this working group a successful bid for the study now known as the MRC Cognitive Function and Ageing Study (CFAS) emerged[1].

STUDY DESIGN

The study is a six-centre multidisciplinary multiphased longitudinal design. There are five identical sites and one with a different sampling and interview structure. This centre (Liverpool, also known as the ALPHA study, see Figure 39.1) was already funded at the time of the discussions noted above and thus started earlier than the other five centres[2]. The other five centres (Cambridgeshire, Gwynedd, Newcastle, Nottingham and Oxford) were able to follow a standardized design and are referred to as the five identical sites. Their basic structure was a two-phase design with a screening interview followed by an assessment interview shortly afterwards, with a repeat at two years. The fieldwork began in 1991 to 1993 (centre dependent)[3] (see Figure 39.2 for flow diagram). Additional features are more fully described on the website (www.cfas.ac.uk).

In 2008 additional funding from the MRC enabled the introduction of a new cohort in three of the original CFAS centres (Cambridgeshire, Newcastle and Nottingham). Further funding from the Economic & Social Research Council (ESRC) in 2009 will enable a new cohort to be recruited to the Gwynedd centre (plus a new centre in Neath, Port Talbot) which focuses more on the social aspects of ageing.

THE AIMS OF THE STUDY

The aims of the study (see Box 39.1) have evolved over its existence and cover a wide range including descriptive epidemiology, neuropathology, policy, molecular epidemiology and ethics. The principal neuropathological aim was to determine the contribution of different underlying pathologies to the rates of dementia and the geographical variation in these rates, and to the burden of disability.

Box 39.1 CFAS core aims

CFAS I core aims:
The main descriptive epidemiological aims include:

- the estimation of the prevalence and incidence of cognitive decline and dementia, and geographical variation in those rates;
- the determination of the natural history of dementia, in particular the rate of progression of cognitive decline including the distribution of the interval between the identification of cognitive impairment and death;
- the identification of factors associated with differing rates of cognitive decline and with the risk of dementia.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Additional aims included:

- to determine the prevalence and severity of pathological lesions in the brain of an unselected cohort of older people with and without cognitive impairment;
- to determine the frequency of specific pathological diagnoses in people with cognitive impairment;
- to correlate severity of specific pathologies with patterns of cognition, function and behaviour in life independently of clinical and pathological diagnostic categories. CFAS II core aims include:
- to update profiles of cognitive and physical function, physical and mental health and disability of people aged 65 or over in four of the original CFAS centres: Cambridgeshire, Gwynedd, Newcastle and Nottingham;
- to estimate the cohort change in prevalence and incidence of cognitive impairment and dementia;
- to investigate whether the measures that characterize the intermediate stage (mild cognitive impairment) best within the original CFAS are stable across generations;
- to quantify medication, health, social service use, social support, residential characteristics and care states, including formal and informal care, of people with dementia, frailty or physical disability across the three sites;
- to assess the contribution of different diseases, particularly dementia, to any change in the burden of disability over time, specifically whether diseases have become more or less disabling and estimate the effect of prevention vs. treatment;
- to compare the size of relationship of known genetic factors with frailty, including cognitive impairment, with those found in the earlier cohort;
- to provide a foundation for other collaborative studies that investigates biomarkers and further investigation of early markers, including imaging, for risk of cognitive decline.

The DNA resource was incorporated in a later phase of CFAS I. In CFAS II saliva is collected at baseline. The main molecular epidemiological aim has been to support genetics studies that have sought genes associated with dementia, Alzheimer's disease, mixed and vascular dementia, cognitive impairment and decline. A later aim of the study was to explore the ethical and legal aspects of brain donation within a population-based sample given changing perception surrounding organ donation. The study also aimed to act as a core resource and provide a framework to support specific sub-studies in lone or joint centres. The Resource Implication Study [4–10] used this framework to achieve the core policy aim (see above).

METHODOLOGY

Because the main study is focused on cognition and dementia it has collected the necessary dimensions of physical and mental health to arrive at a study diagnosis of dementia. It now has four major themes: (i) dementia (covering all aspects including cognition); (ii) depression; (iii) disability and healthy life expectancy; and (iv) health policy and health. In addition it has particular strengths in that it is one of

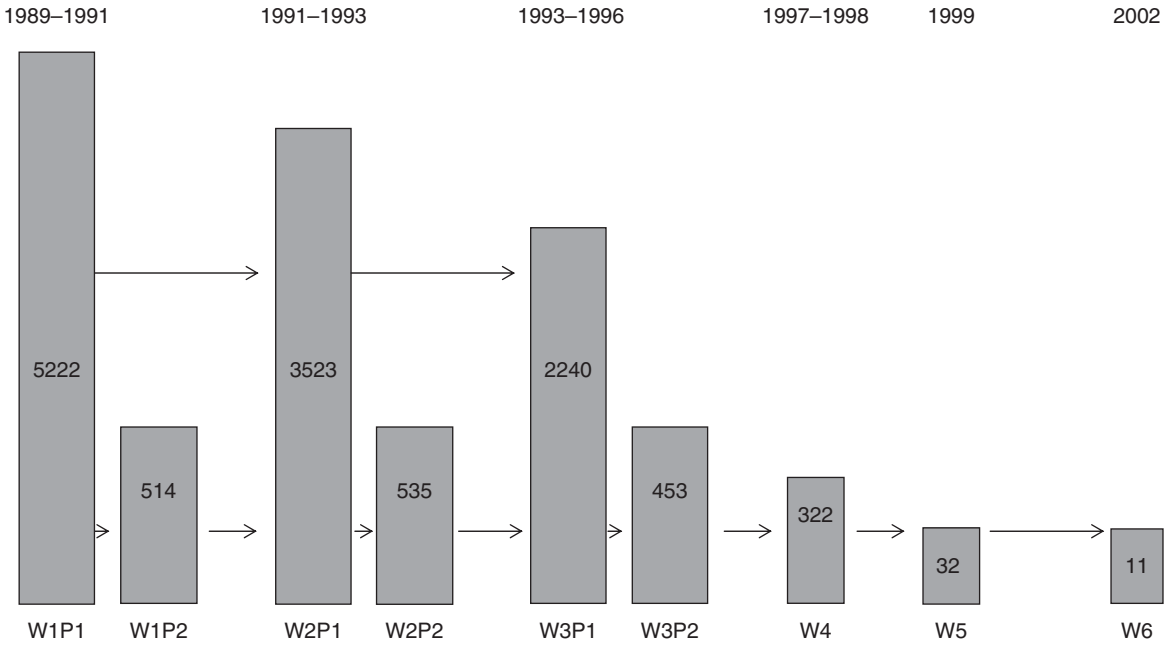

Figure 39.1 MRC Alpha Study: Liverpool centre design number of interviews

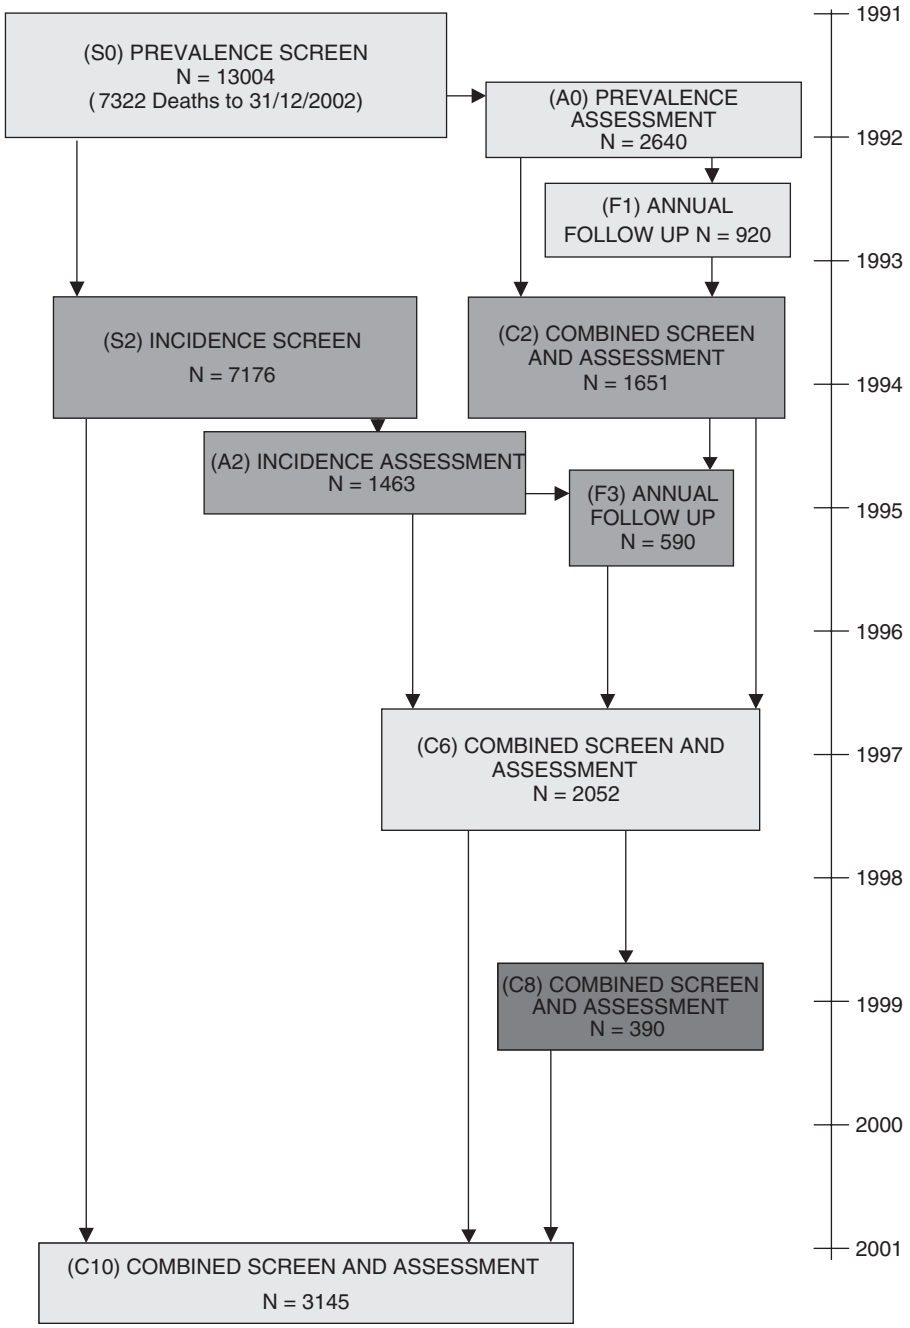

Figure 39.2 CFAS I identical centres study design

the very few truly population-based programmes with a brain donation programme – individuals in the study have indicated whether they wish to contribute to brain research through the donation of their brain after death (declaration of intention to donate).

Study Population

The first aim of the study was to estimate age-specific rates of prevalence of cognitive impairment and dementia among those aged 65 and over. The population is thus all those aged 65 years and over on the index date for centre (1990, 1991), living within a specified geographical location. Background information on the demographics of the populations sampled was collected from the Office of Population Censuses and Surveys (OPCS) 1990–91 census, now Office for National Statistics (ONS), to relate to regional and national data. Family Health Services Authority (FHSA) lists were used as the sampling frame. The frame would be incomplete if eligible members of the population were not registered with a GP. However, individuals

in long-stay hospitals remain registered with their GP two years after institutionalization so sampling from FHSA lists ensured their inclusion. Each centre looked into the practices of long-stay hospitals in their area to confirm this. The FHSA list of individuals was used for sampling on a geographical basis. Each centre defined this area, and the study population was drawn from all those who were resident within it. Problems of inaccuracy, patients who died or moved away but were still on the FHSA list, were resolved by asking GP surgeries to check the lists. On this basis, a sample of sufficient size to yield 2500 interviews of individuals aged 65 years and over, stratified by age (equal numbers aged 65–74 and 75 plus) was chosen from the FHSA lists for each selected area (in Liverpool this was 5000 interviews stratified by sex and five-year age band). The population is flagged at ONS for mortality and the database is updated continuously. The follow-up has been determined by funding and the design of associated bolt-on studies.

The main follow-up waves for the identical sites are captured in the audit trail shown in Figure 39.2, which shows the numbers for the main screen, assessment, one-year follow-up and two-year rescreen, new selection for assessment and further one-year follow-up, six-year follow-up of the assessed (with venepuncture), eight-year follow-up of those with intentions to donate, and 10-year follow-up of the total sample. In addition to this the main associated studies are the Resource Implications Study (four centres – Cambridgeshire, Newcastle, Nottingham, Oxford), which followed those who provided care to the physically and cognitively frail at baseline[4–10], the ESRC-funded Healthy Ageing Project, which interviewed in detail those who were not selected into the Resource Implications Study in Nottingham and Cambridgeshire[11–16], the Network Study conducted in Gwynedd and Liverpool to examine individuals' social networks, an embedded case-control study at two-year incidence stage (Cambridgeshire), and the ongoing brain donation programme in all centres. This programme, in combination with the bloods taken at year 6, form the major components of the biological resource of the study.

CFAS II will also have the same sampling frame and study size (at each centre). CFAS II is longitudinal at outset with two complete sweeps of the data planned. Each phase is two years apart.

Interview Method

All interviews were conducted in the respondent's place of residence, using portable computers with customized software. If the interviewer felt that the respondent was frail and tiring, or becoming agitated, the short 'priority mode' set of questions could be invoked manually. Permission was also sought to access GP and hospital notes.

Content

CFAS I screening interview contains questions on residence, marital status, education and occupation, living circumstances, contact with friends and family, health and social care contact, self-reported physical health, instrumental activities of daily living and activities of daily living, cognitive measures (Mini Mental State Examination (MMSE) with augmentation) and medication. The assessment interview is mainly the Geriatric Mental State Examination (GMS) adapted for CFAS[17–19]. This is a structured psychiatric interview, which collects sufficient information for algorithmic 'diagnosis' in the major psychiatric disorders of old age (dementia, depression, anxiety and psychosis). This has been validated against clinical diagnosis and the instrument has been widely used in Europe and now forms part of the 10/66 international instrument. This interview has been augmented with questions from the CAMDEX (Cambridge Examination for Mental Disorders of the Elderly) including CAMCOG[20], the longer neuropsychological assessment. The relative or carer interview is mainly the History and Aetiology Schedule, the informant interview that accompanies the GMS. The combined screen and assessment interview merges the two interviews but compresses some aspects of data collection. Complete versions of all the interviews including the interview questions and responses are available on the website. CFAS II interview contains all the previous screening and assessment interview information plus additional questions on diet, social activity and objective measures of hearing and physical activity. The neuropathological assessment follows the standardized protocol of the Consortium to Establish a Registry for Alzheimer's Disease (CERAD)[21], with the exception that the neuropathologist is blind to the interview data. This covers in a semiquantitative form the main areas required for the assessment of neurodegenerative and cerebrovascular disorders. The forms are available on the website. The main genetic analyses have been on ApoE and ACE. CFAS II has saliva collection at the outset for genetic comparisons. Data collection in Liverpool was broadly similar to the other five sites except that the screening interview consisted of the GMS plus some of the screening interview questions listed above.

Selected Study Findings

The study has reported on prevalence, incidence (see Figure 39.3) and risk factors of dementia (Table 39.1), and lack of variation in these across the five identical sites[22–24].

It has provided profiles of cognition for MMSE, extended MMSE and CAMCOG, weighted back to the population[25,26]. It has reported on risk for incident dementia including ApoE and ACE (Table 39.2)[27–29].

It has examined the relationship of cognition to mortality[30]. In addition, the study has reported on a variety of impairments to healthy life in old age and their population burden[31–42] and on a variety of neuropathological markers related to dementia and old age (see Table 39.3)[43–54].

Recent publications have also included the investigation of behavioural (BSPD) symptoms of dementia and on stability and population applicability of mild cognitive impairment[55–59]. The Resource Implications Study has provided data for examination of carer burden and the costs of care for the physically and cognitively frail[6,10]. The data have been used for projection forward for these vulnerable groups and also for the costs of long-term care[60]. Liverpool has published on the prevalence of dementia, depression and neurosis, together with incidence of dementia and schizophrenia[2,61–66].

CFAS I AND II AS A RESOURCE

The study is multisite and multidisciplinary. The population is truly representative with high response rates at each stage over diverse sites. Where there is no heterogeneity across sites the study is sufficiently large to provide indicative values for national estimates. The broad scope of measures has allowed the study to contribute to ageing research across a wide range of topics. There are repeat

measures on cognition and function, which allows examination of trajectories. There are only two other population-based studies with brain donation in Europe[67]. The study weighted the sample towards the over 75 age group at baseline, which has provided more robust data for the oldest old. As in all epidemiological research in older populations it would be desirable to have higher response and lower dropout between waves, but analysis can adjust for loss between interviews[68–70]. Blood taking and clinical assessment (including imaging) at baseline was not possible because of funding constraints, but venepuncture was included at year 6. The risk measures are self-report, using the available validated measures of the era. The study actively encourages collaboration, and there are established mechanisms for approaching us via the themes mentioned above. Information is available on the website and also through contact with theme leads.

above, as well as the design and aims of these two studies (started in October 2008). CFAS I and CFAS II are population-based studies of individuals aged 65 and above living in England and Wales. CFAS I has produced a range of results and a selection are shown within the chapter. The study data are part of a facilitated managed resource for collaborations, details of which have been described.

ACKNOWLEDGEMENTS

We are grateful to our respondents, their families and their primary care teams. The study has only been possible because of the dedication of a large number of individuals over the years, who are listed on the website. The MRC CFA study has been supported by major awards from the Medical Research Council and the Department of Health. Thanks are also due to the Biological Resource Advisory Group for overseeing this aspect of study.

The Lundby Study

Mats Bogren, Cecilia Mattisson and Per Nettelbladt

Department of Clinical Sciences, Psychiatry, Lund University Hospital, Sweden

From the Lundby Study, reports on dementias in the elderly for the period 1947–72 have been published. In the EURODERM comparative prevalence studies[1,2], the Lundby prevalence rates of senile dementia of the Alzheimer type (SDAT) in the age intervals 60–69, 70–79 and 80–89 were 0.3%, 2.5% and 10.9%, respectively, and for vascular dementia 0.8%, 3.5% and 6.3%.

In another study[3,4], the cumulative lifetime probability of contracting SDAT was reported to be 25.5% in men and 31.9% in women. For severely impaired cases, the figures were 15.5% and 22.2%, respectively. For vascular dementia the figures were 29.8% in men and 25.1% in women, for severe cases 16.6% and 15.2%, respectively. Background factors to SDAT and vascular dementia have also been studied[5,6]. The last follow-up in 1997 covering the period 1972–97 has now enabled us to compare the population's first incidence of dementia and other organic brain disorders over the two time periods 1947–72 and 1972–97[7].

The Lundby study is a longitudinal investigation of mental disorders in a total population. It originally included all people living in a rural area in 1947 or 1957[8,9]. This population has been investigated in 1947, 1957, 1972 and 1997[8–11] and at each point information has been obtained about the development of the mental and physical health for all individuals alive at the previous investigation providing an opportunity to observe changes of mental disorders in the population over 50 years.

At the inception, the study population lived in two parishes outside the university town Lund in the southern part of Sweden. In 1947 the Lundby area was rural with 2550 inhabitants, aged 0–92 years. In 1957 1013 newcomers were included (one-third born since 1947; and two-thirds immigrated). In all follow-ups, those subjects who had moved out of the area were also investigated. Information was also collected about those who were deceased since the previous follow-up. The present findings apply to the total cohort ($n = 3563$, male 1823, female 1740).

By 1972 gradual urbanization had changed the Lundby area from a farming district into a suburban area[4], which was even more obvious in 1997. Moreover, in 1972, many subjects had moved away from the Lundby area; of the 2827 still alive in 1972, 1424 remained, while 1403 had moved; in 1997, 602 of the 1797 survivors remained, while 1195 had moved.

At the follow-ups the aim has been to obtain as much information as possible about all episodes of mental and somatic disorders in all individuals in the population. Data was gathered from several sources: interviews, case registers, case notes, autopsy reports and key informants[11–14].

Thanks to the many data sources the diagnostic attrition 1947–72 was only 1%; although it was 6% between 1972–97. However, in those over 50 years old in 1972 the attrition 1972–97 was 2% in males and 3% in females.

Psychiatrists have conducted all interviews and evaluations of data. The diagnostic principles have been kept similar and were based on consensus[9–11]. The diagnoses were aimed at getting 'a rough picture of the relative distribution of the main types of mental illness in the population'[9].

Neurotic and psychotic disorders were disorders without evidence of organic aetiopathology. Neurotic, as opposed to psychotic, indicated preserved insight. Organic brain disorders included states with global cognitive dysfunction or gross personality or behavioural disturbance, with obvious organic causation.

Only one diagnosis per episode of disorder was recorded with organic brain disorders ranking higher than psychotic disorders, which in turn takes precedence over neurotic disorders. Furthermore, every episode of disorder was rated along with the degree of dysfunction caused by it (minimal, mild, medium, severe or very severe) according to the criteria defined by Leighton *et al.*[15]. A mild degree of impairment corresponds to a Global Assessment of Functioning (GAF) score of 70–61; medium corresponds to 60–51, and severe to 50–31. Episodes with medium, severe or very severe impairment[16] were chosen to indicate caseness. For all episodes, onset and termination were assessed as closely as possible using all sources of information.

Incidence rates for organic brain disorders in the periods 1947–72 and 1972–97 were obtained as the number of first occurrences of the outcome divided by the total number of person-years under risk for the outcome in individuals who had previously been free from the outcome. Individuals contributed with risk-years until contracting the outcome, dying, dropping out of the study or the end of the study period.

When age- and sex-specific incidences of organic brain disorders in 1947–72 and 1972–97 were compared, the rates had decreased consistently from the first to the last period in all age intervals but 40–49 (Table 40.1). Both male and female age-standardized first-incidence rates decreased significantly from the first to the last period.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

In both periods the age-standardized incidence rate of organic brain disorders was higher in males than females. The difference was significant in 1947–72, but not in 1972–97.

When the impairment threshold to indicate caseness was changed from medium to severe, the age-standardized first incidence per 1000 years at risk of organic brain disorders declined from 3.4 to 2.0 in males and from 2.9 to 2.0 in females from 1947–72 to 1972–97. There were no cases of organic brain disorder with impairment level under medium.

In the period 1947–72 dementia constituted 80% and milder organic brain disorders 20% of the category organic brain disorders. In the period 1972–97 the corresponding figures were fairly similar at 83% and 17%, respectively.

When organic brain disorder was divided into dementia and other organic brain disorders not reaching the dementia threshold, one could still, for both groups, see a decrease of the age-standardized first incidences from the first to the second 25-year investigation period. In males the age-standardized first incidence of dementia fell from 5.1 to 2.1 per 1000 years at risk and in females from 4.0 to 2.1. The age-standardized first incidence of organic brain disorders not reaching the dementia threshold fell from 1.2 to 0.6 in males. Among females there was only a marginal decrease from 0.5 to 0.3.

The age interval responsible for the reduction of the age-standardized first incidence of dementia was above all the 70–99 interval, while the age intervals concerned regarding the reduction of milder organic brain disorders were those under 70. In males aged 70–99 the first incidence of dementia decreased from 28.4 to 10.9 per 1000 years at risk. In females the first incidence decreased from 23.4 to 12.6.

Male and female age-standardized first-incidence rates of dementia and other organic brain disorders every fifth year from 1947–97 are seen in Figure 40.1. In both males and females a trend of decreasing incidences of dementia can be observed from 1947–97, while five-year incidences of other organic brain disorders remained fairly constant through the whole period.

There are a limited number of studies that have tried to ascertain secular trends of dementia incidence. However, in a study from Rochester, Minnesota, no significant change of the incidence of dementia was seen from 1960 to 1984[17,18]. One difference from the Lundby study was the shorter length of the observation period. A long period of study might be needed to be able to see a slow change over many years[18].

The Lundby population offers an opportunity to study the rates of dementia and other organic brain disorders during a period of great transition in society and development of public health. This transition includes changes of lifestyle (e.g. food, smoking) and increased availability of medical care (e.g. antihypertensive and antidiabetic treatment) as well as changes in the physical environment. Thus, the decrease of organic brain disorders in both male and female subjects may be the result of a healthier lifestyle and availability of treatments protecting against the development of organic brain lesions.

Clinical Features of Alzheimer's Disease: Cognitive and Non-cognitive

Oludamilola Salami and Constantine G. Lyketsos

Johns Hopkins School of Medicine and Johns Hopkins Bayview, Baltimore, USA

Alzheimer's disease is best described as a neurodegenerative brain disease that causes a clinical dementia syndrome. It is the most common neurodegenerative disorder, accounting for over 60% of dementia cases in late life. Alzheimer's dementia is estimated to affect over 4 million Americans and 21 million persons worldwide[1].

The dementia associated with Alzheimer's disease is heterogeneous and diverse. Symptoms and signs vary with the progression and severity of the illness. Progressive cognitive decline with impaired ability to function in the person's usual environment is regarded as the hallmark of the clinical syndrome. Memory is invariably affected. There is also dysfunction in other domains of cognition including language, visuo-spatial, perception, recognition, praxis and executive function. Non-cognitive neuropsychiatric symptoms (NPS) are universal over the course of illness and are themselves diverse. These include affective, perceptual, behavioural, motivational and personality changes. Alzheimer's disease is usually indolent in its early course. Progression of the disease is associated with loss of independent function. The impact on sufferers, caregivers and other loved ones is often profound. Estimates of life expectancy in Alzheimer's disease range from 3 to 9 years[2]. The mortality rate associated with Alzheimer's dementia is on the order of 10.6 deaths per 100 000 person-years in the population[3].

Alzheimer's disease and delirium are clinical syndromes with similarities in clinical features and may be co-morbid. In the early stages of Alzheimer's disease, the key differences are the acute onset, fluctuating symptoms and the prominent sleep–wake cycle fragmentation which are seen in delirium and not in Alzheimer's disease. However, advanced Alzheimer's disease is difficult to differentiate from delirium, except by the clinical history[4]. This section focuses on the clinical presentation of Alzheimer's disease, and the occurrence of its clinical features along a spectrum from early disease to the advanced stages.

COGNITIVE SYMPTOMS

Impairment in cognitive function is the core feature of Alzheimer's disease. Several areas of cognition may be affected and the degree of impairment varies with illness severity (Table 41.1).

Memory

Disturbance of memory is regarded as the hallmark of Alzheimer's disease. Memory impairment is, however, not always the initial symptom. Affective symptoms may often precede memory disturbance[5]. It is important to note that the spouse or close relatives of most patients with Alzheimer's disease are usually the ones who bring the memory deficits to clinical attention, not the patients themselves. Early memory symptoms heralding the onset of dementia include difficulty with the registration and retention of new information, leading to repeating questions or comments. There may also be difficulty manipulating stored information associated with working memory. Delayed spontaneous recall of recently acquired information is impaired in early stages[6]. Immediate recall, recognition and registration of information become increasingly affected with progression of illness. As these symptoms worsen, memory dysfunction affects daily function, which is important in differentiating dementia from memory decline associated with normal ageing. Individuals with early Alzheimer's disease may develop difficulty recalling recent tasks, events, directions and appointments.

Those with advanced education or high intellectual reserve may be able to adapt for some time with minimal impact on their daily function. Some resort to memory cues, such as taking notes or keeping journals, to compensate for decline in memory. In moderate to severe stages, long-term memory becomes impaired. There may be inability to accurately recall details of familiar historic events and personal information, including names of family members, birthdays, special occasions or other aspects of declarative memory.

Language

Both oral and written impairments of language are found in Alzheimer's disease. In the early stages, fluent dysphasia may predominate, often in a pattern similar to transcortical sensory aphasia. Characteristic deficits at this stage include diminished vocabulary and word finding difficulty. Individuals with early dementia often have difficulty selecting words and may lose track during conversations[6]. Word repertoire shrinks and use of language

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Table 41.1 Cognitive symptoms associated with Alzheimer's dementia

Memory (working, declarative and procedural impairment)
Language (aphasia, alexia, agraphia, aprosodia, acalculia)
Visuo-spatial dysfunction, recognition impairment or agnosis
Execution of previously learned movements or praxis
Executive dysfunction (planning, sequencing, abstraction, set shifting, organizing)

becomes more simplistic, often described as circumlocutory. There may be paraphasic errors with incorrect word substitutions.

In advanced disease, impaired comprehension and word finding difficulties are more pronounced. The ability to communicate effectively becomes impaired. The patient's speech may become non-fluent with mainly short simple phrases or words. Echolalia and palilalia may also occur as affected individuals develop complete loss of verbal expression. These deficits may extend to reading and writing ability. Some affected individuals may retain their ability to understand and respond to non-verbal and emotional cues.

Visuo-spatial Function

Visuo-spatial cognitive impairment and non-verbal visuo-spatial information processing are the characteristic visuo-spatial disturbances observed in Alzheimer's disease. Visual discrimination, visual recognition and visuo-spatial attention deficits may also occur, but less frequently. Although subtle impairments may be seen with early Alzheimer's disease, deficits occur more commonly in moderate to severe stages of dementia and often become progressive. There may be impairment in ability to synthesize, integrate and organize visual sensory stimuli or other environmental information. There may also be difficulty developing strategies for complex construction. Some persons with Alzheimer's disease have impaired right–left orientation and defective re-visualization, which involves internally re-visualizing and imagining a named object and then describing it accurately when prompted. Some may have difficulty with the synthesis of parts of an object into a whole and then properly identifying the whole (classic agnosia). Patients may also have difficulty copying or drawing objects and, with further progression of the illness, lose the ability to construct complex figures or diagrams. Rarely patients present with reduplicative paramnesia, involving the belief that they are in two or more locations simultaneously. Reduplicative paramnesia, more often seen following head injury, can also be regarded as a misidentification syndrome.

Praxis

Impairments with planned motor movements are closely related to executive dysfunction. These deficits are usually seen in advanced stages of Alzheimer's disease dementia. Ideomotor and ideational apraxias may occur earlier. Ideomotor apraxia is characterized by inability to execute learned movements when prompted despite intact comprehension, sensation, motor strength and coordination. There may be difficulty in organizing and sequencing of movements involved in executing an action, e.g. pantomiming combing one's hair or brushing teeth. Individuals with Alzheimer's disease may exhibit motor perseveration and poor limb positioning. Ideational apraxia is the inability to perform an action comprised of several steps. An example is pantomiming the act of getting dressed or changing the batteries in a remote control. Given the profound limitations to daily function from apraxia, these symptoms can be very distressing to both patients and care providers. There may also be difficulty recalling the ability to perform previously learned tasks such as driving, using utensils, toileting and self-care.

Executive Dysfunction

Impairment of executive function may result in cognitive, mood, behavioural and personality changes. The latter are discussed later as part of NPS. The cognitive symptoms of executive dysfunction are closely related to higher intellectual capacity and involve several aspects of higher intellectual function, including planning, sequencing, abstraction, set shifting and organizing. Features of executive dysfunction arise commonly early in the course of Alzheimer's disease, and may be the primary reason why functioning becomes impaired and care is sought. There is often loss of generative thought, and inability to plan or organize several mental tasks simultaneously without the use of aids. Individuals who previously did not require daily to-do lists to successfully perform tasks may have progressive difficulty completing activities.

It is important to note that there are age-associated declines in executive function; however, the mental flexibility that allows for the adaptive skills in the absence of dementia is often absent with Alzheimer's disease. Ability to solve problems mentally is affected early. In addition, there may be impairment in symbolic and abstract thinking. Thoughts become more concrete and patients may have difficulty accurately interpreting proverbs. Poor response inhibition (e.g. impaired Stroop colour-word interference test), reduced ability to sustain and divide attention, and perseveration of sequential motor tasks can also be seen in Alzheimer's disease at any stage of dementia or in the clinical prodrome to dementia.

NON-COGNITIVE NEUROPSYCHIATRIC SYMPTOMS ASSOCIATED WITH ALZHEIMER'S DISEASE

Neuropsychiatric symptoms such as depression, apathy, agitation and delusions are nearly universal in dementia associated with Alzheimer's disease. Over time, over 98% of individuals with Alzheimer's disease experience at least one NPS disturbance during the course of their illness[7]. In Alzheimer's disease, the presentation, severity and frequency of these symptoms may fluctuate with progression of the illness. NPS can be classified based on individual symptoms or clusters of frequently co-occurring symptoms[8]. The Neuropsychiatric Inventory (NPI) helps distinguish neuropsychiatric symptoms and signs into 12 domains: delusions, hallucinations, agitation, dysphoria, anxiety, apathy, irritability, euphoria, disinhibition, aberrant motor behaviour, night-time behaviour disturbances, and appetite and eating abnormalities[9] (Table 41.2).

NPS may be further differentiated based on a hierarchical approach into clusters of affective disturbance, psychotic disturbance, sleep disturbance, apathetic syndrome and executive dysfunction syndrome[8].

NPS with Prominent Affective Disturbance

Symptoms of disturbed mood are the most common non-cognitive symptoms seen in Alzheimer's disease. These include depression,

Table 41.2 Other neuropsychiatric symptoms associated with Alzheimer's dementia

Behavioural disturbance and personality changes (apathy, aggression, agitation, disinhibition and aberrant motor behaviour)
Mood disturbance (depression, anxiety, irritability)
Psychomotor abnormalities (sleep disturbance, appetite dysregulation)
Perceptual disturbance (delusions, hallucinations, illusions)

anxiety, irritability, agitation and elation. Depression is the most common mood symptom with an estimated five-year cumulative prevalence of 77%, and an average point prevalence of 31%[10] (Figures 41.1 and 41.2). Depressive symptoms which may also present in the context of a typical major depressive episode are often part of an atypical affective syndrome occurring in Alzheimer's disease referred to as 'depression of Alzheimer's disease' (dAD)[11] or 'affective disorder associated with Alzheimer's disease'[12]. Depression is often co-morbid with apathy. More than 40% of apathetic Alzheimer's disease patients present with depression and 56.4% of those with depression also present with apathy[13]. Other symptoms associated with depression in Alzheimer's disease include impaired sleep, anhedonia, poor concentration, diminished energy and appetite disturbances.

Depressive symptoms may herald the onset of Alzheimer's disease. Mood symptoms are more common in mild to moderate than in advanced dementia[13], although this apparent difference may be a result of difficulties evaluating the mental state of patients with advanced disease. Differentiating Alzheimer's disease with depression from other forms of late life depression (e.g. major depressive disorder) may be challenging as the symptoms overlap. Apathy, anxiety, diminished motivation, sleep disturbance and appetite dysregulation are examples of overlapping symptoms. However, the sustained subjective dysphoria seen with major depressive disorder is not characteristic of depression in Alzheimer's disease. Furthermore, unlike individuals with major depressive disorder, depressed patients with Alzheimer's disease may not report hopelessness, worthlessness and suicidal thinking but rather endorse symptoms of irritability, anxiety, and diminished interest and motivation[14]. Less commonly, elation and mood lability may present in Alzheimer's disease. These mood changes are rarely sustained and are often attenuated by redirection. Delusions may occur in the context of either an affective disturbance or a psychotic disturbance. Delusions are rare in late-life depression but occur in over 30% of patients with dAD.

Individuals with Alzheimer's disease have diminished insight as the disease progresses; however, in the early stages they may become demoralized. Feelings of demoralization often resolve as they adjust to the disease or lose insight with illness progression. Appetite dysregulation affects an estimated 37.8% of patients with Alzheimer's disease[15]. These symptoms are more prominent with

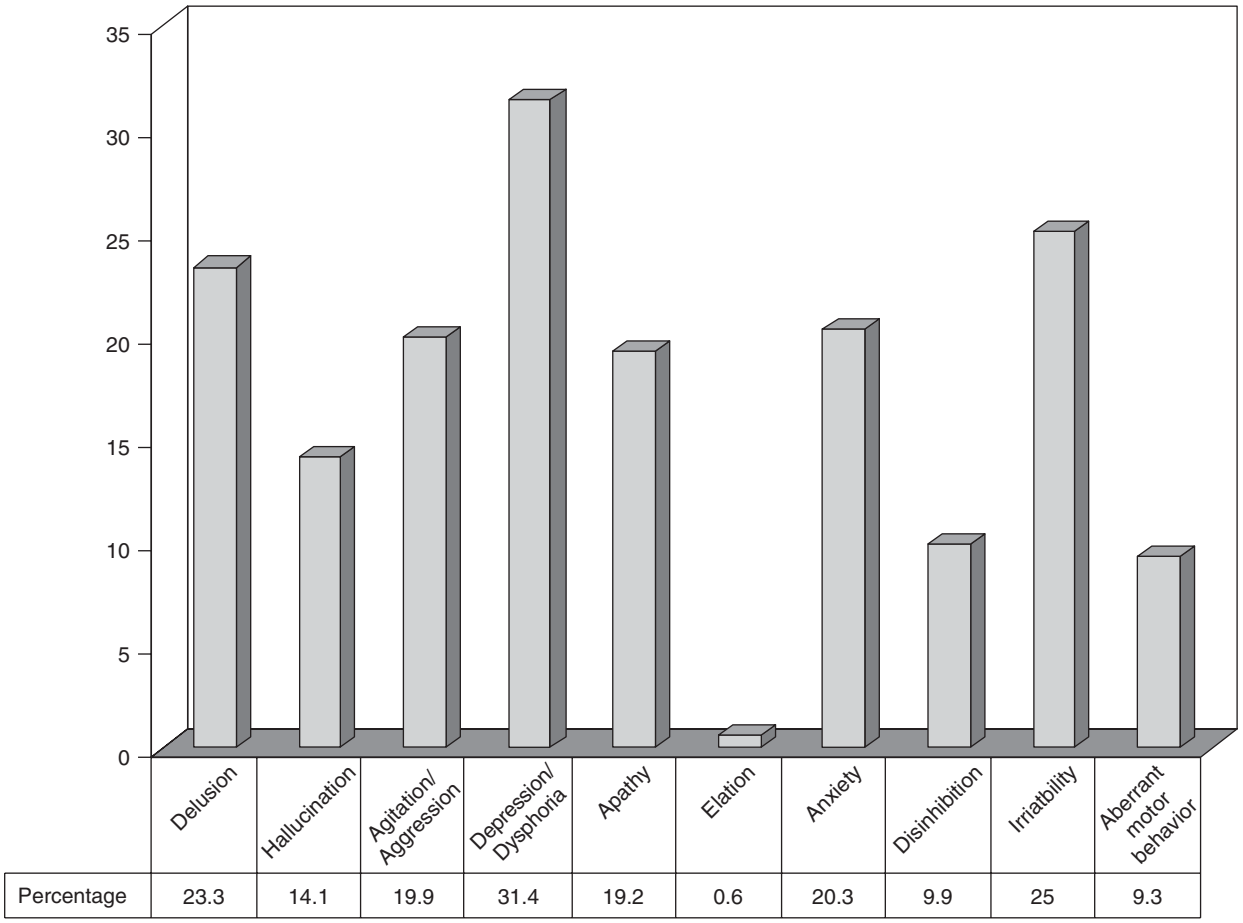

Figure 41.1 Point prevalence of neuropsychiatric symptoms in a community-based US sample[10]

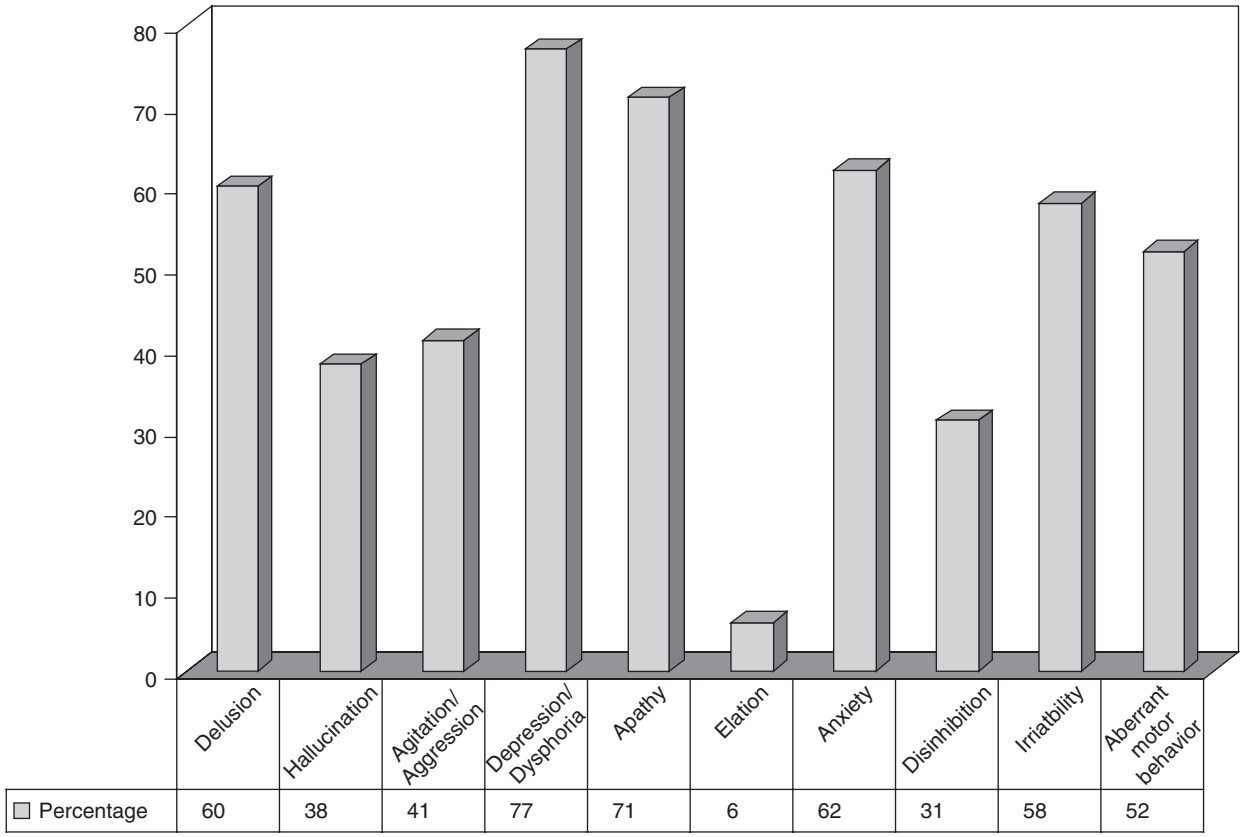

Figure 41.2 Five-year period prevalence of neuropsychiatric symptoms in a community-based US sample[10]

severe Alzheimer's disease. With progressive decline in independent function, individuals with Alzheimer's disease often exhibit irregular nutritional intake. Behavioural disturbances including irritability, agitation and disinhibition may have a greater impact on eating patterns and the quality of nutritional intake than the level of cognitive impairment[16]. Furthermore, there may be loss of appetite secondary to degeneration of hypothalamic regions associated with feeding and satiety. Nevertheless, without adequate supervision, those with advanced dementia have difficulty maintaining adequate daily nutritional support.

Agitation and aggression in Alzheimer's disease often manifest as emotional excitability, irritability, resistive behaviours, shouting or physical aggression. The estimated prevalence of agitation in Alzheimer's disease is 20–25%[10]. Agitated behaviours are not unique to Alzheimer's disease and may also be a part of other late-life conditions, including primary psychotic, depressive or substance use disorders and unrecognized pain. Agitation may also be provoked by environmental stimuli. Agitation and aggressive behaviours occur more commonly with advanced Alzheimer's disease. These behaviours are often seen in institutionalized Alzheimer's disease patients and frequently precipitate institutionalization in those living in the community.

NPS with Prominent Psychotic Disturbance

Delusions are a common neuropsychiatric symptom of Alzheimer's disease with an estimated point prevalence of 23%[10] and a prevalence range of 15–70%[17]. The wide range in rates may be due to different definitions of psychotic disturbance in Alzheimer's disease[18]. Delusions are unshakable false beliefs that are out of context with the individual's social and cultural background, while hallucinations are false sensory perceptions that are not simply distortions or misinterpretations of actual stimuli. Delusions in Alzheimer's disease have been associated with older age, male gender and a lower level of education[19]. Delusions occur more frequently than hallucinations. The most common types are poorly developed paranoid delusions and misidentification syndromes. The features of paranoid delusions are often related to theft, believing personal objects have been misplaced or stolen, and infidelity. Some characteristic misidentification syndromes may include the belief that family members have been replaced by imposters (Capgras syndrome) or that a stranger (often a misidentified close family member) inhabits their homes (phantom boarder). They may also express the belief that they have been removed from their homes and placed in a foreign environment. There may be differences in cognitive deficits among patients with delusions or delusional misidentification. Patients with delusions often have significantly greater impairment of recent memory, while those with delusional misidentification may have greater impairment of receptive language function. Patients with delusions or delusional misidentification are more likely to have some insight into their psychotic symptoms, unlike those who experience visual hallucinations.[20]. Delusions in Alzheimer's disease may be associated with depression, aggression, agitation and anosognosia[21].

Hallucinations are less common in Alzheimer's disease than delusions, occurring in 13–16%[17] of patients with Alzheimer's disease at any point and may occur in up to 38% of these individuals over

a cumulative five-year period[10]. Visual misperceptions are the predominant type of hallucinations in Alzheimer's disease. However, if visual hallucinations occur early in the illness, dementia with Lewy bodies should be considered. There is an increase in cognitive impairment, functional decline, placement in institutionalized care and death associated with delusions and hallucinations[22]. Delusions and hallucinations are seen more often in the moderate stages of Alzheimer's disease and may persist and often recur over the course of the illness[17].

Illusions are not often reported in Alzheimer's disease and clinical evidence describing the features of illusions in this disease is limited. There is, however, some evidence that visual illusions, if present, may worsen with progression of Alzheimer's disease[23].

Sleep Disturbance

Sleep disturbance in dementia is associated with significant caregiver distress and may precipitate institutionalization of community dwelling individuals due to its burden on caregivers. Nocturnal insomnia presents a background for unsupervised and potentially unsafe behaviours such as wandering and pacing and may precipitate serious risk of harm to themselves and others. Environmental stimulation may also play a role in aetiology or propagation of sleep problems in dementia. An estimated 59.2% of those with advanced dementia have some evidence of sleep disturbance, with insomnia, excessive daytime somnolence and napping being most prevalent[24]. Other symptoms include increased nocturnal awakenings and fragmented sleep. Insomnia is more common in patients with mild and moderate dementia while daytime sleepiness is more frequently associated with severe dementia[24]. Objective assessments of sleep using wrist actigraphy and polysomnography indicate that individuals with Alzheimer's disease in long-term care facilities may have increased total sleep time, increased sleep latency, increased REM sleep latency, less sleep efficiency, increased N1 non-REM sleep and decreased REM sleep[25].

Apathetic Syndrome

Degeneration of the anterior cingulate gyrus and adjacent medial frontal lobe structures with disruption of the frontal and subcortical circuits is associated with apathy. Apathy is one of the most prevalent psychiatric phenomena in Alzheimer's disease, affecting an estimated 75% of patients over the course of illness[10]. Features of apathy commonly seen include both emotional and motor phenomena. There is decreased emotional range, reduced motivation, diminished volition to initiate new tasks and a decrease in goal-directed behaviour. Comparisons may be drawn with depressed individuals; however, unlike depression, persons with Alzheimer's disease are not distressed or concerned with these symptoms. In rare cases, with severe dementia, there may be severe apathy in which individuals are awake but do not interact with the environment. They do not eat spontaneously unless fed, and do not attend to personal hygiene or maintain voluntary control over bowel and bladder functions.

Executive Dysfunction Syndrome

Changes in behaviour, mood and personality are often associated with the late stages of Alzheimer's disease. It is, however, not uncommon for these symptoms to present early in the clinical course. Other possible underlying causes, particularly the frontotemporal dementias, should be considered if behavioural and personality changes are seen early in the disease. Disinhibition, environmental dependency and verbal or motor perseveration are less prevalent than most other neuropsychiatric symptoms and present more frequently in the late stages of the illness[26]. Behavioural disinhibition and aberrant motor behaviours frequently precipitate placement into a nursing or assisted living home. Pacing and wandering are behaviours seen with increasing frequency with worsening dementia and may also precipitate placement into institutionalized care.

Other Clinical Features

With progression of Alzheimer's disease, there is an increasing risk of falls. This may be related to impairment in balance and gait, or poor coordination caused by the neurodegenerative process. Falls may also occur due to the effects of medications, orthostatic hypotension from cerebrovascular and cardiovascular dysfunction, and environmental hazards[27]. Falls may be associated with scalp injury, subdural haematoma, traumatic brain injury and rarely skull fractures.

In individuals with severe physical debility who have limited ambulation or are bed-bound, there is a significant elevated risk of decubitus ulcers. Alzheimer's disease may also be a predisposing factor in delirium or infections, particularly of the respiratory and genitourinary tract.

Neuropsychological Assessment of Dementia and Alzheimer's Disease

David Aaron Maroof and Cynthia A. Munro

Department of Psychiatry and Behavioral Sciences, The Johns Hopkins University School of Medicine, Baltimore, USA

INTRODUCTION

Clinical neuropsychology can be conceptualized as both the *study* of affective, behavioural and cognitive manifestations of brain function and the *application* of assessment procedures in quantifying these interrelated processes to inform decisions regarding the causes for dysfunction. The term *neuropsychology* has also been described as a 'merger between experimental psychology and neurological sciences for studying relationships between the brain and behavior'[1] (p. 139). Assessment procedures used by neuropsychologists are tasks that tap various domains of cognition, including, but not limited to, aspects of attention, processing speed, language, visuospatial skills, memory and executive functioning, as well as those assessing mood and aspects of personality. Responses to these tasks provide scores that are used to quantify an individual's functioning in these domains. While we cannot physically observe cognition, we can infer its integrity with the use of standardized psychometric tests. Quantification of an individual's optimal cognitive ability, considering his or her emotional status and personality characteristics and then determining whether one's optimal cognitive ability represents disease, is the cornerstone of the neuropsychological assessment of dementia. In so doing, we improve diagnostic accuracy of dementia above routine clinical evaluation[2]. How we accomplish this is the focus of this chapter.

We have divided this chapter into five sections. First, we will provide a brief introduction to the field of neuropsychology. Second, we will discuss the role of the clinical neuropsychologist in the assessment of dementia. Third, we provide an overview of the basic patterns of cognitive test performance in dementia. Fourth, we discuss some common misconceptions about the practice of neuropsychology. Finally, we present some of the current trends in the neuropsychological assessment of dementia.

INTRODUCTION TO NEUROPSYCHOLOGY

Neuropsychology is an amalgam of many disciplines, influenced by neuroanatomy, neurophysiology, neurochemistry, neuropharmacology, psychology and neurology[3], as well as philosophy, physiology and anatomy[4]. Psychometric theory and application, as they relate to appropriate use of data analyses in test construction and the development of normative data, are the very linchpins of neuropsychological assessment and substantiate the theoretical and conceptual networks of the discipline.

The nexus between current neuropsychological theory and practice harks back to ancient philosophical thought[3]. Ideas such as aestheticism (e.g., is a theory appealing?), rationalism and empiricism still fuel the practice of clinical neuropsychology[5]. Glozman[6] discusses the influence of Russian contributions dating back to the late 18th century from psychiatrists and neurologists and attributed many changes in neuropsychological practice – including combining both quantitative and qualitative approaches, expansion to include social and personality variables and increasing nosological patient groups – to this influence. A main theme that Glozman[6] noted was '. . .not so much diagnostic but prognostic. . .neuropsychological assessment should rather emphasize the subject's strengths which are important. . .and predict his/her ultimate integration into society' (p. 177). The need for a systematic, valid and reliable method of measuring the manifestations of brain function emerged. Test construction thus came on the heels of conceptual and theoretical models of brain function and organization.

Delineating the inception and progression of various neuropsychological tasks is beyond the scope of this chapter. However, we have selected to discuss one very commonly used method for assessing executive functioning to exemplify the manner in which some of our tests have been developed. Executive functioning is a cognitive process involving one's ability to adapt and respond effectively to environmental demands, novel situations and ultimately deduce efficient and effective ways for completing them. Several 'tributaries' of executive functioning have been promulgated, including sequencing behaviours, abstraction, organization and planning. Eling and colleagues[7] report on the influence of Narziss Ach who designed a paradigm for observing concept formation in the early 20th century. Nonsense words (on cards) were attached on various geometric figures of different shapes and sizes and once these cards were removed, the individual was required to deduce how the words related to the features of the objects. The quintessential element of this task is that one must discover the sorting principle. Goldstein and Scheerer[1] underscored the abstract elements of this task, in which one must be able to abstract from a concrete object, while maintaining insight into other potential 'choices'. The Wisconsin Card Sorting Test (WCST)[8] was developed on the basis of these principles. Brenda Milner[9] ultimately demonstrated that lesions in the

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

dorsolateral prefrontal cortex resulted in shifting problems (i.e., perseverating) and subsequent research has repeatedly confirmed that damage to the frontal cortex is associated with poor performance on this task[10].

Integrity of the perforant pathway (the principal source of input to the hippocampal formation) is essential for normal hippocampal function. In Alzheimer's disease, it is the pathological changes in this pathway that preclude its normal operation of acquisition of contextual knowledge, presumably due to a disconnection among the hippocampal formation and input from sensory-specific and multi-modal association cortices[11]. However, as the neuropathology spreads beyond the medial temporal lobe structures to the association cortices of the frontal, temporal and parietal lobes, higher order cognitive deficits result[12]. Regarding cognitive assessment in Alzheimer's disease, it is the juxtaposition of the neuropathological changes along the disease trajectory with administration of specific tests chosen to assess the associated cognitive deficits that is the cornerstone of clinical neuropsychology. The application of statistical methodology provides the intellectual spadework for clinical practice, as the interpretation of test performance requires the understanding of statistical principles underlying test construction and interpretation.

THE ROLE OF THE CLINICAL NEUROPSYCHOLOGIST

The advent of neuroimaging in the 1970s changed the clinical neuropsychologist's role from that of lesion detection to one of description of the cognitive sequelae of disease[13] and/or diagnosis of disease for which imaging is uninformative. In general, there is a chasm between knowledge gleaned from neuroimaging and information gathered through neuropsychological examination. Imaging tells us *what* (e.g. cerebrovascular accident), *where* (e.g. anterior cerebral artery) and *how* (e.g. ruptured aneurysm), whereas neuropsychological examination tells us the consequences, including *how much* (degree of deficit) and *in what way* (memory, language, etc.) functioning has been affected.

Neuropsychological assessment in dementia depends on the context of the referral question. In some cases, the neuropsychologist's role is to determine whether cognitive impairment exists and if so, to assist with the differential diagnosis of its cause. In other cases, diagnosis of the disease causing the dementia has been established and the neuropsychologist is asked to determine areas of cognitive strength and weakness, to assist with the development of compensatory strategies. Neuropsychological assessment is also used to track disease progression through repeated examinations, at times determining whether changes in medication are associated with changes in cognition. In still other cases, neuropsychological assessment provides objective data to assist in determining whether a patient is competent to make independent decisions regarding medical, financial or other matters. Recommendations regarding whether a patient should cease driving or working are also informed by neuropsychological assessment. Thus, the context of the referral, even within the narrow scope of dementia assessment, is important to the information that is provided by the neuropsychologist.

RECOGNIZING PATTERNS OF NEUROCOGNITIVE FUNCTIONING IN THE DEMENTIAS

It is quite often the case that clinical neuropsychologists must disentangle ambiguous complaints of declines in cognitive function. Memory complaints, for example, often dissemble the extent and typology of cognitive deficits. What can present as a memory deficit may be related to the bigger picture of a breakdown in semantic knowledge (e.g. naming), or difficulties with executive function that can affect one's ability to carry out a series of everyday tasks. The pattern of performance exhibited on a neuropsychological examination provides information with regard to these core and peripheral deficits and in conjunction with a comprehensive anamnesis, offers etiological significance.

The cortical–subcortical distinction proffers a heuristically useful model for describing the pattern of neuropsychological performance in various patient groups, despite observations that this is an oversimplified dichotomy[14,15]. This distinction was engendered by the observation of different clinical presentations in patients with cortical compared to subcortical disease[16]. Although the prototypical cortical dementia is that caused by Alzheimer's disease, other diseases, such as frontotemporal lobar degeneration and Creutzfeldt–Jakob disease, are also associated with cortical pathology. Far greater in number, diseases causing subcortical dementia comprise, among others, progressive supranuclear palsy, Parkinson's disease and Huntington's disease and are associated with pathological changes involving the thalamus, basal ganglia and related brain-stem nuclei. Cortical diseases typically develop similar cognitive footprints, including deficits in language, learning and praxis, whereas patients with subcortical dementia typically demonstrate impaired attention/concentration, processing speed and executive function, as well as apathy and depression. Although the cortical/subcortical dichotomy is simplistic and does not account for disorders with both cortical and subcortical features (e.g. cortical-basal degeneration[17]), this distinction remains useful in the differential diagnosis of dementia.

In clinical practice, the neuropsychologist must make several determinations when the question of dementia is being considered. After the tests are administered and the scores are obtained, these scores are compared against a normative sample; that is, a sample of individuals, typically of the same age, but sometimes of the same race, sex and education as the patient. This comparison yields standardized scores (percentiles, z-scores or t-scores) for each raw score. Upon examination of these standardized scores, the neuropsychologist must consider several questions. First, is the examination normal or abnormal? Second, if it is abnormal, does the examination indicate the presence of a cognitive disorder or dementia? Third, is the pattern of cognitive test performance suggestive of cortical or subcortical involvement? Fourth, what disease is underlying the cognitive disorder?

Abnormal scores on individual tests can be defined by several means. In some cases, a score that is obtained by fewer than a particular proportion (often 2%) of the normal population is considered to be abnormal. However, in a large battery of neuropsychological tests, obtaining several scores that are in this 'impaired' range is quite normal[18]. In other instances, an abnormal score is one that is unexpected given a particular patient's premorbid ability. That is, if a patient has limited education or sensory deficits that preclude his or her ability to perform some aspects of a task, then an abnormal score might not represent a decline from premorbid ability. Likewise, if a patient has superior premorbid intellectual functioning, a score in the borderline range on a memory test might be considered an abnormal score for that individual.

A second determination is then made regarding whether the presence of one or more abnormal scores constitutes an abnormal exam. This inference requires one to incorporate other information, such as

the patient's or informant's complaints and the overall pattern of test scores. As already mentioned, the presence of one or more abnormal scores often occurs across a battery of neuropsychological tests in normal healthy adults. Thus, the neuropsychologist must determine whether the pattern of abnormal scores is clinically meaningful. This determination is informed by the clinician's knowledge of patterns of test scores that occur in conditions causing dementia. Incorporating measures of emotional functioning are also useful in informing the clinician's determination of whether an abnormal examination is the product of disease or is psychogenic in nature. The practice of interpreting neuropsychological test results is therefore an integrative process, incorporating the patient's history, complaints and test data. Results from neuroimaging and neurological examination, if available, are also considered.

MISCONCEPTIONS ABOUT THE NEUROPSYCHOLOGICAL ASSESSMENT OF DEMENTIA

The assessment of patients with dementia is often multidisciplinary, involving neurologists, psychiatrists, neuroradiologists, geriatric practitioners and/or family practice physicians. Among non-neuropsychologists, several misconceptions regarding the practice of our discipline appear pervasive. We describe several of these misconceptions, as they can hinder one's understanding of the information provided by the neuropsychologist.

Cutoff Scores

Perhaps a result of epidemiological studies that use various scores – such as a Mini Mental State Examination Score of 24 or below – to exclude individuals who are likely to have cognitive difficulties, the notion that a particular score on a given test can be used to indicate dementia is a common misconception. Such scores, when used for research purposes, are often chosen because they are uncommon in healthy individuals. A score that is equal to or below the 2nd or 10th percentiles, that is, a score that represents poorer performance than what 98% or 90%, respectively, of individuals score, are common 'cutoff' scores for research. However, many factors render these cutoff scores inappropriate for use in clinical practice: premorbid ability, effort and number of tests administered all determine whether a particular score is abnormal. Thus, it is inappropriate to apply a cutoff score to an individual, or to use phrases such as 'he scored below the cutoff for dementia', as such scores differ, depending on the individual. For this reason, the use of norms is a cornerstone of the practice of neuropsychology. Such norms are crucial to answering the basic question, 'is this test score normal or abnormal?' Which demographic factors should be considered in the development of normative tables is a topic with particular currency in the field.

Singularity of Domains Assessed by Particular Tests

Another misconception about the practice of neuropsychological assessment is that each test taps a singular ability that is subserved by a discrete brain structure. In practice, two patients might perform poorly on the same task, but for different reasons. For example, if a patient is unable to copy a complex figure, it might be due to poor visual perception, difficulty with constructional praxis or problems with executive functioning. By administering a battery of tests that assesses these domains in various ways and examining the pattern of test performance, we can then determine which domains are impaired in each patient. It is important to recognize, therefore, that a particular test may require intact functioning in several cognitive domains. It follows that failure to perform a test does not necessarily imply impairment in a single domain.

In addition to the fact that various cognitive processes can subserve performance on the same task, it is also the case that functional networks account for the existence of similar cognitive impairments among individuals with different sites of lesions[19]. A common misconception is that executive functioning is determined by integrity of the frontal lobe. Whereas several executive tasks have been associated with frontal lobe activity[20] and have been shown to be impaired in patients with frontal lobe lesions[21], executive dysfunction can occur in the context of abnormal functioning in other areas as well[22].

Association between Premorbid Ability and Cognitive Test Performance

A third misconception is that individuals with superior premorbid ability should perform in the superior range on all cognitive measures. This logic often leads to the false conclusion that average test performance represents impairment in high-functioning individuals. However, when this notion is tested empirically, it is simply not the case. On the contrary, individuals of above-average intellectual functioning perform better than those with average intelligence on approximately one-third of measures in a test battery. Individuals with lower IQ scores do perform significantly worse, however, than individuals with average intelligence on most measures[23]. Thus, whereas low scores would be expected for individuals with lower intelligence, higher scores on all measures should not be expected among individuals with higher levels of intellectual functioning. While it is possible that average performance across all tests in a domain may represent a decline from premorbid ability in an individual with complaints in that domain, we cannot know this. In such cases, it is important to consider other factors and perhaps even then, the only way we can know whether disease exists is to repeat the examination after some time (usually one year or so) to determine if there is decline in test performance that would suggest the presence of disease.

Time Course of Recovery from Cognitive Deficits in Depression

Depressed individuals can demonstrate cognitive dysfunction in the absence of demonstrable neuropathology[24] and these deficits appear to be more pronounced in depressed elderly compared to younger individuals with depression[25,26]. The most consistently documented deficits among elderly patients with depression involve psychomotor speed, executive functioning and memory for newly learned information[27,28]. Thus, the prototypical cognitive deficits resulting from depression resemble those seen in 'subcortical' dementia[29].

A common misconception concerning the cognitive deficits associated with depression is that they resolve coincident with remission of low mood. Longitudinal studies have shown, however, that cognitive deficits remain during episodes of symptom reduction and even during remission[30]. The more effort a task requires for success, the less well individuals with depression tend to perform on it[31]. Indeed, some evidence suggests that the relationship between

depressive symptoms and performance on many cognitive tests is largely mediated by impairments of effortful processing[28,32]. In a study by Hammar and colleagues[33], depressed patients were impaired on cognitively demanding tasks (those requiring effortful processing) when symptomatic and their impairments persisted even after six months, despite significant improvement in symptoms of depression. Similarly, Nebes and colleagues[24] found that depressed elderly patients whose mood symptoms responded to treatment with an antidepressant medication (paroxetine or nortriptyline) showed no greater improvement over baseline performance in any cognitive domain than untreated healthy control subjects on five follow-up examinations taking place over 12 weeks. These studies and others suggest that the cognitive impairment observed among depressed elderly patients may be an enduring feature[34]. Nevertheless, longitudinal assessment of depressed patients can assist in the differential diagnosis between depression and dementia, based on whether there is progressive cognitive decline over time.

RECENT TRENDS IN THE NEUROPSYCHOLOGICAL ASSESSMENT OF DEMENTIA

The evolving field of neuropsychology is witness to numerous developments in the field of dementia and its treatment. These developments have led to changes in the questions we are asked to address and the approaches we use to conduct our evaluations of patients with dementia.

Early Detection of Neurodegenerative Disorder

It is the deliberate use of neuropsychological testing that parallels the course of neuropathology that informs our choice of tests. In so doing, the neuropsychologist makes inferences regarding whether a pattern of test results relates to a pathological process suggestive of a particular disease. However, very early in the course of disease, our tests are not as sensitive in detecting abnormality as they become later in the course of disease. The goal of detecting and distinguishing from among the potential incipient dementias has implications both for prognosis and in determining whether to start relevant disease-specific treatments[12]. This goal has increasing currency in light of recent studies suggesting that some factors, such as diet and exercise, may act as modifiers to the risk of developing dementia and progression of mild cognitive impairment to dementia[35]. Thus, being able to detect the very subtle cognitive changes that are the earliest manifestation of disease has gained more interest in recent years and includes as an objective the detection of a transitional state between normal ageing and dementia. This transitional state has been given several appellations, the most common in the United States being mild cognitive impairment (MCI)[36]. Attempts at identifying this state have included the refinement of diagnostic nomenclature and increased sensitivity of neurocognitive tests to detect abnormality.

Because many of our tests do not have 'ceiling' effects – that is, even normal healthy individuals do not earn perfect scores on them – the tests themselves are sufficiently difficult for even those with subtle cognitive problems. The interest, therefore, is in improving the diagnostic sensitivity of these tests. One way to do this is by improving the similarity between the normative sample and the patient we are assessing. The use of demographically adjusted scores (discussed in the following sections) is one method of achieving this.

Clinical neuropsychologists sometimes reach an impasse when faced with attempting to detect cognitive changes in the behavioural variant of frontotemporal dementia (FTD). Specifically, the initial symptoms generally include changes in personality and social interaction, as well as disinhibition[37]. Torralva and colleagues[38] demonstrated that while cognitive measures of memory, attention, visuospatial analysis, executive function and language did not significantly differ in patients diagnosed with the behavioural variant of FTD compared to normal healthy individuals, the authors' executive and social cognition battery did distinguish the groups. It is commonly thought that traditional testing environments may fail to induce executive deficits because of the inherent structure provided by the examination process. As such, the development of assessment tools that elicit abnormal behaviour is a challenge for the field.

The Use of Demographically Adjusted Test Scores

Over the past century, neuropsychologists have interpreted individual test scores by comparing an individual's test scores to a normative sample. The field has seen recent controversy regarding the composition of the norms we use. Specifically, which demographic variables should be considered is a matter of debate. The reason we use a normative sample is to determine the degree of deviation from the average, healthy individual, presumably because the patient was premorbidly similar to the average, healthy individual. Typically we choose to compare our patient with a sample of comparable age, due to the influence of age on many of our tests. It is sometimes desirable, however, to compare our patient with an individual who is comparable also in education level, due to the effects of education on test performance. Other normative samples include race and sex as well. Brickman and colleagues[39] point out that the value of neuropsychological assessment is contingent on the psychometric properties of the individual tests. If African Americans, for example, have been shown to perform on average lower than Caucasians, a test based on data from the latter group will cause an increase in false positives (i.e. diagnosing someone as impaired, when in fact he or she is performing within normal limits). Such comparisons allow us to determine how similar our patient is to healthy individuals of the same demographic. A similar approach involves the calculation of a predicted score based on a patient's demographic information[40,41]. Both methods take into account demographic variables in informing the decision about whether a particular score is normal or abnormal and improve the sensitivity of our measures in identifying cognitive impairment. Silverberg and Millis[42] have shown that adjusting scores can actually *decrease* the usefulness of test performance for predicting functional outcomes, such as the ability to work. If, for example, a 90-year-old individual is normal compared to other nonagenarians with regard to psychomotor speed, we may interpret his score as normal. However, given that the typical 90-year-old individual is much slower than the typical middle-aged individual, we may interpret the elder's score as rendering him unable to perform tasks that require fast processing speed (e.g. being an air-traffic controller). Thus, whether to use demographic adjustments depends upon the question we seek to answer.

CONCLUDING COMMENTS

The field of neuropsychology, influenced by such disparate areas of study as philosophy, neuroanatomy and psychology, is heavily reliant on statistical methods to substantiate its theoretical and conceptual frameworks. Psychometric theory and application, as they relate to

appropriate use of data analyses in test construction and the development of normative data, are the very linchpins of clinical practice. Neuropsychological assessment in patients with suspected dementia provides an important source of diagnostic information, resulting from the empirically based choice of test batteries and the use of statistical methods to interpret these batteries.

Although the role of the clinical neuropsychologist has evolved and depends upon the context of the evaluation, the information provided through neuropsychological assessment remains valuable in the differential diagnosis of dementia and improves diagnostic accuracy above routine clinical examination. The cortical/subcortical distinction, despite its being an oversimplification, remains a useful reference in the decision tree for individual cases. Faulty assumptions about our field relating to how we define abnormality, what our tests measure and the nature of cognitive dysfunction in the presence of low mood, can lead to misunderstandings about what our clinical evaluations can offer.

Current trends in the neuropsychological assessment of dementia include, as in other fields, detection of the very earliest manifestation of disease. Increasing the sensitivity of our tests with the use of increasingly sophisticated statistical methods has resulted from the goal of improving our ability to detect subtle cognitive problems. It is not only the application of knowledge of neuropathological changes and clinical presentation of the various diseases causing dementia that distinguishes neuropsychology as a discipline. It is also the dovetailing of sound clinical judgement with appropriate statistical methodology that is required for good clinical practice.

INTRODUCTION

Prevalence and Incidence

Alzheimer's disease (AD) is the most common irreversible, progressive brain disease. It is characterized by a gradual loss of memory and cognitive skills. AD accounts for over 50% of all dementia cases and it presently affects more than 24 million people worldwide. Moreover, over 5 million new cases of AD are reported each year and the incidence is likely to increase as a greater proportion of the population ages[1].

AD prevalence and incidence strongly suggest that age is the most influential known risk factor. Indeed, AD prevalence increases significantly with age and AD incidence increases from 2.8 per 1000 person years for people between 65 and 69 years to 56.1 per 1000 person years for people who are older than 90 years[2]. Approximately 10% of persons older than 70 years have significant memory loss and more than half of these individuals have probable AD. An estimated 25% to 45% of persons older than 85 years have dementia[3]. The duration of disease is typically 8 to 10 years, with a range from 2 to 25 years after diagnosis.

The disease is divided into two subtypes based on the age of onset: early-onset AD (EOAD) and late-onset AD (LOAD). EOAD accounts for approximately 1% to 6% of all cases and ranges roughly from 30 years to 60 or 65 years. On the other hand, LOAD, which is the most common form of AD, is defined as AD with an age at onset later than 60 or 65 years. Both EOAD and LOAD may occur in people with a positive family history of AD. Approximately 60% of EOAD cases have multiple cases of AD within their families and of these familial EOAD cases, 13% are inherited in an autosomal dominant manner with at least three generations affected[4,5]. Early-onset cases can also occur in families with late-onset disease[3]. With the exception of a few autosomal dominant families that are single-gene disorders (see below), most AD cases appear to be a complex disorder that is likely to involve multiple susceptibility genes and environmental factors[3,6–9].

Clinical Symptoms

Both EOAD and LOAD present clinically as dementia that begins with a gradual decline of memory and then slowly increases in severity until the symptoms eventually become incapacitating. Other common symptoms are confusion, poor judgement, language disturbance, agitation, withdrawal and hallucinations. Rare symptoms include seizures, parkinsonism, increased muscle tone, myoclonus, incontinence and mutism. Death commonly occurs from general inanition, malnutrition and pneumonia[3]. Treatment of AD with cholinesterase inhibitors and memantine may result in slowing of cognitive decline in mild to moderate dementia cases, but overall, most patients experience only clinically marginal improvement in measures of cognition and in global assessments of dementia[10,11].

Clinical Diagnosis

Currently, the diagnosis of AD is based on clinical history and neuropsychological tests. The *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition* (DSM-IV), criteria for diagnosing dementia requires the loss of two or more of the following: memory, language, calculation, orientation or judgement[12]. The Mini-Mental State Examination (MMSE) helps to evaluate changes in a patient's cognitive abilities. In addition, a diagnosis of probable AD necessitates the exclusion of other degenerative disorders associated with dementia, such as frontotemporal dementia (including frontotemporal dementia with parkinsonism-17 and Pick's disease), Parkinson's disease, diffuse Lewy body disease, Creutzfeldt–Jakob disease and cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL)[13]. Discriminating AD from other forms of dementia is usually done through clinical history and neuroimaging[3]. In addition, other possible causes of dementia need to be excluded, especially the treatable forms of cognitive impairment, such as impairment due to depression, chronic drug intoxication, chronic central nervous system infection, thyroid disease, vitamin deficiencies (e.g., B12 and thiamine),

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

central nervous system angitis and normal-pressure hydrocephalus[3]. Individuals who do not meet these criteria but have short-term memory loss, have only minimal impairment in other cognitive abilities and are not functionally impaired at work or at home are considered to have 'mild cognitive impairment'[14].

Neuropathological Diagnosis

A definitive diagnosis of AD requires a clinical assessment of probable AD, as well as postmortem confirmation, with the presence of two histopathological features: neurofibrillary tangles and amyloid plaques[15–17]. Before autopsy confirmation, expert clinicians correctly diagnose AD between 80% to 90% of the time[18]. Even though plaques and tangles are often found in cognitively normal age-matched controls, the density and the distribution of these attributes are more severe in patients with AD, according to standardized histological assessments[15]. Amyloid plaques are extracellular with a cross-beta structure that is characteristic of dye-binding (neuritic amyloid plaques contain thioflavin S and Congo red-positive fibrillar deposits with both Aβ40 and Aβ42 present)[19,20]. The major component of amyloid plaques is amyloid beta (Aβ), which can be stained and detected using Aβ antibodies[21,22]. The most common form of Aβ in humans is 40–amino-acids long and is called Aβ40. A 42–amino-acid-long fragment, Aβ42, is less abundant than Aβ40 and differs only in that it has two additional amino-acid residues at the C-terminus. Aβ42 is associated with AD[23].

Aβ is derived from the amyloid precursor protein (APP) by the action of two aspartyl proteases. First, α-secretase (non-neurotoxic 'normal' cleavage) or β-secretase (potential neurotoxic 'abnormal' cleavage) cleave APP (Figure 43.1) and second, γ-secretases cleave APP[24–26]. Upon cleavage by α-secretase, APP releases a large soluble APP alpha fragment (sAPPα) and a membrane-bound C-terminal 83–amino-acid fragment (C83); whereas upon cleavage by β-secretase, APP releases a large soluble APP beta fragment (sAPPβ) and a membrane-bound C-terminal 99–amino-acid fragment (C99)[27,28]. The C99 fragment is subsequently cleaved by γ-secretase to release Aβ and an APP intracellular domain (AICD)[29,30] (Figure 43.1). Thus, depending on the point of cleavage

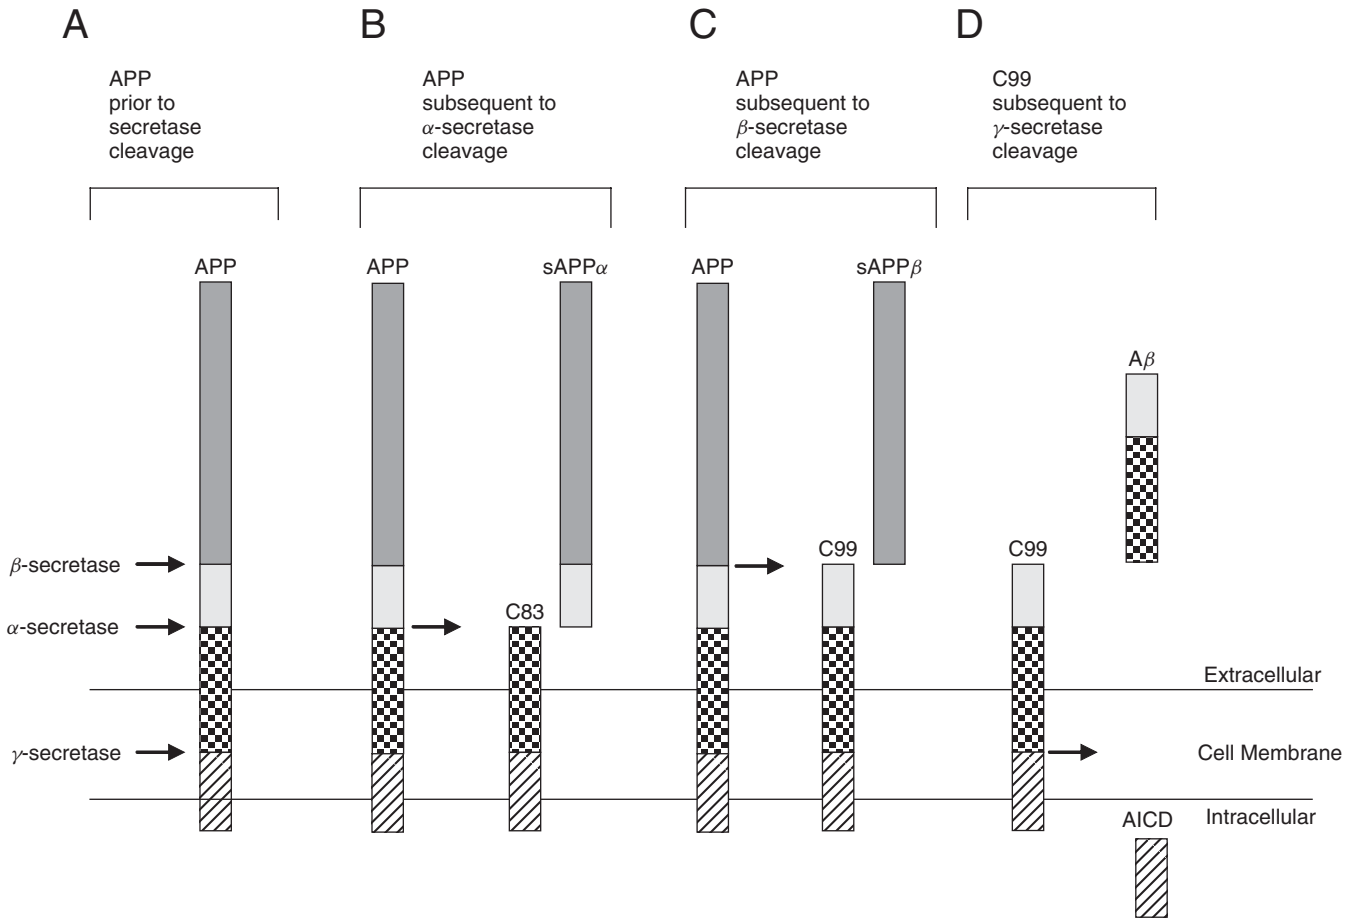

Figure 43.1 APP cleavage. The APP protein can be cleaved by three different secretases; α, β or γ (panel A). Subsequent to 'normal' α-secretase cleavage, sAPPα is produced and released into the extracellular space and the C83 peptide remains in the cell membrane (panel B). Subsequent to β-secretase cleavage, sAPPβ is produced and released into the extracellular space and the C99 peptide remains in the cell membrane (panel C). Subsequent to β-secretase cleavage, the C99 peptide is 'abnormally' cleaved by γ-secretase to yield an Aβ peptide and the AICD peptide (panel D). Scale is approximate

Source: Reproduced from Bekris, Yu, Bird & Tsuang (2010). The Genetics of Alzheimer's and Parkinson's Disease. In: A. Lajtha (Ed.), Handbook of Neurochemistry and Molecular Neurobiology, 3rd edn. by γ-secretase, two main forms of Aβ are produced, consisting of either 40 or 42–amino-acid residues (Aβ40 or Aβ42). The proportion of Aβ40 to Aβ42 that is formed is particularly important in AD because Aβ42 is far more prone to oligomerize and form fibrils than the more abundantly produced Aβ40 peptide. Indeed, although it appears that the production of Aβ isoforms is a normal process of unknown function, in a small number of individuals, an increased proportion of Aβ42 appears sufficient to cause EOAD[16,31].

Neurons bearing neurofibrillary tangles are another frequent finding in AD brains[32,33] and the temporal and spatial appearance of these tangles, which contain hyperphosphorylated tau, more closely reflects disease severity than does the presence of amyloid plaques[34,35]. Tangles are formed by hyperphosphorylation of a microtubule-associated protein known as tau, causing it to aggregate in an insoluble form. However, neurofibrillary tangles are also found in other disorders, such as frontotemporal dementia and progressive supranuclear palsy. Moreover, these tangles are not necessarily associated with the cognitive dysfunction and memory impairment that is typical of AD and mutations in the gene that encodes the tau protein (*MAPT*), a main component of neurofibrillary tangles, has not been genetically linked to AD[22].

GENETICS OF ALZHEIMER'S DISEASE

Introduction

Overall, more than 90% of AD cases appear to be sporadic and to have a later age at onset of 60 to 65 years (LOAD)[36]. Although twin studies support the existence of a genetic component in LOAD, no causative gene has been yet identified. Indeed, the only gene that has been consistently found to be associated with sporadic LOAD, across multiple genetic studies, is the apolipoprotein E (*APOE*) gene[37–41] (Table 43.1). However, many carriers of the *APOE* risk allele (ε4) live into their 90s, which suggests the existence of other LOAD genetic and/or environmental risk factors that have yet to be identified. To this end, several unreplicated genetic variants have been reported and these findings suggest that there may be five to seven major LOAD susceptibility genes[3,42,43]. For a catalogue of candidate gene association studies, please refer to the AlzGene online database (www.alzforum.org/res/com/gen/alzgene/default.asp).

Genes Associated with Autosomal Dominant Alzheimer's Disease

AD1: Amyloid precursor protein (APP)

Inheritance and clinical features In the 1980s, Kang and colleagues purified both plaque and vascular amyloid deposits and isolated their 40-residue constituent peptide (Aβ), which subsequently led to the cloning of the *APP* type I integral membrane glycoprotein from which Aβ is proteolytically derived[44]. The *APP* gene was then mapped to chromosome 21q, which accounted for the observation that Down syndrome patients (trisomy 21) develop amyloid deposits and the neuropathological features of AD when in their 40s[22,45–47].

Since then, over 32 different *APP* missense mutations have been identified in 85 families. Interestingly, most of these mutations are located at the secretase cleavage sites or the *APP* transmembrane domain on exons 16 and 17 (Figure 43.2). Information regarding *APP* mutations are available in the NCBI database and the Alzheimer Disease Mutation Database (www.molgen.ua.ac.be/ADMutations)[48]. Mutations within *APP* account for 10% to 15% of early-onset familial AD (EOFAD)[3,49–51], appear to be family specific and do not occur within the majority of sporadic AD cases. The majority of these EOFAD mutations are in or adjacent to the Aβ peptide sequence (Figure 43.2), the major component of amyloid plaques[52,53]. Most cases containing *APP* mutations have an age of onset in the mid-40s and 50s[54].

Gene location and structure Sequences encoding APP were first cloned by screening cDNA libraries[44]. The initial full-length cDNA clone encoded a 695–amino-acid protein (APP695)[40] and consisted of 18 exons. The *APP* gene, located on chromosome 21q21, is alternatively spliced into several products, named according to their length in amino-acids (i.e., APP695, APP714, APP751, APP770 and APP563) and expressed differentially by tissue type whereby the three isoforms that are most relevant to AD are restricted to the central nervous system (APP695) or expressed in both the peripheral and CNS tissues (APP751 and APP770)[44,55–61].

Gene function and expression APP is a type-I integral-membrane protein[44] that resembles a signal-transduction receptor. It is expressed in many tissues and concentrated in the synapses of neurons. Its primary function is not known, though it has been implicated in neural plasticity[62] and as a regulator of synapse formation[63]. APP is synthesized in the endoplasmic reticulum, post-transcriptionally modified in the golgi (N- and O-linked glycosylation, sulfation and phosphorylation) and transported to the cell surface via the secretory pathway. APP is also endocytosed from the cell surface and processed in the endosomal-lysosomal pathway[64,65]. APP and its byproduct Aβ have been found to be translocated inside mitochondria and implicated in mitochondrial dysfunction[66–68].

Proteolysis of APP by α-secretase or β-secretase leads to the secretion of sAPPα or sAPPβ. This proteolysis generates C-terminal fragments of 10 kDa and 12 kDa, respectively, which are inserted into the membrane. These fragments can be cut by γ-secretase to

Table 43.1 Alzheimer's disease (AD) genes. AD genes are located on four different chromosomes and are associated with autosomal dominant or sporadic inheritance

AD loci	*Gene symbol*	*Gene name*	*Chromosome*	*Inheritance*
AD1	*APP*	Amyloid Precursor Protein	21q21	Autosomal Dominant
AD2	*APOE*	Apolipoprotein E	19q13.32	Sporadic
AD3	*PSEN1*	Presenilin 1	14q24.2	Autosomal Dominant
AD4	*PSEN2*	Presenilin 2	1q42.13	Autosomal Dominant

extracellularly release the Aβ peptide[69] and intracellularly release a cytoplasmic fragment identified as AICD[70] (Figure 43.1). The majority of EOFAD mutations alter this processing of *APP* in such a way that Aβ42 levels are changed relative to other Aβ isoform levels[71,72]. The function of these *APP* proteolytic fragments is still unclear.

The missense *APP* 'Swedish' mutations (*APP*SW, *APP*K670N, M671L) and the 'London' mutations (*APP*LON, *APP*V717I) are examples of *APP* mutations that lead to increased Aβ production and development of AD[73,74]. Transgenic mouse models of such *APP* mutations (PDAPP, Tg2576, APP23, TgCRND8 and J20) have been developed[75]. Each of these mouse models have different APP expression levels and different neurological abnormalities[75,76]. For example, the Tg2576 mouse model that carries the 'Swedish' mutation has high *APP* levels, high Aβ levels and cognitive disturbances[77] that are progressive and start as early as six months of age[78].

Genetic variation *APP* transcripts have been identified in which exons 7, 8 and 15 are alternatively spliced. *APP695*, the predominant isoform in neurons[79], contains exon 15 but excludes exons 7 and 8. The *APP751* isoform and the *APP770* isoform both encode Kunitz-type protease inhibitor (KPI)-containing forms of *APP*[58–60,80,], are present in both peripheral tissue and neurons and contain exon 16 and 17 but exclude exons 7, 8 and 15. The gene region that encodes the portion of *APP* that is cleaved to produce the Aβ peptide is located within exons 16 and 17 of the *APP*770 splice variant[81] (Figure 43.2). Other splice variants have been observed that are missing exon 15 in various combinations with exons 7 and 8; these splice variants are referred to as L-*APP*s[80,82]. A number of studies have indicated that alternative splicing of exons 7 and 8 is modulated in brain during ageing and possibly during AD[82–87]. Even though the function of *APP* and its various splice variants is unknown, differential expression of these splice variants between tissues may imply functional differences. It is important to note that while most of the described splice variants contain Aβ-encoding sequences, two additional rare transcripts, APP365 and APP563 do not, implicating additional functionally important variability in *APP* isoform function[55,88].

The first described and best characterized *APP* mutation (V717I) is located within the transmembrane domain near the γ-secretase cleavage site[73] (Figure 43.2). Other substitutions have since been identified at this site and several groups have reported the V717I mutation in families who are unrelated to the initial London family. Many other *APP* mutations have since been identified, especially near the γ-secretase cleavage site, and the bulk of these mutations have been associated with modulation of Aβ levels. For example, a C-terminal L723P mutation was identified in an Australian family; this mutation is reported to generate an increase of Aβ42 peptide levels in CHO cells[89]. The majority of EOFAD mutations alter processing of APP in such a way that the relative level of Aβ42 is

increased by increasing Aβ42, decreasing Aβ40 peptide levels or increasing Aβ42 while decreasing Aβ40 peptide levels[71,72].

AD3: Presenilin 1 (PSEN1)

Inheritance and clinical features Linkage studies established the presence of an AD3 locus on chromosome 14[90], and positional cloning led to the identification of mutations in the presenilin-1 (*PSEN1*) gene, which encodes a polytopic membrane protein[91]. Presenilins are major components of the atypical aspartyl protease complexes that are responsible for the γ-secretase cleavage of *APP*[92,93]. Mutations in *PSEN1* are the most common cause of EOFAD. Indeed, *PSEN1* missense mutations account for 18% to 50% of autosomal dominant EOFAD cases[94]. Over 176 different *PSEN1* mutations have been identified in 390 families. *PSEN1* mutations appear to increase the ratio of Aβ42 to Aβ40 and thereby result in a change in function that leads to reduced γ-secretase activity[95]. It has been suggested that deposition of Aβ42 may be an early preclinical event in *PSEN1* mutation carriers[96].

Defects in *PSEN1* cause the most severe forms of AD, with complete penetrance and an onset occurring as early as 30 years of age. However, there is a wide variability in age of onset as other *PSEN1*-associated AD cases have a mean age of onset greater than 58 years. *PSEN1*-associated AD is an autosomal dominant neurodegenerative disorder characterized by progressive dementia and parkinsonism, notch signalling modulation and Aβ intracellular domain generation[16,97]. There is also considerable phenotypic variability in *PSEN1*-associated AD cases, including some patients who develop spastic paraparesis and other atypical AD symptoms. Some of these variable clinical phenotypes have been associated with specific mutations. Neuropathological studies often confirm the clinical diagnosis of AD with measurement of amyloid plaque and Braak stage (as described above) as well as other neurodegenerative changes in other brain areas according to the presence of specific *PSEN1* mutations[98,99]. For example, researchers found that the clinical and neuropathological features of a Greek family with a *PSEN1* mutation (N135S) included memory loss when the family members were in their 30s, as well as variable limb spasticity and seizures. Upon neuropathological examination of these family members, the diagnosis of AD was confirmed and there was also histological evidence of corticospinal tract degeneration[99]. Moreover, a *PSEN1* mutation (I143M) that lies in a cluster in the second transmembrane domain of the protein has been described in an African family with an age at onset in the early 50s and a short duration of illness of six to seven years. These family members were diagnosed upon autopsy with severe AD pathology characterized by neuronal loss, abundant Aβ neuritic plaques and neurofibrillary tangles and degeneration extending into the brain stem[100].

Gene location and structure *PSEN1* is located on chromosome 14q24.2. It consists of 12 exons that encode a 467–amino-acid protein that is predicted to traverse the membrane 6 to 10 times; the amino and carboxyl termini are both oriented toward the cytoplasm[101].

Gene function and expression *PSEN1* is a polytopic membrane protein that forms the catalytic core of the γ-secretase complex[92,102]. Gamma-secretase is an integral membrane protein typically found at the cell surface, but it may also be found in the golgi, endoplasmic reticulum and mitochondria[92,103].

PSEN1, nicastrin (Nct), anterior pharynx defective 1 (Aph-1) and presenilin enhancer 2 (PSENEN) are required for the stability and activity of the γ-secretase complex[104–108]. This complex cleaves many type-I transmembrane proteins, including APP and Notch[92,109], two proteins in the hydrophobic environment of the phospholipid bilayer of the membrane[107].

PSEN1 knockout (KO) mice are not viable[110] but a conditional *PSEN1* KO mouse model, where the loss of the gene is limited to the postnatal forebrain, found that KO mice exhibited mild cognitive impairments in long-term spatial reference memory and retention[111]. These findings suggest that presenilins play a role in cognitive memory. Moreover, knockin mice with missense mutations of the endogenous murine *PSEN1* have high Aβ42 levels and perform poorly on the object recognition test[112,113]. Double *PSEN1/APP* transgenics have been developed and these transgenic suggest that *PSEN1, APP* and mutations within these genes play a role in the production of Aβ [76,114].

Genetic variation To date, there have been 176 *PSEN1* mutations reported (Figure 43.3). A comprehensive list of *PSEN1* mutations is available through the NCBI database (www.molgen.ua.ac.be/ADmutations). The majority of these mutations are missense mutations. These missense mutations cause amino-acid substitutions throughout the *PSEN1* protein and appear to result in a relative increase in the ratio of Aβ42 to Aβ40 peptides; this increase seems to occur through increased Aβ42 production, decreased Aβ40 production, or alternatively, a combination of increased Aβ42 production and decreased Aβ40 production[71]. For example, individuals that carry the *PSEN1* L166P mutation can have an age at onset in adolescence, and *in vitro* studies indicate that this mutation induces exceptionally high levels of Aβ42 production as well as impaired notch intracellular domain production and notch signalling[98].

AD4: Presenilin 2 (PSEN2)

Inheritance and clinical features A candidate gene for the chromosome 1 AD4 locus was identified in 1995 in a Volga German AD kindred with a high homology to the AD3 locus (*PSEN1*); this gene was later named presenilin 2 (*PSEN2*)[51,115,116]. In contrast to the mutations in the *PSEN1* gene, missense mutations in the *PSEN2* gene are a rare cause of EOFAD, at least in Caucasian populations. The clinical features of *PSEN2*-affected families appear to differ from the clinical features of *PSEN1*-affected families in that the age of onset in these family members is generally older (45–88 years) than for some family members with *PSEN1* mutations (25–65 years). Furthermore, the age of onset is highly variable among *PSEN2*-affected members of the same family, whereas in families with *PSEN1* mutations, the age of onset is generally quite similar among affected family members, and it is even similar among people from different families with the same mutation[5,51,91,116]. Missense mutations in the *PSEN2* gene may be of lower penetrance than in the *PSEN1* gene and therefore may be subject to the modifying action of other genes or environmental influences[51,117].

Gene location and structure The *PSEN2* gene is located on chromosome 1 (1q42.13) and was identified by sequence homology and then cloned[115,116]. *PSEN2* has 12 exons and is organized into 10 translated exons that encode a 448–amino-acid peptide. The PSEN2 protein is predicted to consist of nine transmembrane domains

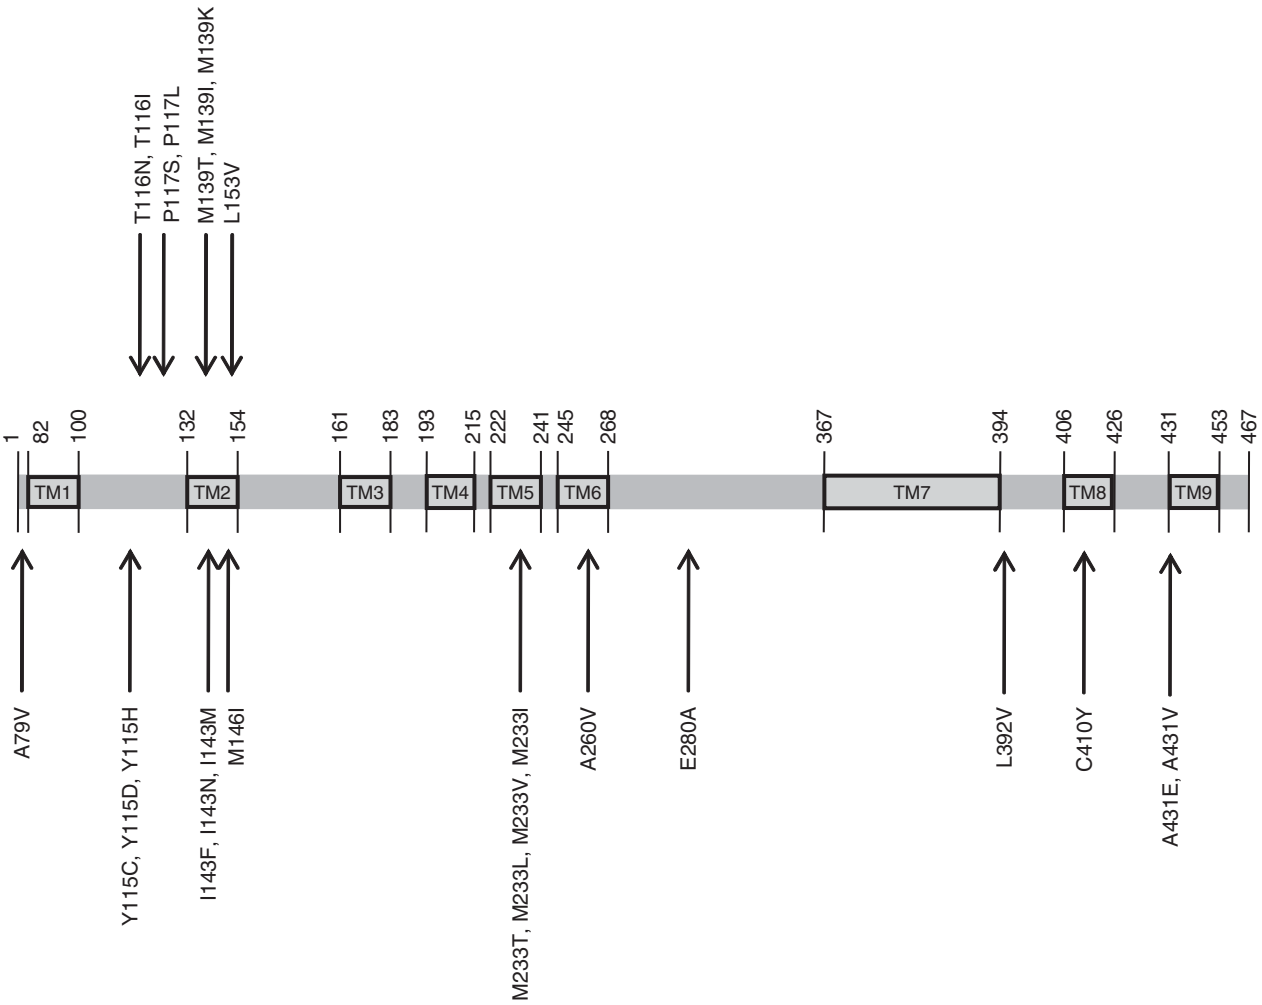

Figure 43.3 AD3: *PSEN1* structure and mutations. Thus far, there have been at least 123 mutations in the *PSEN1* gene described, of which a few are shown. For a more complete list of *PSEN1* mutations see www.molgen.ua.ac.be/ADMutations. TM: Transmembrane domains. Scale is approximate

Source: Reproduced from Bekris, Yu, Bird & Tsuang (2010). The Genetics of Alzheimer's and Parkinson's Disease. In: A. Lajtha (Ed.), Handbook of Neurochemistry and Molecular Neurobiology, 3rd edn. Neurochemical Mechanisms in Disease, Vol. 36. New York: Springer-Verlag. With kind permission of Springer Science+Business Media

and a large loop structure between the sixth and seventh domains (Figure 43.4). *PSEN2* also displays tissue-specific alternative splicing[115,116,118–120].

Gene function and expression Like PSEN1, PSEN2 has been described as a component of the atypical aspartyl protease called γ-secretase, which is responsible for the cleavage of Aβ[92,93]. *PSEN2* is expressed in a variety of tissues, including the brain, where it is expressed primarily in neurons[121]. *PSEN2*-associated mutations have been reported to increase the ratio of Aβ42 to Aβ40 (Aβ42/Aβ40) in mice and humans[71,95], indicating that presenilins might modify the way in which γ-secretase cuts APP.

APP processing at the γ-secretase site has been reported to be differentially affected by specific presenilin mutations. For example, *PSEN1*-L166P mutations cause a reduction in Aβ production whereas *PSEN1*-G384A mutations significantly increase Aβ42. In contrast, *PSEN*2 appears to be a less efficient producer of Aβ than *PSEN*1[23]. The functions and biological importance of presenilin splice variants are poorly understood, but it appears that differential expression of presenilin isoforms may lead to differential regulation of the proteolytic processing of the APP protein. For example, aberrant *PSEN2* transcripts lacking exon 5 appear to increase the rate of production of Aβ peptide[122], whereas naturally occurring isoforms without exons 3 and 4 and/or without exon 8 do not affect production of Aβ[123].

Genetic variation Mutations in *PSEN2* are a much rarer cause of familial AD than are *PSEN1* mutations; *PSEN2* mutations have been described in six families, including the Volga-German kindred where a founder effect has been demonstrated[48,51,115,116], whereas *PSEN1* mutations have been found in 390 families. To date as many as 14 *PSEN2* mutations have been identified. One of the first mutations to be identified was a point mutation located within the second transmembrane domain that resulted in the substitution of an isoleucine for an asparagine at residues 141 (N141I)[115]. Most recently, a V393M mutation

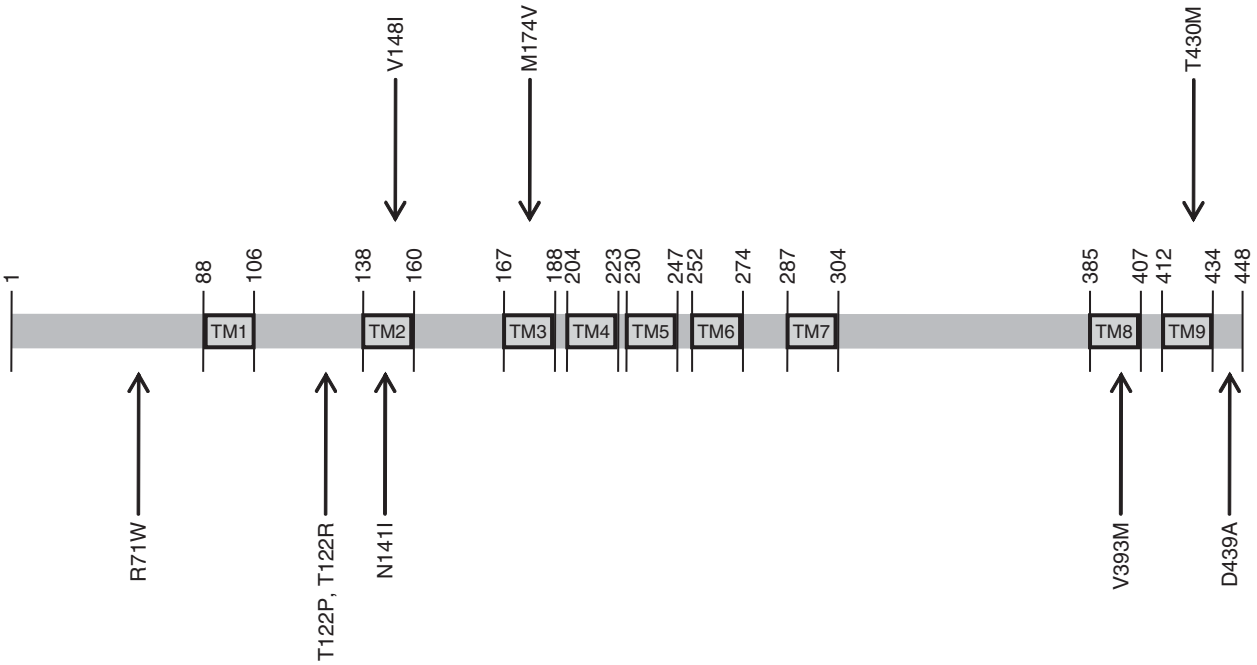

Figure 43.4 AD4: *PSEN2* structure and mutations. Thus far, there have been at least 16 mutations in the *PSEN2* gene described, of which a few are shown. For a more complete list of *PSEN2* mutations see www.molgen.ua.ac.be/ADMutations. TM: Transmembrane domains. The V393M novel mutation was most recently found in one case[124]. Scale is approximate

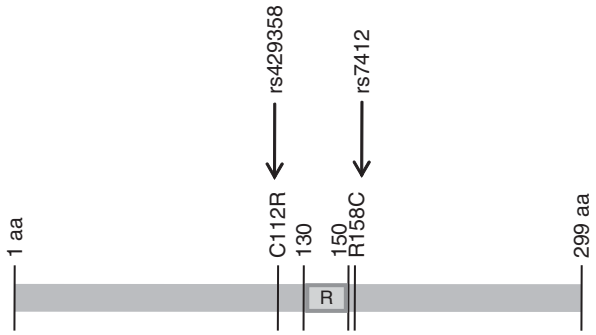
located within the seventh transmembrane domain has been described[124] (Figure 43.4). A comprehensive list of *PSEN2* mutations is available through the NCBI database (www.molgen.ua.ac.be/ADmutations).

Genes Associated with Risk in Sporadic Alzheimer's Disease

AD2: APOE



Inheritance and clinical features The *APOE* gene has been associated with both familial late-onset and sporadic late-onset AD in numerous studies of multiple ethnic groups. The *APOE* ε4 genotype is associated with higher risk of AD[125], earlier age of onset of both AD[126] and Down syndrome (where there is an additional copy of chromosome 21 carrying the *APP* gene)[127] and a worse outcome after head trauma[128] and stroke, both in humans[129] and in transgenic mice expressing human apoE4[130]. The frequency of the *APOE* ε4 allele varies between ethnic groups, but regardless of ethnic group, *APOE* ε4-carriers are more frequently found in controls, and *APOE* ε4+ carriers are more frequently found in AD patients[39–41,131–140].

Gene location and structure The *APOE* gene is located on chromosome 19q13.2 and consists of four exons that encode a 299–amino-acid protein. The *APOE* gene is in a cluster with other apolipoprotein genes: *APOC1, APOC2* and *APOC4*. The *APOE* ε4 loci are located within exon 4 of the gene. The three *APOE* ε4 alleles (ε2, ε3 and ε4) are defined by two single nucleotide polymorphisms, rs429358 and rs7412, which encode three protein isoforms (E2, E3 and E4). The most frequent apoE isoform is apoE3, which contains cysteine and arginine at amino-acid positions 112 and 158. In contrast, these positions contain only cysteine residues in apoE2 and only arginine residues in apoE4 (Figure 43.5). The cysteine-arginine substitution affects the three-dimensional structure and the lipid-binding properties between isoforms. In apoE4, the amino-acid substitution results in the formation of a salt bridge between an arginine in position 61 and a glutamic acid in 255; whereas apoE3 and apoE2 bind preferentially to high-density lipoproteins (HDLs), this changed structure causes the apoE4 isoform to bind preferentially to very low-density lipoproteins (VLDLs)[141].

Gene function and expression The mechanisms that govern apoE toxicity in brain tissue are not fully understood. Some proposed mechanisms include isoform-specific toxicity, *APOE* ε4-mediated amyloid aggregation and *APOE* ε4-mediated tau hyperphosphorylation[142].

The *APOE* polymorphism is unique to humans and has been proposed to have evolved as a result of adaptive changes to diet[143,144]. It is known that apoE plays an important role in the distribution and metabolism of cholesterol and triglycerides within many organs and cell types in the human body[141]. Individuals carrying *APOE* ε4 have higher total and LDL cholesterol[145]. Moreover, *in vitro* neurons have a cholesterol uptake that is lower when lipid are bound to apoE4 compared to apoE2 and apoE3[146], and apoE4 appears to be less efficient than the other isoforms in promoting cholesterol efflux from both neurons and astrocytes[147].

As the major apolipoprotein of the chylomicron in the brain, apoE binds to a specific receptor and works through receptor-mediated

Allele	SNP Position (Amino-Acid) rs429358 (C112R)	rs7412 (R158C)

The *APOE* $\varepsilon 2, \varepsilon 3, \varepsilon 4$ haplotype is shown in panel B

Source: Reproduced from Bekris, Yu, Bird & Tsuang (2010). The Genetics of Alzheimer's and Parkinson's Disease. In: A. Lajtha (Ed.), Handbook of Neurochemistry and Molecular Neurobiology, 3rd edn. Neurochemical Mechanisms in Disease, Vol. 36. New York: Springer-Verlag. With kind permission of Springer Science+Business Media

endocytosis to rapidly remove chylomicron and VLDL remnants from circulation; this process is essential for the normal catabolism of triglyceride-rich lipoprotein constituents[148]. In the brain, lipidated apoE binds aggregated Aβ in an apoE isoform-specific manner, with apoE4 being much more effective than the apoE3 isoform. Researchers have also proposed that the more efficient binding process of apoE4 enhances the deposition of the Aβ peptide[149].

Brain cells from *APOE* knockout (*APOE*-/-) mice are more sensitive to excitotoxic and age-related synaptic loss[150], and Aβ-induced synaptosomal dysfunction in these mice is also enhanced compared to control animals[151]. When human apoE isoforms (apoE3 and apoE4) are expressed in *APOE*-/- mice, the expression of apoE3, but not apoE4, is protective against age-related neurodegeneration[150] and Aβ toxicity[151]. In addition, astrocytes from *APOE*-/- mice that express human apoE3 release more cholesterol than those expressing apoE4; this suggests that apoE isoforms may modulate the amount of lipid available for neurons. Other studies report apoE-specific effects on Aβ removal from the extracellular space whereby the apoE3 isoform has a higher Aβ-binding capacity than apoE4[152,153]. Animal and *in vitro* models show that, in the brain, astrocytes and microglia are the main producers of secreted apoE[154,155]. ApoE secretion in human primary astrocytes can be reduced by a combination of cytokines[156]; whereas under stress conditions, neurons appear to be the main producers of apoE[157,158]. In a rodent model, moderate injury has been shown to induce enhancement of apoE levels in clusters of CA1 and CA3 pyramidal neurons[159] and in another rodent model, apoE levels have been shown to increase in response to peripheral nerve injury[161].

In addition, individuals carrying *APOE* $\varepsilon 4$ have higher amyloid and tangle pathology[160] and an increase in mitochondrial damage[162] compared to those carrying other *APOE* polymorphisms.

Genetic variation The gene dose of *APOE* $\varepsilon 4$ is a major risk factor for AD, with many studies reporting an association between gene dose, age at onset[163] and cognitive decline[164]. After age 65, the risk of AD among individuals with a family member with AD increases depending on the number of $\varepsilon 4$ alleles present in the affected individual. Risks to family members with the *APOE* 2/2 and 2/3 genotypes are nearly identical at all ages to risks for family members with the *APOE* 3/3 genotype. Among family members with *APOE* 3/3, the lifetime risk for AD by age 90 can be as much as three times greater than the expected risk found in *APOE* $\varepsilon 4$ carriers, suggesting that factors other than *APOE* contribute to AD risk. In addition, a 44% risk of AD by age 93 among family members of *APOE* 4/4 carriers indicates that as many as 50% of people having at least one $\varepsilon 4$ allele do not develop AD. There also appears to be a gender modification effect because the risk to male family members with *APOE* 3/4 is similar to that for the *APOE* 3/3 carriers but is significantly less than the risk for the *APOE* 4/4 carriers, whereas among female family members, the risk for the *APOE* 3/4 carriers is nearly twice that for the *APOE* 3/3 carriers[131,133–140].

SUMMARY

AD is characterized by an irreversible, progressive loss of memory and cognitive skills that can occur in rare familial cases as early as the third decade. Currently, there is no cure for AD, and treatments only manage to slow down the progression of AD progression in some patients[10,11]. The early-onset familial forms of AD have an autosomal dominant inheritance linked to three genes: *APP, PSEN1* and *PSEN2*, whereas the most common sporadic form of AD, which occurs after the age of 60, has thus far been consistently, across numerous studies, associated with only one gene, the *APOE* gene. The mechanistic contribution of these genes in AD pathogenesis has been studied extensively, but the specific biology involved in the progression of AD remains unclear, suggesting that AD is a genetic and environmentally complex disease.

GENETIC TESTING AND COUNSELLING

APOE $\varepsilon 4$ is most highly associated with AD for individuals with a family history of dementia and this association is highest for individuals that carry two *APOE* $\varepsilon 4$ alleles ($\varepsilon 4/\varepsilon 4$ genotypes). The $\varepsilon 4/\varepsilon 4$ genotype is uncommon and although the ethnicity of the population may alter the expected prevalence, the genotype occurs in about 1% of normal Caucasian controls. In contrast, the $\varepsilon 4/\varepsilon 4$ genotype

occurs in nearly 19% of familial LOAD populations. *APOE* ε4-associated risk is also found in African Americans and Caribbean Hispanics[165,166]. Women with an *APOE* ε4/ε4 genotype have a 45% probability of developing AD by age 73 years[167], whereas men have a 25% risk of developing AD by that age[168]. AD risk is also lower for individuals with only one *APOE* ε4 allele (by age 87) or no *APOE* ε4 allele (by age 95)[168]. Approximately 42% of persons with LOAD do not have an *APOE* ε4 allele[169]. Thus, the absence of the *APOE* ε4 allele does not rule out a LOAD diagnosis. First-degree relatives of a person with LOAD have a cumulative lifetime risk of approximately 20% to 25%, whereas the risk in the general population is 10.4%[134,170]. It is still not known whether the age of onset of a LOAD patient changes the risk to first-degree relatives of LOAD patients. But the number of additional affected family members most likely increases the risk to close relatives[171]. Given the low predictive value of the *APOE* ε4 allele, the general consensus is that *APOE* genetic testing has limited value in asymptomatic persons for predicting AD risk[172,173]. Family history may therefore be a better predictor of LOAD risk[171].

In contrast, EOFAD, with an age at onset before 60 to 65 years old, has an autosomal dominant mode of inheritance in which 20% to 70% of cases are estimated to have a *PSEN1* mutation, 10% to 15% of cases are estimated to have an *APP* mutation and *PSEN2* mutations are rare[172,174]. Indeed, approximately 60% of patients with EOAD have another known affected family member. The remaining 40% of EOAD patients may lack a family history because of an early death of a parent, failure to recognize the disorder in family members, or, very rarely, a *de novo* mutation[5]. If an EOAD patient's parent has a mutant allele, then the risk to the patient's sibling of inheriting the mutant allele is 50%. The child of an EOAD patient who carries a mutation (*APP, PSEN1*, or *PSEN2*) has a 50% chance of transmitting the mutant allele to each of their children.

Testing of asymptomatic adults who are at risk for EOAD caused by mutations in the *PSEN1*, *PSEN2*, or *APP* genes is available clinically. However, genetic testing results for at-risk asymptomatic adults can only be interpreted after the disease-causing mutation has first been identified in the affected family member. It should be emphasized that testing of asymptomatic at-risk individuals with non specific or equivocal symptoms is predictive not diagnostic. In addition, obtaining results from genetic testing can affect an individual's personal relationships as well as their emotional well-being and it may even cause depression. The principal arguments against testing asymptomatic individuals during childhood are that the testing then removes their choice to know or not know this information, it raises the possibility of stigmatization within the family and in other social settings and it could have serious educational and career implications. Thus, the general consensus is that individuals who are at risk for adult-onset disorders should not be tested during childhood. Prenatal genetic testing for mutations in the *PSEN1* gene is possible if the *PSEN1* allele has been identified in an affected family member first. Preimplantation genetic diagnosis is also available for families that have a disease-causing mutation. However, parental requests for prenatal or preimplantation genetic testing of adult-onset diseases is rare[3].

Mouse Models of Alzheimer's Disease

Esther Oh, Constantine Lyketsos and Philip Wong

Johns Hopkins School of Medicine and Johns Hopkins Bayview, Baltimore, USA

Advances in the development of animal models of neurodegenerative diseases have accelerated translation of basic science research into application in humans. While many different animal models are currently being studied in research settings, this chapter will focus on transgenic (tg) mouse models of Alzheimer's disease (AD). There are two main types of tg mouse models of AD: models of amyloidosis and/or of tauopathy. These two types represent the two major pathological changes seen in AD, amyloid plaques and neurofibrillary tangles (NFTs). More recently, a model combining both features has been developed, allowing researchers to study their interaction. Important variations are conditional tg mouse models of AD in which the expression of transgenes can be manipulated – induced or inhibited – by external controls, and models in which normal (or endogenous) genes of interest have been deleted from a selected locus ('knock-outs'). The following sections describe representative models in each category, and discuss advantages and disadvantages of each model. Finally, clinical implications of findings from animal studies are discussed.

TRANSGENIC MOUSE MODELS OF AMYLOID-BETA AMYLOIDOSIS

Although human familial AD (FAD) comprises a small portion of AD cases, the identification of genetic mutations associated with FAD in genes coding for the amyloid precursor protein (APP) or presenilin 1 and 2 (PS1, PS2) led to development of the earliest tg mouse models. APP is cleaved by proteolytic enzymes, β- and γ-secretases, to form amyloid-beta (Aβ) 40 and 42, the main components of the amyloid plaques[1]. Mutations in the APP gene create excess Aβ deposition by enhancing β-secretase cleavage of APP or by altering the pattern of γ-secretase cleavage of APP. This results in a higher Aβ42 to Aβ40 ratio, which in turn enhances Aβ fibrillogenesis.

One of the first strategies to create AD-like pathology in mice was to develop tg mouse models that over-express human APP with FAD mutations. While over-expression of APP is not a general feature of AD, this approach led to tg mice with significant Aβ production and deposition over their lifetime. One such tg mouse model, known as PDAPP, uses a platelet-derived growth factor β (*PDGF* β) promoter to enhance in mice the expression of human APP with V717F mutation[2]. Another early tg mouse model, Tg2576, uses the hamster prion protein promoter (*PrP*) to enhance the expression of human APP with a double Swedish mutation (K670N/M671L)[3]. Both models have been extensively studied as models of Aβ amyloidosis (Table 44.1).

Another approach to developing tg AD mouse models involved the insertion of human presenilin genes with mutations known to cause AD into the mouse genome. Presenilins are part of the γ-secretase complex, which is involved in the cleavage of APP along with β-secretase. However, mouse models with PS1 mutations alone do not develop amyloid pathology[4,5]. When both APP and PS1 mutations are expressed together in tg mice, such as in APPswe/PS1dE9 (Table 44.1)[6], the PS1 mutation increases the ratio of Aβ42 to Aβ40, resulting in more Aβ deposition due to the higher fibrillogenic nature of Aβ42[7].

Many of the tg mouse models of amyloidosis also develop other pathologies seen in the human disease such as neuritic plaques, gliosis or synaptic loss, allowing for observation of the effect of amyloid on neuronal pathologies. Significantly, monoaminergic neurodegeneration, a feature of the human disease, occurs in at least one mouse model[8]. These models have been very useful to the identification of mechanism-based therapeutics, specifically, anti-amyloid therapies. However, a major limitation is that the amyloidosis models do not develop NFTs, one of the hallmark neuropathological changes seen in AD.

TRANSGENIC MOUSE MODELS OF TAUOPATHY

The amyloid cascade hypothesis[1] proposes that Aβ is an early upstream agent that is followed by excess phosphorylation of tau, an intracellular, microtubule-associated protein. Hyperphosphorylation of tau is thought to lead to the formation of paired helical filaments (PHF), which progress to become NFTs in the neuronal cell body. However, as mentioned above, tg mouse models of amyloidosis do not form NFTs. One reason may be differences in tau isoforms across humans and mice. Six human isoforms of tau exist, each derived from alternative splicing in the brain of the same gene. There are only three isoforms in mice, which may result in a lower propensity for hyperphosphorylation[9].

There is currently no known tau mutation in AD. However, independent of amyloid plaques, tau inclusions are found in other neurogenerative diseases such as progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), Pick's disease (PiD) and frontotemporal dementia (FTD). Therefore, tg mouse models of tauopathy have been created using human mutations in the tau

Table 44.1 Examples of mouse models of Alzheimer's disease

Model	*Pros*	*Cons*	*Best use of model*
PDAPP mice (line 109)[2]	Diffuse and neuritic plaques, synaptic loss, astrocytosis and microgliosis; significant impairment on a variety of different learning and memory tests	Some early age-independent memory and behavioural deficits; noncongenic strain background; no NFT or tau aggregates	Studies of passive and active anti-Aβ immunization; interactions between Aβ and apolipoproteins
APPswe (Tg2576)[3]	Numerous Aβ plaques, oxidative lipid and glycoxidative damages; memory deficits seen in 9–10-month-old Tg mice	No NTF or tau aggregates; early deficits in Morris water maze with visible platform; noncongenic strain background	Studies of immunotherapeutic approaches; breeding with other AD models; use of NSAIDs and other treatments
Double transgenic mice: Mo/Hu APPswe/PS1dE9[6]	Exhibit accelerated Aβ deposition despite relatively low level of APPswe over-expression; both transgenes are co-segregated; a similar model, line C3-3/S9, shows age-related deficits in behaviour[31]	Noncongenic strain background; no NFT or tau aggregates	Studies of efficacy of different experimental treatments; breeding of these mice to other transgenic mice is efficient owing to co-segregation of the transgenes
Conditional transgenic mice: rTg4510[14]	These mice express repressible human FTDP-17 mutation P301L (4R0N tau_{p301L}); progressive age-related NFT, neuronal loss and functional deficits are present; after the suppression of transgenic tau, memory function recovered and neuron numbers stabilized, but NFTs continued to accumulate	No Aβ accumulation; gross forebrain atrophy, with preservation of hindbrain structures	Studies of reversibility of cognitive and pathological alterations
Conditional transgenic mice: CaMKIIα-tTA $\times$ tet-APPswe/ind[13]	These mice express repressible APP transgene with Swedish and Indiana mutations; they develop progressive amyloid plaques	No NFT or tau aggregates; high expression lines are hyperactive	Studies of reversibility of pathological alterations
Triple transgenic mice: 3xTg-AD PS1, APPswe,tau[11]	Amyloid plaque develops before tau pathology, and the regional distribution of amyloid and tau closely mimics human AD pathology; age-dependent decline in both spatial and contextual learning and memory	May be difficult to differentiate the effect of amyloid from tau	Studies of anti-Aβ immunization; understanding the relationship between amyloid and tau pathology; testing the amyloid cascade hypothesis

Source: Adapted from Savonenko *et al*., 2005

gene linked to familial frontotemporal dementia with Parkinsonism on chromosome 17 (FTDP-17). One such model, expressing the FTDP-17 mutation P301L, forms NFTs in diencephalon, brainstem, cerebellum and spinal cord. However, this model also has motor deficits due to spinal cord lesions such as fibrillary gliosis and axonal degeneration[10].

More recently, models which reproduce both amyloid plaques and NFTs have been developed, the triple transgenic mice 3xTg-AD, which carry PS1 (M146V), APP (K670N/M671L) and tau (P301L) transgenes (Table 44.1)[11]. Interestingly, even though both APP and tau transgenes are expressed to similar levels in these mice, Aβ deposits emerge prior to tau pathology, consistent with the amyloid cascade hypothesis. Immunotherapy experiments involving direct injection of anti-Aβ antibodies into the hippocampus showed clearance of Aβ deposits followed by clearance of earlier (non-hyperphosphorylated) forms of tau. Aβ deposits re-emerged by 30 days post-injection, with tau pathology re-emerging at a later time point. Injection of anti-tau antibody had no observable effect on either Aβ or tau deposits. The data from these experiments further support the view that Aβ precedes tau pathology per the amyloid

cascade hypothesis[12]. These triple transgenic models are therefore quite useful for studying the role of tau protein in neurodegenerative diseases, and especially its interaction with amyloid pathology.

CONDITIONAL TRANSGENIC MOUSE MODELS

Researchers have also developed variations of the above models in which the expression of APP, tau or both transgenes are temporally controlled. The approach used, commonly known as the 'tet-off system,' creates a tg model in which administration of a tetracycline analogue, such as doxycycline, turns off transcription of the transgene. Conditional tg models allow study of the effects of temporal variation (early vs. late, short vs. long) in the expression of the transgene. Such systems also model pharmaceutical interventions in which the expression of a transgene is suppressed, allowing assessment of potential treatment effect[13]. They can also test the hypothesis of whether certain structural and biochemical changes are related to the expression of the transgene[14].

A well-known conditional APP tg mouse model is CaMKIIα-tTA $\times$ tet-APPswe/ind (Table 44.1). This model expresses amyloid plaques starting eight weeks of age, and amyloid deposition is severe by six months of age. APP expression is reduced by greater than 95% two weeks after initiation of doxycycline treatment. When doxycycline was given to examine the effects of Aβ suppression after the onset of deposition, further progression of Aβ deposition was halted, but there was limited to no clearance of previously deposited amyloid plaques even after six months of treatment. These results suggested that inhibition of Aβ production may halt further progression of the pathology, but may not clear the pre-existing amyloid plaques[13].

A tg mouse model with conditional tau expression is rTg4510, in which mutant tau (P301L) expression is suppressed by administration of doxycycline (Table 44.1). This model has age-dependent formation of NFTs, loss of neurons, generalized forebrain atrophy and deficits in spatial memory. While formation of NFTs has been linked to subsequent neuronal loss and cognitive deficits, suppression of mutant tau gene starting at four months of age in these mice did not halt the accumulation of NFTs, even though there was a cessation in the loss of neurons and brain weight[14]. In addition, there was improvement in memory function in these mice, despite progressive NFT accumulation. These findings imply that early memory deficits may be due to reversible neuronal dysfunction rather than irreversible development of NFTs or that there may be neuronal remodelling after the mutant tau gene suppression that allows recovery. Another implication from this study is that NFTs may not entirely account for the neuronal loss[14].

Recently, the conditional triple tg mouse rTg3696AB that harbours two human Swedish APP mutations (K670N and M671L) at the β-secretase site, the London mutation (V717I) at the γ-secretase site (APP_{NLI}) and a tau mutation (P301L) has been created. This model shows Aβ deposits from 4 months of age, and NFTs from 11 months of age. Neuronal loss occurs at 13 months of age. Studies of the effects of transgene suppression, mimicking potential human therapeutic strategies, on pathologic and cognitive behavioural outcomes are in progress[15]. This discussion illustrates the advantages of conditional tg mouse models, where temporal variations in the expression of transgenes as well as inhibition of select transgenes can demonstrate the potential role they play in the pathogenesis of neurodegeneration and cognitive behavioural symptoms.

KNOCK-OUT MOUSE MODELS

Knock-out models are mice in which genes of interest have been selectively silenced. They are useful for determining the function of a specific protein or an enzyme, and for studying biological models of the enzyme inhibition.

The APP gene is located on chromosome 21, and has many putative roles. Along with its homologues, the amyloid precursor-like proteins 1 and 2 (APLP1 and APLP 2), APP is thought to have roles in cell adhesion, motility, neuronal survival and neurite outgrowth. Interestingly, one of the APP knock-out mouse models (APP-/-) produces mice that are relatively healthy and fertile, with slightly lower body weight, decreased locomotion and increased reactive gliosis. The ability to maintain a relatively normal litter size was attributed to possible compensation for the loss of APP by its homologues[16]. However, subsequent studies revealed behavioural deficit, defective long-term potentiation and GABA-mediated postsynaptic response in these mice[17].

The microtubule-associated protein tau (MAPT) gene is located on chromosome 17q21. In normal human brain, tau is thought to be involved in stabilizing microtubles, which are located predominantly in axons. MAPT knock-out mice (Mapt -/-) do not have overt histological abnormalities. However, they exhibit muscle weakness on a rod walking (balance coordination) or a wire hanging (traction) test. They also demonstrate impaired contextual fear conditioning in foot shock experiments, which are thought to test amygdala and hippocampal functions. However, these impairments in Mapt -/- mice are thought to be due to hyperactivity of the mice rather than due to memory impairment since they exhibit hyperactivity in open fields but have intact spatial learning tasks[18,19]. As with the APP knock-out models, the lack of significant pathologic deficits in tau knock-out models such as Mapt -/- may be due to compensation by other microtubule-associated proteins that may have overlapping function with MAPT protein[19].

One example of a knock-out mouse model that demonstrates the function of an enzyme while serving as a biological model of enzyme inhibition is the BACE1 knock-out model (BACE1 -/-). This model demonstrates the role of the β-site amyloid precursor cleaving enzyme 1 (BACE1) in APP cleavage. Primary cortical cultures from the BACE1 -/- mouse embryos have undetectable levels of most Aβ40 and 42 species, demonstrating that amyloid is not produced, thus establishing BACE1 as the principal β-secretase in cortical neurons. More importantly, because the BACE1 -/- mouse model was viable, this model suggested that it may be possible to develop therapeutic β-secretase inhibitors to reduce Aβ deposition without mechanism-based adverse effects[20].

While abnormal processing of APP and tau may result in neurotoxic substances, such as Aβ and NFTs, respectively, these knock-out mouse models demonstrate that APP and tau both play important roles in normal neuronal function. In addition, knock-out mouse models of enzymes such as BACE1 demonstrate the biological role of enzymes and the effects of targeting them as part of AD therapy.

DISCUSSION

While Tg mouse models of amyloidosis do not fully reproduce the pathological changes seen in human AD, they have contributed significantly to our understanding of the pathophysiology of AD. Amyloid plaques, along with neurites, neurofibrillary tangles, loss of synapses and death of neurons, are the pathological hallmarks

of AD[21,22]. Most tg mouse models express either amyloid or tau pathology, although more recent models express both[12,15]. Many models do not show loss of neurons[23,24], a critical feature of human AD. Several explanations have been proposed, including species variability in neuronal vulnerability, lack of key human-type inflammatory factors[1], species variability in amyloid burden, and differences in types of plaques that accumulate in different tg mouse models[25]. Some tg mouse models also show *age-independent* behavioural deficits *prior* to Aβ deposition in the brain[26], which is different from human AD, in which amyloid deposition begins years before the clinical manifestations are evident.

Model to model variability can also be attributed to the use of different promoters, resulting in different phenotypic expressions. Some tg mouse models have tissue-specific (e.g. brain)[13] or more broadly expressed[3] transgenes, depending on the promoter type. Differences in promoters can also result in differences in transgene expression levels, expression in irrelevant brain areas as well as expression at different times. Differences in background strains can also result in different phenotypic expressions even within the same tg mouse model[19].

Despite limitations, tg mouse models are essential tools for investigating biological mechanisms and assessing potential treatments for AD. AD is characterized by gradual onset and progression of the brain disease over many years. One of the more difficult aspects of human AD research is the long duration of clinical trials, which can become prohibitive due to high patient attrition and costs. In addition, more researchers are focusing their efforts on the period preceding the AD diagnosis, preclinical and mild cognitive impairment (MCI) stages, extending the duration of the study. Tg mouse models have rapid breeding time and lower maintenance costs compared to primate models, allowing accelerated investigation of the mutated gene of interest. This results in shorter lead-time before the development of pathology (e.g. amyloid deposition in the brain) and the resultant behavioural changes. It also enables a researcher to design an intervention and observe pathological and behavioural changes within a short time frame. Many of these models have been used for evaluation of a treatment tool such as immunotherapy[27]. They are also useful for environmental modifications such as enrichment[28] and caloric restriction[29], and direct observation of their effects on behaviour as well as on neuropathology.

Many of the tg mouse models develop impairments in learning and memory as assessed by well-established methods including the Morris water maze task[9,30]. The difficulty of interpreting mouse behaviour partly arises from age-independent behaviours. These behaviours may be due to factors that are unrelated to Aβ toxicity such as transgene insertion and expression levels, strain background and promoter types[9]. Differences in the timing of behavioural onset in relation to the Aβ deposition may also be due to the use of different tasks for behavioural testing as well as assessment of behaviour at different stages of learning[9]. Recently, there have been efforts to elucidate potential soluble Aβ species that may contribute to the behavioural deficits, and that may, in part, explain the age-independent behaviors[26].

Some of the difficulties in human AD research arise from heterogeneity within the study population, which introduces confounders. Tg mouse models allow researchers to minimize the biological heterogeneity that may influence the outcome of interest by repeated backcrosses to an inbred breeding strain of mouse model up to at least tenth generation, creating a 'congenic' strain of the model. In conclusion, tg mouse models are useful for studying molecular mechanisms of a disease as well as for assessing therapeutic effect of drugs or environmental modifications, and continue to make significant contributions towards further understanding of AD.

Physiological Neuroimaging in Ageing and Dementia: Metabolic and Molecular Scanning

Markus Donix, Susan Y. Bookheimer and Gary W. Small

David Geffen School of Medicine at UCLA, Los Angeles, USA

INTRODUCTION

It is well recognized that in a process of cognitive decline leading to mild cognitive impairment (MCI) and dementia, detection of the underlying changes in brain structure and function will contribute to establishing an accurate diagnosis, with direct implications for pharmacological and non-pharmacological therapy planning. Since the first positron imaging device in 1950 or the first tomographs from single photon emission data in the 1960s, scientific advances in radionuclide development and detection research have led us to look beyond the brain's regional blood flow (SPECT) or glucose metabolism (FDG-PET) into the patterns of amyloid plaque (PIB-PET) and tau tangle brain deposits (FDDNP-PET) or neuronal disintegrity (MPPF-PET). With new methods entering clinical settings, we will need to balance our expectations for these new tools against availability and costs. Here we review the current state of metabolic and molecular imaging tools used in ageing and dementia, their utility, promise, as well as potential difficulties in bringing them into common practice. We will first review the basic techniques and then discuss their applications, including practical guidelines and results from the most recent studies reporting sensitivity, specificity and optimal uses.

SPECT

Image Acquisition

Single photon emission computed tomography (SPECT) measures the distribution of radioligands in the brain reflecting regional cerebral blood flow (rCBF), which itself is linked to brain metabolism. The tracer accumulates in proportion to the rate of delivery of blood to a distinct volume of brain tissue. Decades ago to patients this would have meant injection of ^{133}Xe or ^{85}Kr into the carotid artery. Today, within the commercial and experimental available radioligands technetium-99m labelled hexamethylpropyleneamine (^{99m}Tc-HMPAO) and ethylcysteinate dimer (^{99m}Tc-ECD) tracers are commonly used in brain SPECT imaging. After intravenous injection, these lipophilic compounds quickly cross the blood–brain barrier by diffusion and, due to slow brain clearance, the distribution of the radioligands then remains stable for hours. The underlying multicompartment clearance ('microsphere') model assumes that the tracer is freely diffusible, completely extracted to the brain and 'fixed' without redistribution. The emitted single photons can be detected by a rotating gamma camera or ring-type imaging system. Spatial resolution is about 10 mm and could reach 5–6 mm using special-purpose detection systems that usually are not available for routine clinical scans.

Spatial resolution in SPECT is only limited by technology (whereas PET resolution also depends on other factors[1]; see below) but today SPECT cannot compete with PET on image resolution and begins to lose its uniqueness within other factors. Cost-effectiveness still remains a controversy from a perspective that would take diagnostic accuracy and secondary costs into account; further, PET has become much more available, which also will make it less expensive. Resulting from physics-based differences, the possibility of simultaneous imaging of more than one radioagent is SPECT territory and a growing field of interest. Since all PET tracers share the same energy level, it would be much more difficult to perform simultaneous multiple tracer studies in PET. Signals would have to be separated based upon half-life or kinetics, which seems feasible in the future[1,2].

Advanced SPECT technology is heavily reliant on detector improvements, use of hybrid imaging (e.g. SPECT/CT) and incorporation of attenuation or collimator-detector response modelling into image reconstruction algorithms (for review see[1]).

The clinical protocol requires the application of 20 mCi (740 MBq) of ^{99m}Tc-HMPAO or ^{99m}Tc-ECD 10 to 20 minutes before imaging with HMPAO and 30 to 60 minutes before image acquisition with ECD. Image acquisition itself will take 30 minutes or less. Total radiation exposure is small (about 9 mSv) and in the range from one to three times of the annual natural background.

Memory Impairment and SPECT Imaging

In the field of dementia and related disorders, SPECT has been used widely for both basic science and clinical applications. Alzheimer's disease patients display a characteristic pattern of posterior temporal and parietal perfusion deficits. Sometimes additional reduced frontal rCBF has been detected, associated with behavioural disturbances, such as depressed mood or apathy[3]. Correlations between neuropsychological performance and rCBF have been reported consistently, especially with focus on language and global functioning[4]. Pharmacological activation studies demonstrated the relationship of, e.g. cholinergic stimulation and rCBF[5].

In addition to clinical assessment, SPECT studies have been shown to improve diagnostic precision. Jagust and colleagues reported that

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

a positive SPECT result would increase the likelihood of a diagnosis of Alzheimer's disease by a factor of five[6]. In a meta-analysis, ^{99m}Tc-HMPAO-SPECT could discriminate between Alzheimer's disease, vascular dementia (VaD), frontotemporal dementia (FTD) and normal controls with sensitivities between 66% and 72% and specificities between 76% and 79%. Diagnostic accuracy is improved especially in patients who present with additional signs of cerebrovascular disease or who do not exactly match clinical criteria[7]. Furthermore, SPECT has been shown to be useful predicting the conversion to Alzheimer's disease in patients with MCI[8].

Measuring cerebral metabolism indirectly using rCBF enhances vulnerability to vascular-related confounders, such as hypertension and other specific cerebrovascular diseases. It has been shown that rCBF differences can be found with respect to gender and advanced age itself[9]. Changes in rCBF are not unique to memory disorders and have been observed in depression[10] and obsessive–compulsive disorder[11] as well.

Currently, most clinical SPECT scans are performed in cardiology. ^{99m}Tc-labelled tracers can be used to perform dynamic imaging (e.g. myocardial perfusion SPECT) but in the future, dynamic PET (e.g. ^{82}Rb-based cardiac PET) imaging might have an intrinsic advantage over SPECT since temporal resolution is very closely related to the imaging system's specificity[1].

In addition to regional cerebral perfusion, various neurotransmitter systems have been a target of interest in SPECT tracer development. Dopamine transporter imaging with ^{123}I-2β-carbomethoxy-3β-(4-iodophenyl)-*N*-(3-fluoropropyl) nortropane (^{123}I-FPCIT), which can be used in the differential diagnosis of Parkinson's disease, could help to distinguish between dementia with Lewy bodies (DLB) and Alzheimer's disease, if the clinical diagnosis remains ambiguous. Since the cholinergic system is of particular interest in dementia, radiolabelled muscarinic and nicotinic acetylcholine SPECT ligands are currently under investigation in preliminary studies.

PET

Image Acquisition

Positron emission tomography (PET) has more diverse applications in imaging in ageing and dementia, as it can be used to generate images of regional cerebral blood flow (e.g. [^{15}O]H_2O-PET), metabolic activity (e.g. [^{18}F]FDG-PET), microstructures (e.g. [^{18}F]FDDNP-PET) or neurotransmitter receptor distribution (e.g. [^{18}F]MPPF-PET) in the brain. After being injected intravenously, the isotope emits a positron, which after travelling a few millimetres annihilates with an electron. As a result, two 511 keV gamma photons, moving in almost opposite directions, are produced and then detected using a scintillator material (luminescent when excited by ionizing radiation) in the ring-type scanner. Only coincident arrivals of photons are recognized (within a few nanoseconds' error margin). Because of the peculiar dataset ('coincidence events', each representing a line connecting the two points of detection along which the annihilation occurred) compared to other neuroimaging techniques data, preprocessing and mathematical image reconstruction are challenging. Spatial resolution of PET images is about 3 mm and higher and limited by technological factors (detector-related effects) but also physics-related limitations (positron range and photon non-collinearity)[1]. Improvements in PET technology will be seen in both cases. New scintillators for reduction of random coincidences and silicon-based photodetectors will improve detection. PET/MRI hybrid imaging systems could be used for monitoring patient motion via MRI to incorporate the data in PET image reconstruction, maybe replacing PET/CT in the future[1,12]. Even ultimate limitations (positron range/photon non-collinearity) have been a target since new statistical reconstruction algorithms could incorporate their probability distributions into image processing or a strong magnetic field (preferably 5 T or higher) of a future PET/MRI system should be able to reduce positron range and therefore enhance scanner resolution[1]. Time-of-flight-PET, as one of the most promising technological advances, uses the nanosecond difference of photon arrival times to restrict the position of the positron emission to a subsection of the photons' connection line, which reduces the statistical noise variance in PET reconstruction[1].

PET isotopes usually have shorter half-lives compared to SPECT ligands. The most common PET isotopes are ^{11}C (half-life: 20 min), ^{13}N (10 min), ^{15}O (2 min) and ^{18}F (110 min). Only a few hospitals have costly on-site cyclotrons, needed to produce them. Third-party suppliers are able to provide ^{18}F because of its relatively long half-life and therefore clinical use is often restricted to ^{18}F-labelled ligands. On the other hand, short half-lives allow the safe injection of higher activities, increasing detectable radiation.

The most common clinical application of PET is in resting measures of glucose metabolism, with [^{18}F]FDG. In the standard clinical procedures, the tracer is injected (usually 5–6 MBq/kg for FDG) after a resting period (15–20 min). [^{18}F]FDG-PET additionally requires at least four hours of fasting before the scan to minimize competitive inhibition of FDG uptake by blood glucose. About 40 min later (uptake phase) scans are performed (at least 20 min for conventional and 4 min for rapid scan procedures[13]).

The number of PET tracers is rapidly growing and we will focus on today's most promising ligands in the field of memory disorders. Thus, we will not further discuss others that may be relevant in the future, such as [^{18}F]-BAY94-9172 (amyloid-β plaque labelling ligand, which has been shown to discriminate Alzheimer's disease from FTD patients and healthy controls), [^{11}C]-nicotine (visualization of nicotine binding sites in patients under cholinesterase inhibitor treatment) or [^{11}C](R)-PK11195 (visualization of microglial activation and immune response) (for review see[14]). Second, certain techniques, such as PET activation measurements, primarily performed in healthy subjects to identify regional brain activation underlying specific cognitive activities, or regional blood flow measurements with [^{15}O]H_2O-PET, will not be discussed either because of their decreasing relevance in current diagnostic procedures of memory impairment.

Finally, it must be mentioned that correction for possible confounding parameters is as important as in other neuroimaging techniques. Motion correction must be computed, and limitation in spatial resolution and brain atrophy in the particular patient group discussed here enhances the likelihood of partial volume effects. For adequate correction MRI scans of the subjects should be available.

[^{18}F]FDG-PET

In PET brain imaging the radiolabelled glucose analogue [^{18}F]fluorodeoxyglucose ([^{18}F]FDG) is the most common PET ligand. FDG is transported into cells like glucose but not metabolized after the first step in the glycolytic pathway. Thus, the distribution of [^{18}F]FDG reflects cerebral glucose metabolism, providing information on the distribution of neuronal loss and synapse dysfunction. Glucose provides energy for neurotransmitter

synthesis, and synaptic dysfunction and neuronal degeneration cause a decline of glucose metabolism in the affected parts of the brain[15].

In patients with Alzheimer's disease most affected brain regions with reduced FDG uptake are temporoparietal association cortex, posterior cingulate cortex, precuneus and variably also frontolateral association cortex[15]. These highly reproducible findings provide excellent separation of Alzheimer's disease patients from normal controls. Different FDG uptake patterns can also be observed in Alzheimer's disease patients with early (<65 years) versus late onset of the disease or high versus low education profile[16]. Because it is crucially important to identify predictors of future cognitive decline, a growing number of studies is being performed in people carrying risk factors (e.g. genetic) for developing Alzheimer's disease. It has been demonstrated that presymptomatic *APOE4* genotype carriers show abnormal uptake reductions using [^{18}F]FDG-PET in an Alzheimer's disease-like pattern in the absence of cortical atrophy[17]. Although an Alzheimer's disease-like pattern has been found to be predictive for future cognitive decline in normal ageing[18], it remains a controversy if hypometabolism in *APOE4* carriers can be considered a sign of pathology or just a genetic consequence[16].

In patients with MCI, AD-like [^{18}F]FDG-PET patterns are predictive for conversion to Alzheimer's disease[19]. In general, glucose hypometabolism has been reliably observed in MCI subjects, especially in posterior cingulate cortex of amnestic type patients. Metabolic changes in parietotemporal areas seem to be the best predictor for a patient's decline from MCI to Alzheimer's disease[16].

To differentiate Alzheimer's disease from other types of dementia, [^{18}F]FDG-PET can be helpful in addition to a clinical examination, given the typical metabolic deficit patterns (frontal and anterior temporal and/or mesiotemporal in FTD; similar to Alzheimer's disease but less sparing of occipital and cerebellar cortices in DLB; diffuse cortical and subcortical in VaD); however, accuracy of discrimination has rarely been reported[16].

Today, [^{18}F]FDG-PET is the best established and growingly available diagnostic tool to observe the metabolic consequences of structural brain alterations in cognitive decline and it is increasingly accepted for reimbursement in countries' medical systems. In today's comparison to SPECT the superiority of PET is evident. Better spatial resolution allows the investigation of smaller brain regions, like the hippocampus, which is of particular interest in the field of memory disorders. In SPECT the occasional loss of the coupling of cortical metabolism and perfusion due to vascular disorders could bias the findings. The effect of hypometabolism shown with [^{18}F]FDG-PET is generally greater than hypoperfusion effects in SPECT[20] and, most importantly, the achievable diagnostic accuracy with PET (sensitivity/specificity: 93%/93% for moderate and 84%/93% for mild [MMSE 24 or higher] Alzheimer's disease versus controls[21]) is higher than with SPECT (66%/79% for Alzheimer's disease versus controls[6]).

Again, an ultimate limitation of studying metabolic patterns is that different diseases could produce the same pattern of metabolic change. As an example, frontal cortical hypometabolism has been reported in both Alzheimer's disease and depression[22], and the diverse clinical manifestations of Alzheimer's disease, often including behavioural changes or mood abnormalities, underline the importance of a detailed clinical evaluation preceding brain imaging.

[^{11}C]PIB-PET and [^{18}F]FDDNP-PET

Direct detection of Alzheimer's disease's histopathological hallmarks, such as amyloid-β plaques and tau tangles *in vivo* using PET, can be seen as a milestone in PET tracer development. Among more than 10 ligands that have been developed in this respect within the past decade, [^{11}C]N-methyl-2-(4-methylaminophenyl)-6-hydroxybenzothiazole ([^{11}C]PIB) has been most extensively studied. [^{11}C]PIB binds to amyloid-β plaques only, and in several Alzheimer's disease patients who have been followed to autopsy after a [^{11}C]PIB-PET scan, areas of high *in vivo* [^{11}C]PIB retention correspond to postmortem regions showing amyloid-β plaque deposition. Today, the ligand is being used in more than 40 centres worldwide. A disadvantage in terms of commercialization of a [^{11}C]PIB is the short half-life of ^{11}C (20 minutes), which requires on-site cyclotron capabilities, limiting more widespread use. However, in contrast to ^{18}F-labelled tracers (110 minute half-life), different imaging studies (e.g. [^{11}C]PIB followed by [^{18}F]FDG) can be performed on the same day.

In Alzheimer's disease patients, [^{11}C]PIB retention is significantly increased in cortical areas compared to controls, particularly in the frontal cortex. [^{11}C]PIB retention has been shown equivalent in patients and controls in areas known to be relatively unaffected by amyloid-β plaques (e.g. white matter, pons, cerebellum)[23]. To determine sensitivity and specificity, larger studies will be necessary.

[^{11}C]PIB has also been studied in patients with amnestic MCI. About half of those subjects showed higher [^{11}C]PIB retention compared to controls[24]. Recent investigations suggest this MCI subgroup might be at a higher risk of Alzheimer's disease conversion and therefore measuring [^{11}C]PIB retention would improve the identification of possible converters. In addition, a good correlation between [^{11}C]PIB and other biomarkers (e.g. CSF Aβ_{1-42}) has been reported[25].

There could also be a possible role for [^{11}C]PIB in the differential diagnosis of dementia. [^{11}C]PIB retention was lower and more variable in DLB and absent in FTD compared to Alzheimer's disease patients[26].

In a two-year follow-up analysis, Alzheimer's disease patients showed a pronounced decrease in glucose metabolism, measured with [^{18}F]FDG-PET, and cognitive decline but surprisingly stable [^{11}C]PIB retention. It has been argued that only a part of amyloid-β plaques might be accessible to exogenous tracer binding or retention could reach an equilibrium state and that additional processes, such as microglial activation and inflammation, should be taken into account in future PET multitracer binding studies[27]. However, such longitudinal findings of relatively stable levels of [^{11}C]PIB retention[27] despite declines in glucose metabolism and cognitive function may limit its utility as a short-term predictor of future cognitive decline.

[^{11}C]PIB-PET has been shown to detect cerebrovascular amyloid in patients with cerebral amyloid angiopathy, a major cause of haemorrhagic stroke. This raises the possibility of extending the future use of [^{11}C]PIB-PET[28].

2-(1-[{6-[(2-[^{18}F]fluoroethyl)(methyl)amino]-2-naphthyl}ethylidene)malononitrile ([^{18}F]FDDNP) is the only molecular imaging probe known to bind to *both* amyloid-β plaques and tau neurofibrillary tangles. Irrespective of its not yet widespread use compared to [^{11}C]PIB, it might be the more promising candidate from a clinical perspective. Moreover, the longer half-life of ^{18}F could make it more accessible to clinical settings without a cyclotron on site. [^{18}F]FDDNP has been shown to provide good visualization of plaques and tangles in autopsy-obtained human brain tissue specimens, and it clearly distinguishes between Alzheimer's disease and MCI patients and control subjects. Global [^{18}F]FDDNP values were more accurate for diagnostic classification than [^{18}F]FDG-PET or volumetric MRI measurements[29]. [^{18}F]FDDNP-PET signal is

highly correlated with cognitive performance, and the agreement between *in vivo* and histopathological postmortem tau and tangle burden maps is remarkable[30].

It has become obvious that tau tangle load and not amyloid-β plaque load is associated with age-related cognitive decline[31]. Direct comparison of [^{11}C]PIB and [^{18}F]FDDNP in the same subjects showed highest [^{18}F]FDDNP but lowest [^{11}C]PIB binding in the medial temporal cortex of Alzheimer's disease patients, again suggesting that tau tangles are the driving pathological factor in this region[32] and maybe in Alzheimer's disease itself.

[^{18}F]MPPF-PET

Changes in neuronal integrity and neuronal loss are a consequence of the molecular processes in AD pathology and are highly correlated with the decline of cognitive abilities. Therefore, any new possibility to (preferably presymptomatically) detect these changes in brain regions known to be the first affected in the development of the disease (e.g. entorhinal cortex and hippocampus CA1 and subicular fields) would be of interest to contribute to diagnostic precision and our understanding of pathology.

The correlation between neuronal death of large pyramidal cells in hippocampus CA1 field and serotonin 1A receptor density (although glutamatergic, these neurons receive high inhibitory serotonergic input via serotonin 1A receptors) has been studied in rodents using autoradiography[33]. With the development of 4-[^{18}F]fluoro-N-{2-[1-(2-methoxyphenyl)-piperazinyl]ethyl}-N-(2-pyridinyl)benzamide ([^{18}F]MPPF) as a serotonin 1A receptor binding PET ligand, *in vivo* measurements of receptor density could be performed in humans. Results indicate that [^{18}F]MPPF-PET clearly distinguishes Alzheimer's disease, MCI and control subjects. Whereas Alzheimer's disease subjects showed the most widespread decrease in [^{18}F]MPPF binding, with primarily hippocampus but also raphe nuclei being affected, the maybe most remarkable finding was that receptor densities were clearly decreased in MCI patients with only mild cognitive decline[34]. Despite the fact that the relationship between serotonin 1A receptor density, possible related compensatory and adaptive processes, and disease progression needs to be further examined, [^{18}F]MPPF-PET, especially in addition to other techniques, such as [^{18}F]FDDNP-PET, could be a next step to an early and exclusive *in vivo* diagnosis of Alzheimer's disease.

CONCLUDING REMARKS

In the years to come, nuclear medicine techniques will face new competitors. Namely, molecular magnetic resonance imaging, using iron oxide based contrast agents, designed with affinity to receptors or cell surface components may provide molecular pathway or receptor distribution mapping with superior spatial resolution[35]. Only a few years ago SPECT brain imaging was believed to undoubtedly persist in brain research and diagnostic procedures but today it struggles to survive in a PET environment. But to draw conclusions about whether one imaging technique would overcome another maybe also means to underestimate the next both hardware- and software-based technological advances.

INTRODUCTION

Alzheimer's disease (AD) is the most common form of dementia, afflicting over 24 million people worldwide. In early AD, short-term memory function is typically among the first to be impaired, followed by a progressive decline in other cognitive functions along with emotional/behavioural disturbances. At present, there is no cure for AD, whose natural course is insidious yet gradually debilitating, and is typically fatal at its most advanced stage, usually due to medical complications. In recent years, scientific interest has also focused on mild cognitive impairment (MCI), a pre-dementia stage that carries a four- to six-fold increased risk of future diagnosis of dementia, relative to the general population[1–3].

Many investigators have used MRI and PET imaging to measure longitudinal progression of brain changes in normal aging, MCI and AD, with varying results. As drug candidates that might slow the progression of Alzheimer's pathology began to be developed, the need for robust and sensitive imaging methods to quantify progression of Alzheimer's disease has become increasingly important. As a result, we are starting to see large collaborative multicentre imaging studies on Alzheimer's disease. For example, the National Institute of Aging and pharmaceutical industry funded the Alzheimer's Disease Neuroimaging Initiative[4,5] (ADNI), with the goal of developing improved methods based on imaging and other biomarkers, for AD treatment trials.

Major advances are occurring in scanning techniques and in image analysis, making it easier to track disease progression with greater power. In studies of hundreds of subjects scanned over time, databases of images can now be combined to visualize the disease trajectory, showing the spread of cortical atrophy, impaired metabolism, and even plaque and tangle accumulation. Ultra-high-field MRI reveals early changes in specific hippocampal subfields[4,5], and new PET ligands are emerging to visualize plaque and tangle pathology[6–9].

In this chapter, we review several strategies of computational anatomy in mapping brain deficits in AD and early dementia. These strategies include cortical thickness mapping, tensor-based morphometry (TBM) and hippocampal surface modelling. Mathematical concepts from surface modelling, non-linear three-dimensional volume registration, fluid mechanics and multivariate statistics are used across subjects for group and interval comparisons. They can be exploited to distinguish diseases from normal variations in brain structure, and help yield insights into the dynamics of AD and MCI.

COMPUTATIONAL ANATOMY

Computational anatomy is a general term covering a broad class of mathematical methods that model anatomical structures in images as three-dimensional curves, surfaces and volumes, and combine them across subjects to create statistical maps of brain structural differences.

Cortical Thickness Mapping

In this approach, in order to precisely quantify the amount of tissue loss, overall grey and white matter volumes can be computed from brain MRI scans. Tissue classification methods can assign each image voxel to a specific tissue class. If grey matter maps from many subjects are aligned to a standard three-dimensional digital brain atlas, on which lobar subdivisions have been labelled, regional statistics for subdivisions can be derived. These region-of-interest measures, in conjunction with manual tracings of the hippocampus and other subcortical structures, have been the mainstay of morphometric analysis for nearly two decades.

One approach for cortical thickness mapping is presented in Figure 46.1, which shows a computational pipeline for processing MRI scans as described by Thompson *et al.*[10]. For each scan, a three-dimensional map is first computed quantifying the distance of cortical grey matter voxels to the grey/white matter interface. Thickness values are calculated from the inner cortical surface to the outer cortical surface, and are plotted at each point on a cortical surface model extracted from the scan. To combine thickness data across subjects (Figure 46.1, second row), a spherical coordinate system is imposed onto each subject's cortical surface. This serves as a reference grid so that thickness data can be compared at a given surface-based coordinate across subjects. If sulcal/gyral landmarks are traced onto the cortical models, data from corresponding cortical regions can be averaged across subjects using a technique known as cortical pattern matching[10] (CPM), where the sulcal pattern is digitized and matched across subjects using a flow field in spherical coordinates. By doing so, an average cortical model can be created

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

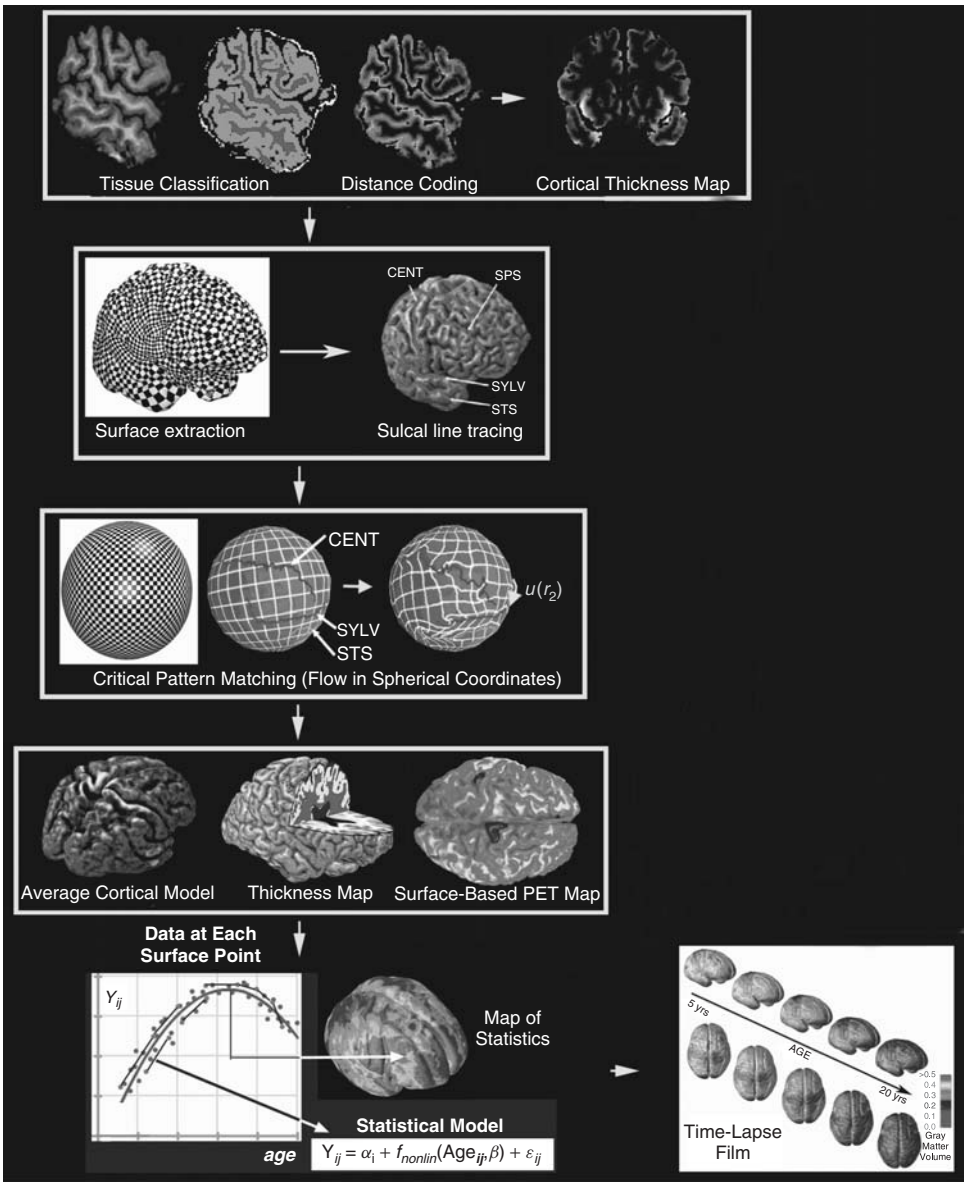

Figure 46.1 Flowchart showing an image analysis pipeline (adapted from[10]) that can map changes of various neuroanatomical measures in the cortex, such as grey matter atrophy. Cortical thickness profiles, for example, can be averaged across subjects or compared across time. Tissue classification techniques can be used to identify grey and white matter and to produce cortical thickness maps (row 1). The CPM approach can be applied by tracing sulcal landmarks on extracted brain surface models (row 2) that serve as anchors to guide a flow field matching gyral regions across subjects (row 3). Then maps of cortical thickness, or other cortical signals (such as co-registered PET images, shown here), can be fluidly aligned to an average cortical model (row 4). Statistical models are fitted to data from all the subjects at each cortical point. This can assess whether imaging signals are associated with age (bottom row), or other parameters of interest. Effects of ageing on cortical measures – or changes relative to baseline – may be animated as a time-lapse film to reveal the disease trajectory. *A full colour version of this figure appears in the colour plate section*

for a group of subjects (such as an AD or MCI population), with well-defined sulcal features in their mean spatial locations (Figure 46.1, fourth row). Moreover, maps of cortical thickness in each individual can be transferred onto this average model while adjusting for the individual gyral pattern differences across subjects. This method allows pixel-by-pixel averaging of values within each delineated region across all subjects, allowing comparisons of patients with controls. Lastly, a statistical model can be fitted to the thickness measures from all subjects at each surface point (Figure 46.1, bottom row). In brain mapping studies, it is common to fit statistical models to data at each location in an image, to assess effects of age, diagnosis or experimental parameters (an approach known as statistical parametric mapping; SPM[11]). The results are displayed in the form of a three-dimensional map of statistics, and the overall significance of the map can be colour-coded to show the distribution of atrophy[10].

Cortical thickness mapping is related to several simpler but widely used methods. For example, the 'boundary shift integral' technique

quantifies differences between two successive co-registered 3D MRIs by examining the magnitude of the shifting of grey–white junction[12]. Before algorithms became widely available for computing cortical thickness accurately from MRI scans, it was more common to compute a local measure of grey matter volume called 'grey matter density' (GMD). This is defined, at each point in an image, as the proportion of tissue segmented as grey matter in a small spherical region (typically of 10–12 mm radius) centred at that point[13,14]. GMD and thickness are highly correlated[15], except at the temporal lobe tips, where cortical curvature is high.

Cortical Maps in AD and MCI

Cortical mapping methods have distinguished patterns of atrophy typical of late- versus early-onset AD[16], and different dementia subtypes[17]. Sowell *et al*.[18] applied cortical pattern matching to 176 scans of subjects aged 7 to 87, and compiled trajectories of grey matter thinning, for each cortical point, over the life span. Encouragingly, there was close regional correspondence between the cortical thickness maps created from *in vivo* MRI and the 1929 postmortem data of von Economo. The cortex does not age in a homogeneous way; each cortical region has a somewhat distinctive trajectory[18,19]. A related study by Gogtay *et al*.[20] created a time-lapse map of cortical development from ages 4 to 22, and showed the earliest maturing cortex is least vulnerable to aging and AD.

Apostolova *et al*.[21] compared grey matter profiles in 26 amnestic MCI and 31 mild AD subjects, showing strikingly greater atrophy in mild AD (Figure 46.2A), conforming to the pattern of spread of AD pathology observed postmortem through the brain. A related VBM study found significantly greater parietal, anterior and posterior cingulate atrophy in mild to severe AD relative to MCI[23].

In Apostolova *et al*.[22], we also examined the structural correlates of apathy in AD, by applying cortical mapping to 35 AD patients with and without apathy (Figure 46.2B). Apathy severity was associated with cortical grey matter atrophy in bilateral anterior cingulate (Brodmann area BA 24; $r = 0.39$–0.42, $p = 0.01$) and left medial frontal cortex (BA 8 and 9; $r = 0.4$, $p < 0.02$). A subsequent study found associations between the Boston Naming Test and the animal fluency tests and cortical atrophy in 19 probable AD and 5 multiple-domain amnestic MCI patients who later converted to AD[24]. The degree of language impairment correlated with cortical atrophy in the left temporal and parietal lobes, especially in the perisylvian language cortices.

Time-Lapse Maps and the Trajectory of AD

The cortical pattern matching approach may be extended to time-varying or functional imaging data. If longitudinal scans are available, a time-lapse movie of disease progression can be created by fitting a trajectory to cortical thickness, or any other imaging parameter, at each cortical point (Figure 46.1, bottom right)[25]. A movie 'frame' can then be written out for each time-point and the series of frames can be animated. An example of this type of dynamic map may be viewed at www.loni.ucla.edu/~thompson/AD_4D/dynamic.html. Here, a time-dependent model was fitted to cortical grey matter density in 14 AD patients and 12 controls scanned longitudinally for 4 years. Maps of the degree of deficits – either as a percentage or as a significance map – show that the cortex is thinner in medial and lateral temporal lobes in early AD and deficits advance anteriorly to engulf the cingulate and frontal cortex.

Figure 46.3 shows two time-points from this animation, showing that cortical atrophy on MRI proceeds in approximately the same anatomical sequence as plaque and tangle burden in histopathological studies of AD. Plaque and tangle deposition starts in medial temporal regions[26] and affects the posterior limbic system first due to its close connections to the posterior cingulate gyrus[27]. Hypometabolism of the posterior cingulate is observed early in AD, even when no atrophy is detected in this region[28]. On the other hand, in frontotemporal lobar degeneration, neuronal loss is first observed in the frontal regions closely connected to the anterior cingulate cortex[29].

Cortical pattern matching can also be used to understand how amyloid load spreads in the living brain. Braskie *et al*.[8,30] applied cortical pattern matching to 23 subjects (10 controls, 6 amnestic MCI, 7 AD) scanned with both MRI and [^{18}F]FDDNP, a recently developed PET ligand sensitive to plaque and tangle pathology[7,31]. They aligned parametric PET images of amyloid load to MRI scans from the same subjects, textured the PET signals onto the cortex, and combined them across subjects using cortical pattern matching (Figure 46.1, fourth row). They showed that the advancing pathology also follows the classical Braak trajectory for neurofibrillary tangle accumulation. Related work by Mintun *et al*.[9] and Rowe *et al*.[32] with Pittsburgh Compound-B ([^{11}C]PIB) show frontal lobe labelling

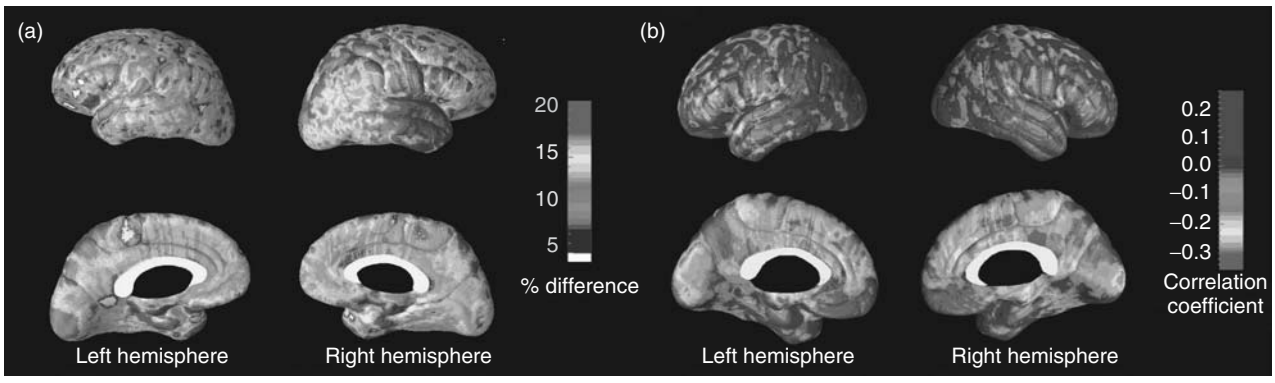

Figure 46.2 (A) Cortical thinning of up to 20% occurs between MCI and AD, in widely distributed cortical areas (greatest tissue loss is coded in red). (B). Grey matter atrophy in the anterior cingulate and supplementary motor cortices is correlated with the presence or absence of apathy in AD. Regions where structural variation correlates with clinical or behavioural differences can be identified using correlation maps such as these (strong associations are shown here in red colours). Data adapted from[21,22]. *A full colour version of this figure appears in the colour plate section*

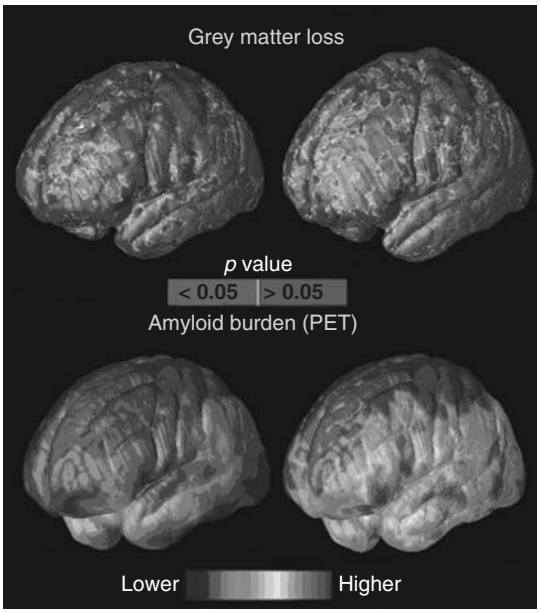

Figure 46.3 Progression of AD based on MRI and [^{18}F]FDDNP PET. On MRI (top row), the areas with grey matter deficits in mild AD (left panel) include primarily the temporal lobe, but in moderate AD (right panel) these deficits have spread to involve the frontal cortex (adapted from a longitudinal study by Thompson *et al*.[25]). Finally, cerebral amyloid estimated *in vivo* from the PET ligand FDDNP is low in controls, but higher in those with impaired cognition (bottom row; adapted from Braskie *et al*.[8]). The anatomical agreement is striking between these *in vivo* maps and the well-established post-mortem maps for the staging of AD. In all maps, the sensorimotor cortex shows least disease-related degeneration. *A full colour version of this figure appears in the colour plate section*

early in the degenerative sequence. The PIB progression pattern is consistent with the Braak trajectory for amyloid deposition, which, unlike tangle deposition, shows early increases in the basal neocortex, particularly in frontal and temporal lobes and primarily in poorly myelinated regions such as the perirhinal cortex.

Tensor-Based Morphometry

While the methods described so far provide detailed maps of changes in cortical measures, tensor-based morphometry (TBM) can identify regional volumetric differences in the structure of the brain, both cross-sectionally and longitudinally, from the gradients of the deformation fields that align, or 'warp', images. In a longitudinal design, TBM can track structural changes between serial 3D MRI images, by producing rates of atrophy over time (in percentage points per year). In a cross-sectional design, TBM can compare structural scans of two different groups, such as AD versus controls or MCI versus controls.

Figure 46.4 shows the premise of TBM. If a pair of scans is collected from the same subject over time, they can be aligned with each other, using a fluid transformation that applies compressions and expansions at a local level throughout the anatomy. One class of registration methods models the baseline image as a deformable elastic medium or as a viscous fluid, and applies distributed internal forces to reconfigure the earlier scan to match the later one. The spatial gradient of this transformation (deformed grid in Figure 46.4) provides information on how much tissue is lost over the time interval between the scans, and can be plotted and colour-coded. Applied to a sequence of scans acquired over time from the same patient, these voxel expansion/compression maps[12], also known as Jacobian maps, can reveal the extent and spread of atrophy. They are also amenable to voxel-by-voxel averaging, to make a map of the average voxel-wise atrophy rate.

As part of the ADNI project, Thompson and Leow have applied the TBM approach and analysed the ADNI dataset using both cross-sectional and longitudinal designs. Leow *et al*.[33] studied the serial high-resolution MRI scans (12 months apart) from 40 normal controls, 40 MCI, and 20 AD patients from ADNI. These individual Jacobian maps, representing annual atrophy rates, are then nonlinearly registered to a common template, followed by voxel-wise statistical testing to detect group differences. These maps can also be correlated, on a voxel level, with biomarkers and neuropsychological measures. Moreover, these Jacobian maps can also be summarized on an ROI level to give overall atrophy rates in regions of interest (Figure 46.5; right panel). In the MCI group, temporal lobe atrophy rates were correlated with changes in mini-mental state exam

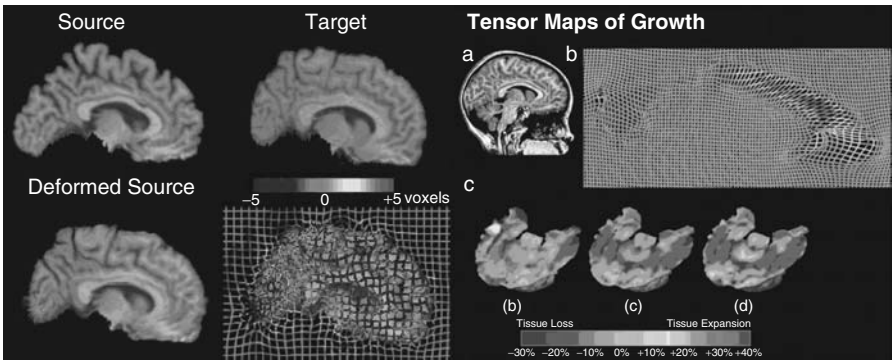

Figure 46.4 Tensor-based morphometry. In TBM, a fluid transformation (*deformed grid*) is applied to a baseline scan (*source*) to reconfigure it (*deformed source*) into the shape of a follow-up scan (*target*). The local expansions (*red colours*) or atrophies (*blue colours*) can be plotted in brain regions such as the corpus callosum (shown in the green box in [a]). Voxel expansions (*red colours*) or contractions (*blue colours*) can be plotted onto a sequence of scans collected from the same subject (shown here in axial view illustrating progressive temporal lobe atrophy in a subject with frontotemporal lobe atrophy) during a degenerative brain disease, emphasizing regions with progressive atrophy. These maps may be averaged across subjects or compared across populations to assess factors that influence degenerative rates in each region of the brain. *A full colour version of this figure appears in the colour plate section*

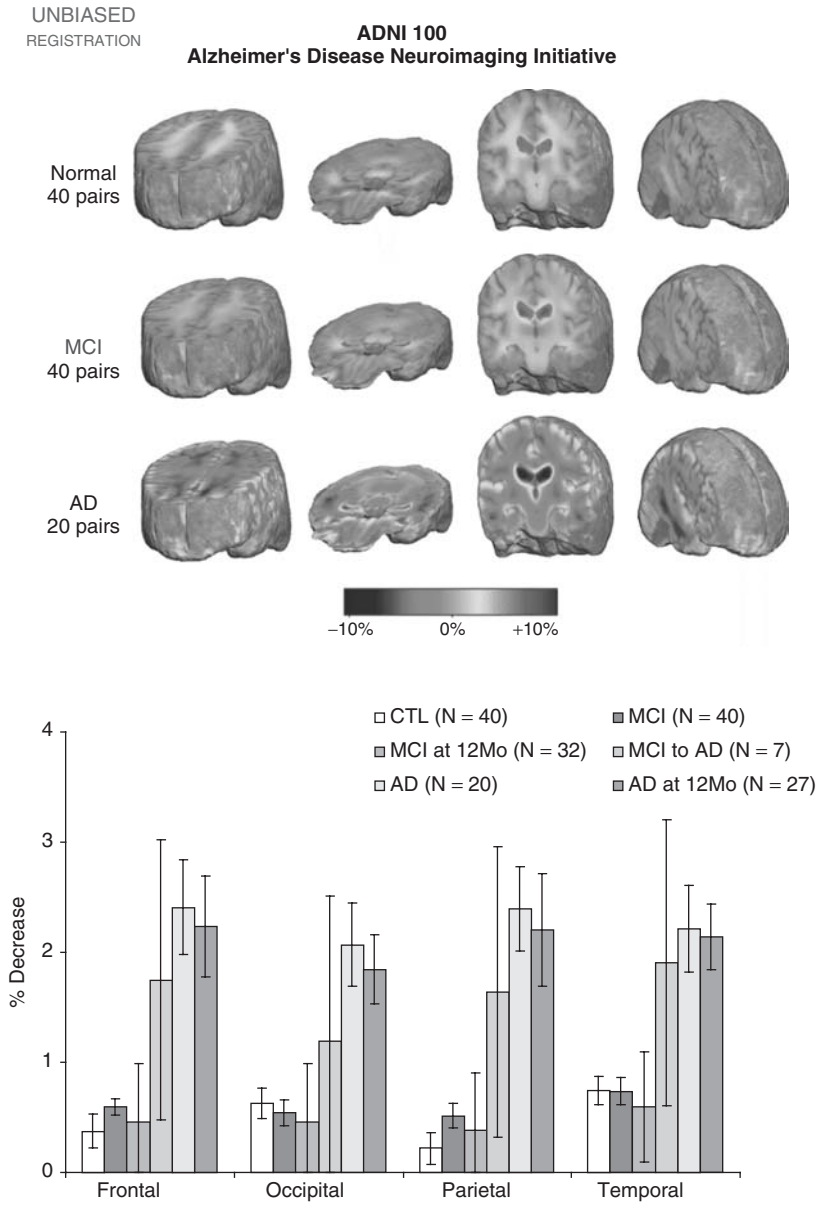

Figure 46.5 (Top panel) average longitudinal tissue atrophy/expansion rate for 40 normal, 40 MCI and 20 AD subjects, using serial MRI scans from the ADNI dataset scanned at 12 months apart. Ventricular expansion (third column) and temporal lobe atrophy (fourth column) are most prominent in the AD group. (Bottom panel) Percentage brain tissue loss from baseline to follow-up within each lobe can be computed by averaging the maps in the left panel for each region of interest (with CSF excluded). The diagnoses for the AD, MCI and CTL groups were determined at baseline. Here, MCI at 12Mo denotes subjects diagnosed as MCI at baseline who did not convert to AD at 12-month follow-up, whereas MCI to AD signifies those who had converted to AD at 12-month follow-up. One MCI subject's diagnosis converted back to control at follow-up, and thus was excluded from the MCI subgroups. The first bar in each group (coloured *white*) shows mild but significant progressive atrophy in controls. The second bar (*turquoise*) denotes MCI subjects at baseline, and is followed by bars denoting converters and non-converters. Mean rates are typically higher in the converters, comparable to subjects diagnosed as AD at both time-points, or AD at the last time-point (*last two bars*). This figure is adapted from the results in[33]. *A full colour version of this figure appears in the colour plate section*

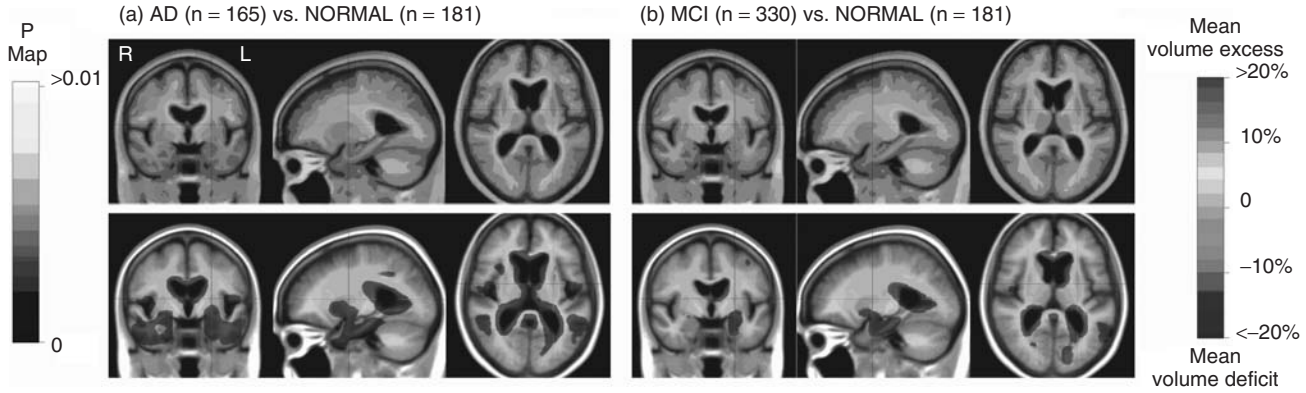
(MMSE) scores, clinical dementia rating (CDR) and logical/verbal learning memory scores. In the AD group, temporal atrophy rates were correlated with several biomarker indices, including a higher CSF level of p-tau protein, and a greater CSF tau/beta amyloid 1–42 (ABeta42) ratio. Temporal lobe atrophy rate was significantly higher in MCI subjects who converted to AD than in non-converters. Serial MRI scans can therefore be analysed with TBM to relate ongoing neurodegeneration to a variety of pathological biomarkers, cognitive changes and conversion from MCI to AD, tracking disease progression in three-dimensional detail.

Using a cross-sectional design, Hua *et al.*[34] computed the statistical maps of group differences using 40 normal controls, 40 MCI subjects



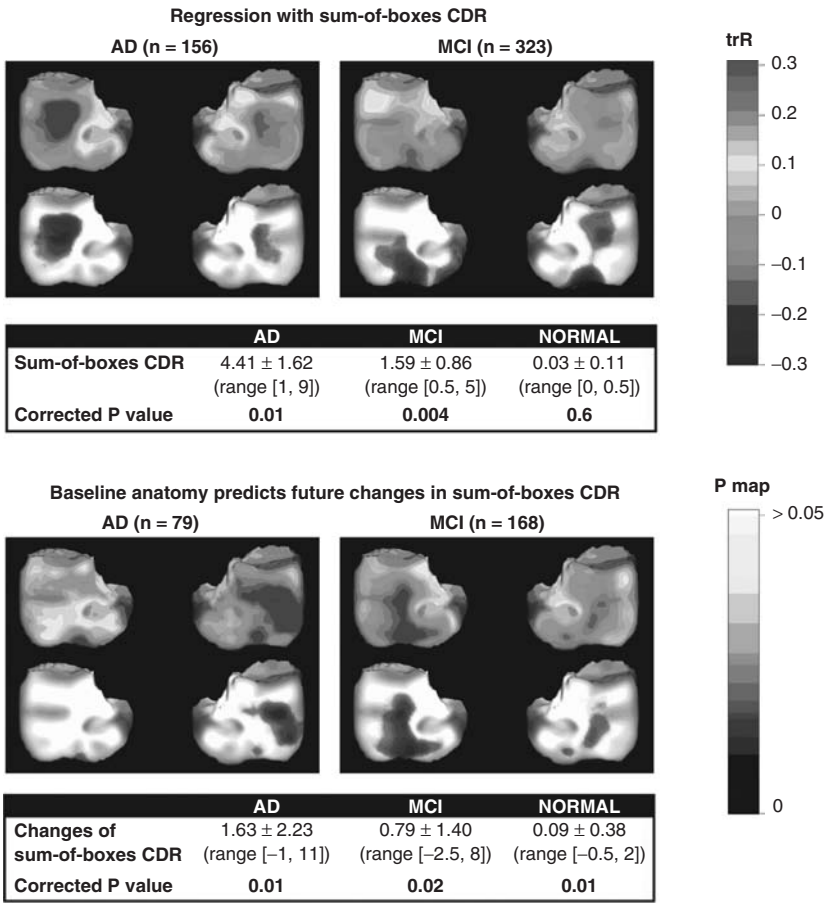


Figure 46.6 3D maps of brain atrophy comparing group differences between MCI ($n = 330$) versus normal ($n = 181$), and AD subjects ($n = 165$) versus normal. The top rows of panels (a) and (b) show the mean level of atrophy as a percentage reduction in volume. The bottom rows show the significance of these reductions, revealing highly significant atrophy in AD but a more anatomically restricted atrophic pattern in MCI. In MCI (b), atrophy is most prominent in the left hippocampus; ventricular expansion is also substantial. When AD is compared with MCI (not shown here), additional temporal lobe degeneration is evident. The overall level of ventricular expansion is about 10–15% for MCI and greater than 20% for the AD group. This figure is adapted from the results in[35]. *A full colour version of this figure appears in the colour plate section*

	AD	MCI	NORMAL
Sum-of-boxes CDR	4.41 ± 1.62 (range [1, 9])	1.59 ± 0.86 (range [0.5, 5])	0.03 ± 0.11 (range [0, 0.5])
Corrected P value	**0.01**	**0.004**	**0.6**

	AD	MCI	NORMAL
Changes of sum-of-boxes CDR	1.63 ± 2.23 (range [–1, 11])	0.79 ± 1.40 (range [–2.5, 8])	0.09 ± 0.38 (range [–0.5, 2])
Corrected P value	**0.01**	**0.02**	**0.01**

Figure 46.7 Temporal lobe atrophy correlates with sum-of-boxes clinical dementia rating and future clinical decline. Top row negative correlations are detected between temporal lobe atrophy and higher CDR scores at the time of the initial scan (i.e. a higher CDR score correlates with a faster rate of atrophy). The corrected P values in the table (inset) provide an overall estimate of significance, corrected for multiple comparisons. Bottom row atrophy of the temporal lobe also predicts future cognitive decline, as reflected by an increase in CDR scores, which indicates deteriorating cognitive function over the following year. trR denotes partial correlation coefficient. This figure is adapted from the results in[35]. *A full colour version of this figure appears in the colour plate section*

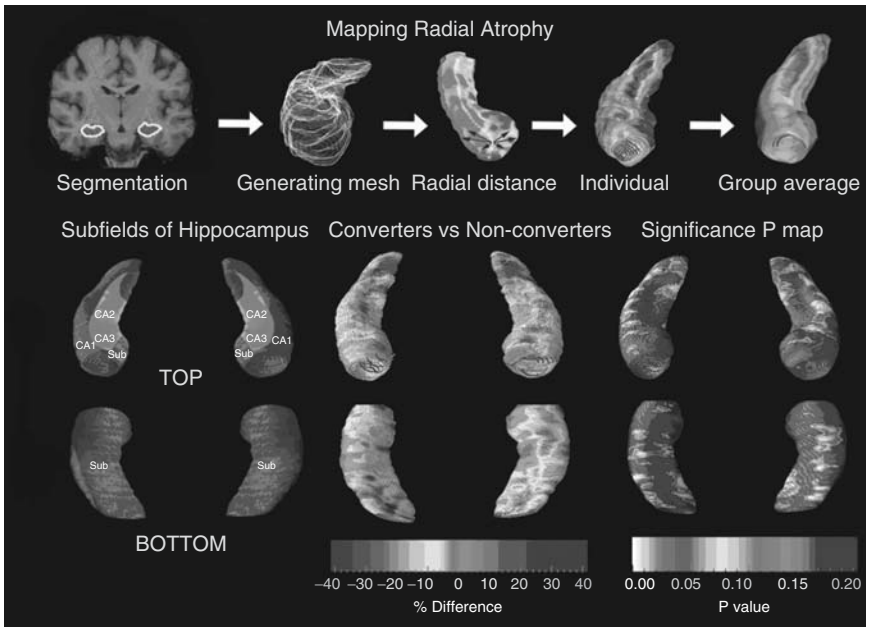

Figure 46.8 Mapping hippocampal atrophy. The radial atrophy mapping method (*top row*) relies on manually or automatically segmenting the hippocampus, computing a 3D parametric mesh model of the structure, estimating the distance between the central core of the structure to each surface point (i.e. the radial distance), and recording radial distance estimates at each surface point to create individual and group average colour-coded maps of the radial distance. These are then statistically compared between groups or conditions. One longitudinal 3D MRI study[50] compared baseline hippocampal atrophy in MCI subjects who converted to AD versus MCI subjects who remained stable or improved cognitively during three years of clinical follow-up. Greater atrophy at baseline was seen in the CA1 and subicular areas in subjects who subsequently convert to clinically probable AD (*bottom right panels*). The bottom panels show a schematic representation of the hippocampal subfields (*left*), the proportional difference in atrophy levels between converters and non-converters (in percentage points; *middle panels*), and the significance of these differences taking into account normal structural variation (*bottom right panel*). *A full colour version of this figure appears in the colour plate section*

and 40 AD subjects enrolled in ADNI, and reported widespread medial temporal and limbic atrophy in AD, with a lesser, more restricted distribution in MCI. Moreover, correlation studies showed that atrophy and CSF space expansion both correlated strongly with MMSE scores and CDR.

Hua *et al*.[35] increased the sample size and mapped the structural differences between groups using 676 subjects from ADNI (165 AD, 330 MCI and 181 controls). Figure 46.6 visualizes these group differences, revealing highly significant atrophy in AD but a more anatomically restricted atrophic pattern in MCI. These maps can also be correlated with neuropsychological test results or biomarkers. In Figure 46.7, these correlations (between atrophy rates and sum-of-box CDR scores) are plotted on the surface of the temporal lobes. Using this 676-subject sample, baseline temporal lobe atrophy is shown to be correlated with current cognitive performance, future cognitive decline and conversion from MCI to AD over the following year; it predicted future decline even in healthy subjects. In this particular sample, over half of the AD and MCI subjects carried the *APOE4* gene, which increases risk for AD; they showed greater hippocampal and temporal lobe deficits than non-carriers. *APOE2* gene carriers – 1/6 of the normal group – showed reduced ventricular expansion, suggesting a protective effect.

Compared to manual tracing employed in cortical pattern matching, TBM is attractive for clinical trials, as large samples can be studied with no manual interaction. Power is also slightly increased if all brains are aligned to a common brain template that is representative of the mean anatomy of all subjects in the population.

Hippocampal Radial Mapping

Even though TBM can map patterns of atrophic changes throughout the brain, the fact remains that the medial temporal lobe is the site of earliest structural change in AD. The hippocampus, in particular, is one of the most researched brain regions in dementia and aging. In general, studies have shown that AD pathology is associated with hippocampal shrinkage[36], and is linked to memory decline. In normal aging, hippocampal volume loss is on average 1.6–1.7% per year[37,38] while that of the entorhinal cortex is ~1.4% per year[39]. Much higher hippocampal rates are observed in MCI and AD, with faster atrophy rates in MCI subjects who progress to AD relative to those who remain stable (annual hippocampal atrophy rate for MCI patients who remain stable = 2.8%, for MCI converters = 3.7% and for AD = 3.5–4%[36]).

In addition to manual tracing on high resolution MRI, several techniques have been proposed for segmenting the hippocampus. A deformable template approach has been proposed that utilizes a predefined hippocampal template[40–43]. Fully automatic methods do not require any user input, and are usually based on extracting and combining some set of image features. For example, Powell *et al*.[44] used artificial neural networks and Golland *et al*.[45] proposed to use a large feature pool, and principal component analysis (PCA) to reduce the size of the feature pool. Another fully automated approach for subcortical segmentation is FreeSurfer by Fischl *et al*.[46,47]. FreeSurfer uses a Markov random field to approximate the posterior distribution

for anatomical labellings. Morra *et al*. recently developed a new and powerful hippocampal segmentation approach based on adaptive boosting or AdaBoost. AdaBoost is highly underutilized in medical imaging, although it has generated great interest in pattern recognition and other related fields[48].

Once the hippocampus is segmented, it can serve as a basis for other advanced surface- or volume-based computational anatomy techniques. In an effort to localize these changes to specific hippocampal sectors, Thompson *et al*.[49] proposed a radial atrophy mapping (RAM) approach, which creates surface models to represent the hippocampus, imposes a regular grid structure on anatomical models from different individuals, and uses this structure to compute average shape models for different groups. As a local index of atrophy, the distance of each surface point to a centreline threading down the centre of the structure is plotted on the surface (Figure 46.8). Surface-based statistics on this measure can then be used to identify regions where atrophy is associated with diagnosis, cognition, genotype or medication.

CONCLUSION

Here we surveyed a range of computational anatomy methods to monitor dementia progression, each focusing on specific features of the degenerative process. Cortical thickness maps, for example, localize changes relative to gyral and sulcal landmarks, and can be used to create time-lapse movies, but require some time investment in extracting cortical surface models. If data collection is time-consuming and power requirements are high, this approach is still useful even in a clinical trial, as it may detect disease-related changes over short time intervals. Higher-throughput methods, such as TBM and automated hippocampal mapping, are well suited to very large-scale studies. These may be the first mapping methods to routinely analyse databases of images from thousands of subjects. As such, they are natural approaches to use in epidemiological studies of potential risk factors or protective factors that may influence disease onset, conversion or the normal aging process.

INTRODUCTION

Dementia is a significant cause of disability and mortality among the elderly[1], accounting for nearly 30% of the population-attributable risk of death after age 85[2]. With the continued growth of the world's oldest population segments, the numbers affected by dementia are expected to rise exponentially, reaching 81.1 million by the year 2040[3]. The most common form of late-life dementia, Alzheimer's disease (AD) accounts for about 50% of dementia among people in their 60s, but may represent as much as 80% in those over age 80[4,5]. The annual cost of caring for one person with AD is estimated to range from $9000 early in the disease course to nearly $20 000 in mid-course[6]. Given the rapid growth in the proportion of those who survive into the latest stages of AD, in the United States alone, the total annual economic burden of the disorder is estimated at $100 billion[7], making it the country's third most costly health condition after cancer and heart disease[8].

With the exception of familial, early-onset forms of AD, there is no single identified cause of the disorder. Current treatments are largely symptomatic, providing only temporary improvement in cognition and neuropsychiatric symptoms. The past several decades have witnessed an explosion of research into risk and protective factors for AD, which someday may yield effective strategies for prevention. This chapter will review the current evidence for risk and protective factors associated with AD and end with a discussion of preventive strategies.

IMMUTABLE RISK FACTORS

Age and Sex

In discussion of prevention, it is useful to dichotomize those risk or protective factors for AD that are potentially subject to intervention versus others. The latter, immutable risk factors are age, female sex and family history. Family history and genetic risk are reviewed by Tsuang (Chapter 43) and are not addressed here. Age is the single strongest risk factor for AD. After age 65, the prevalence and incidence of the condition appear to double with every five years of additional age until 90[9], when the rates either plateau or decline. In the Cache County, Utah, population, for example, prevalence estimates ranged between 0.61% at ages 65–69 to nearly 19% at ages 85–89[10]. Incidence rates exhibited a similar trend[11]. Although data are scarce for persons older than age 90, some studies have suggested a plateau or even a decline in incidence rates in extreme old age.

Second only to age in importance is genotype at the polymorphic locus *APOE* that encodes the cholesterol transport protein apoE. The onset of AD is strongly accelerated among individuals homozygous for allele $\varepsilon 4$ (about 2% of most populations), but also tends to be earlier in people with a single $\varepsilon 4$ allele (typically 25–30%). These allele-specific modifications in onset result in increased AD incidence at younger ages, which appear as an overall increase in risk estimates that are typically adjusted for age[12].

Sex differences in the prevalence and incidence for AD have also been reported, with higher percentages observed in females in some (e.g. see[10,11,13,14]) but not all populations (e.g. see[15,16]). Whether this trend is found in any one study may depend on its relative proportions of very old subjects, among whom rates in women may be disproportionately elevated[11,14].

The mechanisms underlying the sex-specific difference in AD risk are of interest, but are presently unknown. Some authors have attributed the difference in risk to the greater longevity of women or the higher prevalence of vascular dementia in men (possibly deterring a diagnosis of AD even in the presence of its characteristic pathology), possible hormonal effects, or even the notion that current cohorts of elderly women have less neural or cognitive reserve than men, owing to fewer years of formal education[17]. The last explanation seems to us not only contentious but unlikely.

The increasing risk of AD with age (and in women) may instead reflect a host of background physiological changes that accompany ageing including programmed 'intrinsic' factors such as apoptosis, dysfunction of repair processes by progenitor cells in the dentate gyrus of the hippocampus or vascular endothelium, chromosome telomere shortening which signals apoptosis and damage to mitochondrial DNA (reviewed by Drachman[18]). 'Extrinsic' factors that occur as the result of normal wear and tear or exposures that accumulate over the lifetime may also contribute. These processes include oxidative stress and the glycation of proteins which interact with reactive oxygen species to form advanced glycation endproducts (AGE). AGE may trigger inflammatory cytokines that damage the

vascular endothelium. Chaperone proteins that normally repair or eliminate misfolded proteins may fail[18], leading to myelin breakdown. Cortico-cortical association fibres are especially vulnerable, and correspond to brain regions most affected in AD (reviewed by Bartzokis[19]). The degree to which individuals experience these age-related changes likely varies according to their genes, environmental exposures and lifestyle factors, at least some of which may be related to biological sex or gender roles.

MODIFIABLE RISK FACTORS

Neural and Cognitive Reserve

The notion of neural and cognitive reserve reflects an underlying idea that the brain can withstand some degree of compromise while still maintaining normal cognitive and behavioural functions through the recruitment of alternative neural networks[20,21]. Cognitive reserve (first proposed by Robert Katzman) is a concept whereby various cognitive strategies may be used to compensate for deficits. Both forms of reserve are malleable and may be built up through the accumulation of life experiences. Years of occupational and educational attainment are thus seen as predictors of reserve. Theoretically, higher levels of reserve could provide some degree of protection against the expression of clinical AD symptoms in the face of a specified burden of pathological change. Indeed, many epidemiological studies have reported an inverse relation between educational or occupational attainment and risk of AD, but studies have also failed to find this association (reviewed by Stern)[21]. The discrepant results may reflect inadequate assessment, particularly of activities in late life that continue to build neural and cognitive reserve. There is some evidence that stimulating activities in late life may reduce the risk of AD or dementia (see lifestyle factors under preventive strategies). Other explanations are possible, however, particularly when the studies employ two-stage screening and examination for dementia[22].

Traumatic Brain Injury (TBI)

Several epidemiological studies have reported an increased risk of AD among persons with a history of head trauma. A meta-analysis of case-control studies reports a 1.8-fold increase in risk among those with TBI with loss of consciousness. Adjusting for other factors, the higher AD risk was found only among men (relative risk of 2.7[23]), a result confirmed by a subsequent meta-analysis[24]. Interactions of TBI with *APOE* genotype have been reported by some[25] but not others[26]. The mechanism underlying the association between TBI and AD is unclear. Studies have reported an increase in beta-amyloid deposition and AD pathology following TBI[27], and higher frequency of *APOE ε4* carriers among those with cortical plaques[28]. In animal studies, results have varied according to species and genetic variation. Increased beta-amyloid deposition was found later in the course of recovery in rodents, but earlier in pigs. In Alzheimer's PDAPP transgenic mice, beta-amyloid levels increased acutely, but without an increase in deposition, whereas in Tg2576 APP transgenic mice, repeated trauma resulted in greater beta-amyloid deposition[29]. Compounds that reduce beta-amyloid deposition after brain trauma are under active investigation to reduce the neurocognitive sequelae post injury and the risk of AD (e.g. see[30,31]).

VASCULAR RISK FACTORS

A number of risk factors for cardiovascular disease have been associated with AD. Hypertension, high cholesterol, diabetes, smoking and atherosclerosis have all been associated with increased risk. For hypertension, studies report a 1.2- to 4.5-fold increase in risk for AD, depending upon the age at measurement and whether systolic or diastolic measures are taken[32–35]. The relation between blood pressure and AD may be non-linear, as *low* diastolic blood pressure in mid-life has also been associated with an elevated risk[33]. Elevated cholesterol is associated with a 1.4- to 2-fold increase in AD risk[32], diabetes, nearly a 2- to 3.4-fold increase[34,36,37], smoking, a 1.6- to 2-fold increase[34,38] and severe atherosclerosis, a 3-fold increase in risk[39]. With each additional vascular risk factor, there is a corresponding increase in risk[34,35].

Interestingly, some studies report that the relation between cardiovascular risk factors and later dementia risk varies according to the timing of measurement relative to the onset of dementia as well as genotype at *APOE*. Although elevated blood pressure or cholesterol levels predict later AD onset, measurements of each decline prior to the onset of dementia[37,40]. This phenomenon may explain the negative findings reported by some studies (reviewed by Launer[41]). *APOE* genotype may also modify the association between vascular factors and AD. In a large Dutch population study of dementia and cognitive decline, the risk of AD with significant atherosclerosis (two or more indicators of plaques in the carotid artery, thickening of the intima media wall of the carotid artery, or evidence of peripheral artery disease) varied according to *APOE* genotype: among those with at least one *APOE ε4* allele, the risk of AD was 3.9, and for others, 1.4[39]. For smoking, increased risk of AD was found only among those without $\varepsilon 4$[38]. Further study of the interaction between vascular risk factors and *APOE* genotype is needed.

The mechanism underlying the relation between vascular risk factors and AD risk is unclear. Cerebrovascular pathology is common in AD brains, and includes such changes as amyloid angiopathy, cerebrovascular atherosclerosis, endothelial damage and periventricular white matter lesions[42]. Co-existing vascular lesions occur in approximately 24–28% of individuals with AD[43,44] and also contribute to the dementia syndrome[45]. However, vascular risk factors may also promote the formation of AD lesions or otherwise contribute to toxic physiological processes. In autopsies of participants of the Honolulu Asia Aging Study, mid-life elevations in systolic and diastolic blood pressure were associated with number of senile plaques and neurofibrillary tangles, respectively[46,47]. In the absence of dementia, increased plaques and tangles have also been reported in middle-aged hypertensive individuals[48]. Cholesterol has also been found to promote the accumulation of beta-amyloid[49,50].

Hypertension damages blood vessel walls and contributes to atherosclerosis[47]. When combined with the diminished elasticity of arterial walls, atherosclerosis reduces the brain's capacity to eliminate beta-amyloid. Normally, beta-amyloid is cleared from brain parenchyma by drainage through the cerebral arteries. A reduction in the elasticity of the arterial walls diminishes the force needed to drain the substance[51]. Furthermore, damage to arterial walls may also result in a variety of negative consequences including accumulation of amyloid precursor protein (APP), oxidative stress and dysfunction of the blood–brain barrier[47].

In addition to increasing the risk for adverse vascular outcomes, diabetes may affect AD risk through other mechanisms. The location of insulin receptors in the hippocampus and temporal cortex implicates insulin's involvement in long-term potentiation and other memory-related functions[52]. Normally, insulin crosses the blood–brain barrier and is thought to promote beta-amyloid clearance. In diabetics, however, insulin resistance and hyperinsulinemia in the periphery can result in reduced brain insulin levels,

therefore affecting the rate of beta-amyloid clearance[53]. However, at autopsy, several studies report no association between diabetes and AD neuropathological markers[54,55], but an association with microvascular infarcts instead[55]. Furthermore, diabetes is associated with the production of advanced glycation endproducts, oxidative stress and inflammation[52].

Obesity

Obesity is typically measured by body mass index (BMI), which is a ratio of weight to height or kg to metres squared, waist circumference (a measure of central obesity), or a hip-to-waist ratio[53]. A number of studies have examined the relation between BMI and risk for dementia (reviewed by Gufstafson[56]). A majority of the studies indicates an elevated risk for dementia, and specifically for AD, in those with high BMI. Similar to the effects of blood pressure, the relation between BMI and AD appears to vary according to the timing of measurement in relation to dementia onset. The majority of studies examining BMI 10 or more years prior to dementia diagnosis report an increase in risk. For individuals meeting a definition of obese (BMI $\geq$ 30) the risk of dementia is approximately two-to-five times that of normal weight individuals. A few studies have reported no association or an increase in AD risk with *lower* BMI. However, most of those studies have used a relatively short follow-up period (e.g. within five years of dementia onset), and this raises the possibility that weight loss in this context is an indicator of incipient dementia rather than a risk factor[56].

The relationship between obesity and AD risk may operate through several pathways. First, obesity is a risk factor for a number of other adverse health outcomes including insulin resistance, diabetes and cardiovascular risk factors and conditions, and these in turn are risk factors for AD and vascular dementia[53]. Second, in the USA, obesity is associated with demographic characteristics that are also associated with AD. These include lower education and socioeconomic status and Hispanic or black race. Third, obesity is associated with higher consumption of dietary fat and calories and lower physical activity levels, which also have been associated with AD[53].

Psychosocial Stress

Several studies have reported an association between psychosocial stress and dementia. A prospective, Swedish population-based cohort study of 70 year olds examined the effects of 18 stressful life events experienced in childhood, early adulthood and late adulthood in predicting incident dementia. Death of a parent in childhood and physical illness in a spouse or serious illness in a child in late life were each associated with a 6- to 7-fold increase in dementia risk. Experience of manual labour was associated with a 26-fold increase. The number of risk factors experienced was associated with increasing risk[57]. Similarly, the Cache County (UT) population study reported a 3-fold increase in dementia risk with early-life death of a father[58]. This effect was not observed with mother's death, and it was hypothesized that the association reflected the effects of socioeconomic adversity, limited access to health care and other lost opportunities. Although the outcome examined was all-cause dementia, the predominant form of dementia in this population is AD[10,11].

In a case-control study from a large health maintenance organization (HMO) in Washington state, number of siblings was associated with increased risk of AD. The risk increased with each additional child so that having five or more siblings was associated with a 39% increase in risk, seven to nine siblings with a 72% increase, and 10 or more siblings with more than a 2-fold increase in risk[59]. Residence in the suburbs was associated with a reduction in risk. Drawing from the same HMO database and linking to US Census records and birth certificates, Moceri and colleagues examined the subsequent risk of AD associated with a number of psychosocial factors. Father's work in unskilled manual labour and number of persons in household were each associated with greater risk. Furthermore, these early life experiences interacted with *APOE* genotype. Among those with one or more $\varepsilon 4$ alleles, those whose fathers worked in manual labour had an odds ratio for AD of 2.35 (95% CI = 1.07–5.16), but those without $\varepsilon 4$ had an odds ratio of 1.40 (95% CI = 0.78–2.52). Compared to individuals with neither the early-life risk factors nor the $\varepsilon 4$ allele, having father's work in manual labour, a household size exceeding six members and having an $\varepsilon 4$ allele was associated with an odds ratio of 14.80 (95% CI = 4.90–46) for AD[60]. A similar interaction between *APOE* genotype and early-life risk factors was reported in a large sample of Japanese Americans living in King County, Washington. Here, more than four children in household and smaller head circumference were associated with increased risk of AD among bearers of an *APOE ε4* allele[61].

Other studies have examined the influence of experiences later in life such as loneliness or lack of social support, the latter of which can potentially mitigate the effects of stressful events. Individuals scoring at the 90th percentile of a loneliness questionnaire exhibited a 2-fold increase in risk for AD as compared to those reporting few feelings of loneliness. The elevated risk for loneliness was also associated with more rapid cognitive decline and persisted when controlling for the effects of social network and activity. Interestingly, these effects were independent of the degree of AD neuropathology[62].

Additional work has examined personality traits, particularly distress proneness or neuroticism. In a sample of elderly Catholic clergy, distress proneness was associated with increased risk for AD. Because personality traits are considered to be relatively stable, the measure of distress proneness was thought to reflect cumulative, psychological distress experienced over the life span. Relative to those with a low level on this trait, individuals at the 90th percentile exhibited a 2-fold increase in AD risk. The effects remained after statistical control for depressive symptoms and engagement in cognitive activities. Distress proneness was also associated with more rapid cognitive decline, particularly in episodic memory. Again, baseline scores on distress proneness were not associated with degree of AD neuropathology at death[63], suggesting that the relationship with dementia works through other mechanisms[64].

Activation of the hypothalamic-pituitary-adrenal (HPA) axis has been suggested to underlie the association between psychosocial stress and AD. Broadly speaking, this process mobilizes resources in response to a 'stressor' by releasing glucocorticoids that promote energy metabolism and modulate immune functions[65]. However, with chronic and excessive activation of the HPA axis, high levels of glucocorticoids may lead to cell death in regions of the hippocampus, and this phenomenon in turn can diminish the normal inhibitory feedback loop, leading to further activation and release of glucocorticoids. This 'glucocorticoid cascade' (see Sapolsky[66]) has been invoked to underlie the hippocampal damage and corresponding cognitive impairment observed with chronic stress in aged organisms[66]. In relation to AD risk, hippocampal damage from chronic glucocorticoid release may functionally reduce the brain's capacity (reserve) to compensate for the neuronal degeneration that accompanies AD. Alternatively, animal studies suggest that glucocorticoids can directly promote the development of AD-type pathology. In transgenic mouse

models of AD, the administration of an experiental stressor or direct glucocorticoid challenge increased beta-amyloid deposition[67,68] and tau pathology. Clearly, more research examining the role of stress and physiological changes in the brain is warranted.

Early-life stressors may also have their effects through the limitation of financial resources. Early parental death, lower parental socioeconomic occupations and higher sibling density may limit the financial resources available during critical periods of brain development. Nutritional or environmental deprivation associated with low socioeconomic resources may limit brain growth and maturation, and therefore, neural reserve. Access to health care and educational and vocational opportunities may also be curtailed. In addition, the accessibility of emotional resources may be limited, particularly in the case of early parental death. Such non-normative loss may plausibly result in psychological growth and maturation under less than ideal circumstances, potentially leading to maladaptive coping strategies and stress reactivity, that affect brain development[69]. Later, in the face of AD pathology, less neural reserve and poor coping strategies may result in a lower threshold for the clinical expression of dementia.

STRATEGIES FOR THE PREVENTION OF AD

Any of the modifiable risk factors discussed above may present a potential target for intervention. The following sections will briefly summarize the literature regarding potential strategies to reduce the risk of AD. Some of these strategies involve pharmacological compounds that theoretically reduce AD-related neuropathology, whereas others are intended to build neural reserve or promote cardiovascular health. None of these potential prevention strategies has been proven efficacious, but a number are of sufficient promise to warrant discussion here. These include anti-inflammatory drugs, lipid-lowering agents, hormone replacement therapy, antioxidants and lifestyle factors including diet, social support and engagement in physical, cognitive and social activities.

Pharmacological Interventions

Non-steroidal anti-inflammatory drugs

Interest in the use of anti-inflammatory agents in the prevention of AD began with the observation of a lower-than-expected frequency of AD in patients with rheumatoid arthritis[70]. It was speculated that this association reflected the widespread use of non-steroidal anti-inflammatory drugs (NSAIDs) by patients with this condition. The inverse association of AD and NSAID use has subsequently been examined in numerous observational studies, many of which report a reduction in AD risk among NSAID users. Animal studies provide further support for the possibility that NSAIDs may protect against AD pathogenesis (reviewed by Cole *et al.*[71]). Despite early signs of promise, the results of randomized controlled treatment trials have been disappointing. Except for encouraging results of a pilot AD treatment trial[72], trials with NSAIDS[73–77], low dose corticosteroids[78] and hydroxychloroquine[79] have shown no benefit. A secondary prevention trial to prevent progression from mild cognitive impairment to AD was not beneficial, and suggested harm in the treatment group[80]. Notably, however, all of these trials tested the effect of the drugs on individuals who already exhibited symptoms of dementia or cognitive deterioration – a topic not addressed by the observational literature on NSAIDs and AD *incidence*. In fact, recent studies had suggested that any protection was limited to NSAID use initiated more than two years before AD onset[81–83]. To date, the only large-scale NSAID primary prevention trial is the Alzheimer's Disease Anti-inflammatory Prevention Trial (ADAPT) in which celecoxib or naproxen was tested against placebo in subjects with a family history of AD. Owing to unexpected cardiovascular safety concerns, the treatments were stopped after an average of two years of treatment. Analyses at that time showed no reduction in incidence of AD in participants assigned to either celecoxib or naproxen, but instead a suggestion of increased risk[84–86]. Compounding the disappointment from these results, a recent community-based study that utilized pharmacy records to assess NSAID exposure showed an *increase* in AD incidence with NSAID use, regardless of the recency of such use. The authors of this study speculated that, because the participants in this study were considerably older than those examined previously, the beneficial effects of NSAIDs might be limited to younger individuals, before the onset of AD neuropathology. Alternatively, they conjectured that NSAID use effected a *delay in the onset* of dementia, thereby increasing the numbers of AD cases in older age groups[87].

Lipid-lowering agents

Based on observations suggesting an increased risk of AD among those with high cholesterol, the use of lipid-lowering agents such as 3-hydroxy-methyl-glutaryl-CoA reductase inhibitors (statins) have been studied as potential protective agents. As previously mentioned, cholesterol promotes beta-amyloid production[49,50] and reduction in cholesterol levels might inhibit it[88]. Statins have other effects as well, such as prevention of atherothrombosis or reduction of inflammation.

Several case-control studies have reported a reduction in AD risk among users of lipid-lowering agents, typically with statins[89–93]. However, most of these studies have been cross-sectional in nature. Prospective studies examining statin use and subsequent dementia onset have been disappointing, with negative findings reported from the Cardiovascular Health Study Cognition Study, the Cache County Study and the Adult Changes in Thought Study[94–96]. Three published randomized controlled trials have found no evidence of a protective effect against cognitive decline as an outcome[97–99]. Further research is needed to determine whether the effectiveness of statins may differ by *APOE* genotype[94].

Hormone replacement therapies

Several observational studies have reported a reduction of AD incidence among women treated with postmenopausal oestrogen replacement therapy (e.g. see[100–103]), but negative findings have been reported as well (e.g. see[104,105]). Oestrogen has noted beneficial neurotrophic and neuroprotective effects (see review by Morrison *et al.*[106]). Thus a strong rationale exists for potential protection against AD. However, the results of randomized controlled trials have been disappointing. No benefit was reported in treatment trials with women with AD[107–109], with the exception of one study using 17-beta estradiol administered by a transdermal patch[110]. The well-known Women's Health Initiative randomized controlled trials examined hormone users for the prevention of AD, finding no benefit and a suggestion of harm in both treatment groups[111–113]. Although these results are disappointing, there is limited evidence to suggest that oestrogen may yield positive effects, but only if administered well *prior to* the onset of AD symptoms, and perhaps when there is little or no accumulated AD neuropathology. Thus, observational

studies in which exposure and case detection were constrained to a 10-year window report no effect for oestrogen replacement therapy[104,105], but protective effects have been reported for use exceeding 10 years[103,114]. Consistent with this notion are studies of cell cultures in which oestrogen protects against apoptotic cell death, but promotes cell death in the presence of beta-amyloid$_{42}$[115,116].

Lifestyle Factors

Diet and nutritional supplements

A number of observational studies have reported certain beneficial effects of nutrients from food sources or dietary supplements. Consumption of fish[117,118], intake of omega 3 fatty acids[117], a Mediterranean style diet[119], light-to-moderate alcohol consumption[120,121] and the antioxidant vitamins, E and C (e.g. see[122,123]) have been associated with a reduction in AD risk in observational studies. Inconsistent findings have also been reported, for example, with antioxidant vitamins (e.g. see[124]). The underlying mechanisms are unclear but may involve improvements in cardiovascular health, reduced insulin insensitivity, antioxidant and anti-inflammatory effects, and improvement in neuronal lipid membrane function (e.g. see[120,125–127]). Furthermore, the associations between nutrients and risk of AD may vary by *APOE* genotype. For example, in some studies, higher total calorie and fat intake was associated with increased risk of AD, but only among those with an *APOE ε4* allele[125,128]. This finding is consistent with the observation that moderate intake of saturated fat in mid-life increased the risk of AD among *APOE ε4* carriers[129].

Few randomized controlled prevention trials have been conducted with dietary supplements, but two have examined n-3 polyunsaturated fatty acids, docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). As reviewed in Cunnane *et al.*[127], a four-month trial was conducted with DHA with and without lutein (an antioxidant) vs. placebo. Verbal fluency scores improved in both treatment arms, whereas memory functions improved only in the DHA + lutein arm. A 26-week trial of combined EPA and DHA supplements (1800 mg/day or 400 mg/day) provided no benefit on cognitive outcomes, except that among *APOE ε4*-positive individuals there was suggestion of improved attention[130].

A few treatment trials have also been conducted with antioxidant supplements. In a large intervention trial of antioxidants and heart disease, the vitamin E arm of the United Kingdom Heart Protection Study showed no differences after five years, in percent of individuals who developed dementia or who were classified as cognitively impaired on a telephone cognitive screening test[131]. Additionally, high dose treatment with vitamin E had no benefit in delaying the onset of AD among those with mild cognitive impairment[132]. These findings appear to contradict those of observational studies. It is commonly conjectured that the latter have been vulnerable to error from a variety of confounding factors, but another possible explanation is that neuroprotective effects are observed only with a combination of lipid-soluble and water-soluble agents such as vitamins E and C in combination[123]. Additional intervention trials are needed to examine the effectiveness of dietary and supplement interventions for the primary prevention of AD.

Physical activity

Many studies report significant benefits of physical activity with respect to maintenance of cognitive ability (e.g. see[133,134]) and a reduction in risk of AD and other dementias (e.g. see[135–137]). The reduction in risk varies by degree of activity. For example a 50% reduction in cognitive decline was seen in those with high levels of exercise (more than three times per week of moderate to high intensity activity[135], or more than four activities per week[136]). Interactions between activity and *APOE* status are inconsistent: one study reports reduction in risk among non-carriers of the *APOE ε4* allele[136] while another reports greater effects among carriers[137]. Mechanisms purported to underlie the beneficial effects of physical activity on cognitive outcomes include improved cardiovascular health, increased cerebral blood flow and increased attention[138,139]. A recent randomized controlled trial of individuals aged 50 or older reported significant differences between an exercise intervention as compared with education controls on a global measure of cognitive ability (Alzheimer's Disease Assessment Scale-Cognitive (ADAS-Cog) subscale) and a measure of delayed recall[140]. The intervention was conducted over a 24-week period among individuals with subjective memory complaint, and follow-ups were obtained at 6, 12 and 18 months. Improved performance was also observed on a measure of delayed recall and functional ability. Post-hoc comparisons indicated greater effects among those without an *APOE ε4* allele[140].

Leisure activity

Active engagement in leisure activities in late life may continue to build neurocognitive reserve and thereby reduce the risk of dementia. Several observational studies report beneficial effects of high engagement in leisure-time activities such as social interaction, physical conditioning, volunteer work and cognitive activities such as reading or playing games. In a large community-based study with up to seven years follow-up, greater engagement in total activities was associated with reduced dementia risk (RR = 0.88, 95% CI = 0.83–0.93)[141]. When activities were combined with accrued reserve (as reflected in educational or occupational attainment), the risk of dementia among those with low accrued reserve and low engagement in late-life activities was approximately 1.9–2.3 times that of high reserve and high engagement in late-life activities[141]. Similar effects have been reported for those with limited social networks[142,143].

The mechanisms underlying such positive effects of leisure-time activities include building of neurocognitive reserve, increased synaptogenesis promoted by stimulating activities and stress reduction associated with greater activity and social support (see review by Fratiglioni *et al.*[144]). Although there are no randomized controlled trials of leisure interventions, one large trial examined the effects of a cognitive intervention on cognitive and functional outcomes in elderly individuals. Over 2000 individuals between the ages of 65–94 were randomly assigned to one of four training groups: memory, reasoning, speed of information processing and a no-contact control. The interventions (and booster session) resulted in significant improvements in each of the targeted cognitive domains immediately after training and after two years follow-up[145]. No effect was observed on the functional outcome measure, although this was thought to reflect limited change in that domain.

CONCLUSION

The scientific literature identifies numerous risk factors that are putatively associated with AD. These processes are not necessarily specific to the disease, but may be changes associated with ageing that

effectively reduce the neurocognitive reserve and resources built over the life span. Other risk factors may affect vascular factors and neuroendocrine response to stress which are purported to promote AD neuropathology or negatively impact vulnerable brain regions important for learning and memory. The large number of risk factors and biological processes that increase the risk of AD suggests the disorder results from multiple causes. As a result, the search for prevention strategies may similarly need to consider multiple factors.

Down Syndrome: Genetic and Clinical Overlap with Dementia

Giles M.Y. Tan and Declan G.M. Murphy

Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry at the Maudsley, King's College London, UK

Down syndrome (DS) or trisomy 21 is the most common chromosomal abnormality associated with learning disability and affects approximately 1 per 650–1 000 live births. People with DS are more likely to develop Alzheimer's disease (AD) when compared to the general population. There is a well-established link between the neuropathology of AD and DS[1,2].

EPIDEMIOLOGY

Age of onset for dementia is typically between 50 and 55 years with a median age of onset of dementia of 55.5 years and an age range of 45 to 74 years[3]. Prevalence rates of clinical AD in DS vary substantially depending on the population studied, which ranges from 4% in a community sample[4] to 88% in an institution-based sample[5]. Many of the studies suffered from small sample sizes especially in the numbers of elderly DS persons included. A population-based study found that prevalence rates of AD increased with age – 8.9% (age 45–49), 17.7% (age 50–54), 32.1% (age 55–59) – up to age 60 years then decreased again – 25.6% (age above 60) – with an overall prevalence of 16.8%. The decrease was possibly accounted for by the increased mortality among the elderly demented DS persons[6].

While congenital malformations and especially congenital heart defects are the commonest cause of mortality in early life, survival rates for people with DS have improved significantly over the years with advances in medical care and more are now living longer and into old age. Life expectancy was 9 years in 1929 and 12 in 1949 but more recent data indicate that the median age at death has increased from 25 years in 1983 to 49 years in 1997, an average increase of 1.7 years per year studied[7]. Survival beyond 60 years of age has also improved, with 44.4% and 13.6% of live born DS individuals now surviving to 60 and 68 years, respectively[8]. Recent evidence suggests that age, presence of dementia and mobility restrictions predict mortality in DS. When compared with the general population, it was found that impaired mobility, severity of learning disability, the presence of epilepsy and visual impairment, but not cardiovascular risk factors or sex, predicted survival[9]. There is mounting evidence that the presence of the APOEε2 allele increases longevity[10] while non-demented DS individuals with at least one APOEε4 allele have increased mortality and up to five times the risks of dying within a 5- to 7-year follow-up period than those without an APOEε4 allele[11].

NEUROPATHOLOGY AND GENETICS

The neuropathological manifestation of AD in DS has been attributed to the triplication and over-expression of the APP gene located on chromosome 21[12]. This neuropathology is invariably found in the brains of individuals with DS over the age of 40 years[13]. The characteristic neuropathological changes in AD include the deposition of beta-amyloid (Aβ) as both extracellular diffuse and neuritic plaques as well as in meningeal and cerebral blood vessels and the intracellular accumulation of neurofibrillary tangles (NFTs) consisting of hyperphosphorylated tau in the form of paired helical filaments[1]. The accumulation of the diffuse plaques, which contain non-fibrillar amyloid, are commonly seen in DS before age 50 years and are not associated with AD whereas the neuritic plaques, which contain fibrillized amyloid and accumulate most commonly after age 50 years in DS, are associated with neuronal degeneration and loss of function[10]. NFTs occur at a later age in DS brains than amyloid plaques[14] and have been associated with dementia status in DS[3].

Aβ, which consists of the two major species Aβ1-40 and Aβ1-42, is produced from β-amyloid precursor protein (APP) by sequential proteolytic cleavage by β- and γ- secretases[15]. Starting from a young age, Aβ1-42 precedes Aβ1-40 in the course of amyloid deposition in the brains of people with DS[16]. Plasma Aβ levels are also elevated in DS persons from childhood[17]. Plasma levels of Aβ1-40 and Aβ1-42 may be correlated with age in older DS adults[18] and plasma Aβ1-42 levels were found to be higher in DS persons with dementia compared to those without in some studies[19] but not others, which found no association between plasma Aβ1-40 and Aβ1-42 levels and the presence of dementia, APOE genotype or duration of dementia[20] or age of onset[21].

Genetic Factors

Studies in the general population with AD have identified mutations in APP, presenilin 1 (PS-1) and presenilin 2 (PS-2) to be associated with early-onset familial forms of AD and the *APOE* gene polymorphisms with the more common late-onset AD. However, in DS persons, PS-1 polymorphisms do not appear to have the same detrimental effects and are not associated with the development of dementia[22].

Apolipoprotein E, which is involved in cholesterol transport and lipid metabolism and occurs in three allelic forms as ε2, ε3 and ε4

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

on chromosome 19, has been shown to modulate the risk of AD in the general population[23] with the APOEε4 allele associated with both late-onset familial and sporadic AD and the APOEε2 allele conferring a protective effect on the risk of developing AD[24]. In persons with DS, the relationship between APOEε4 and risk of AD remains controversial. Some studies have shown APOEε4 allele to be associated with increased risk of AD in persons with DS[25,26] while others have not[27,28]. A recent meta-analysis showed APOEε4 to be significantly associated with the prevalence of AD in DS[29].

The extended tau haplotype occurs in two forms, as H1 and H2, and has been associated with earlier onset of AD in the presence of the APOEε4 allele in the general population. Individuals with DS are at increased risk of developing dementia before age 45 years if they are heterozygous for the extended tau haplotype. Its lack of association with the APOE genotype suggests that it may be an independent risk factor for early onset dementia in DS[30].

The genes for proteins that regulate tau phosphorylation, *DYRK1A* (dual-specificity tyrosine-regulated kinase 1A) and calcipressin, are located on chromosome 21 and their increased expression in DS may promote NFT formation. Furthermore, increased expression of both occur in response to increased Aβ load and helps explain why NFTs occur at a later stage in the dementia process[31].

Tetranucleotide repeat in intron 7 of APP (attt5-8) has been associated with earlier age of onset of dementia by up to 13 years in DS[21].

GENDER AND THE ROLE OF OESTROGENS

Women in the general population are at increased risk of developing AD compared with men and oestrogen deficiency has been implicated in the cascade of pathological processes leading to AD. This has been reviewed recently[32].

The evidence for the effect of gender on risk of AD in DS is contradictory, with some studies finding no differences in age of onset[33], earlier onset[34] or later onset[35]. Postmenopausal DS women with low levels of bioavailable oestradiol have been found to have an increased risk of developing AD[36]. The average age of menopause in DS women was younger than in the general population and the age of onset of AD correlated with the age of menopause, hence it has been suggested that oestrogen deficiency may be a possible independent risk factor for AD in DS[37].

BRAIN METABOLITES: THE POTENTIAL ROLE OF MYO-INOSITOL

The Na^+/*myo*-inositol co-transporter gene (SCL5A3) is located on chromosome 21 and *myo*-inositol significantly affects neuronal development and survival, neuronal osmolarity, membrane metabolism, signal transduction, protein kinase C activation and amyloid deposition[38].

Proton magnetic resonance spectroscopy studies in healthy DS persons have reported significant increases in brain choline and *myo*-inositol, but no differences in brain NAA or creatine, and it has been suggested that the abnormal membrane turnover/degradation and increase in *myo*-inositol reflect a 'predementia' phase in which the neuropathology of AD is accumulating and precedes the loss of neurons[39,40]. The increased brain *myo*-inositol concentrations in healthy DS persons have been shown to be negatively correlated with overall cognitive and memory abilities[41].

In a study comparing brain metabolites in demented, mild cognitively impaired (MCI) and healthy controls in the general population

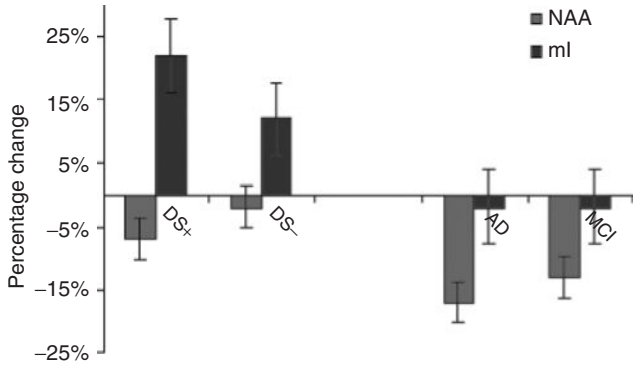

Figure 48.1 The percentage change in unadjusted averages of hippocampal concentrations of NAA and mI by group comparisons (i.e. DS+ to DS−, AD to HC, DS− to HC and MCI to HC)

with demented (DS+) and non-demented (DS−) DS individuals, NAA concentrations were found to be reduced in persons with AD and MCI in the general population but not in either the demented or non-demented DS persons, suggesting that dementia in DS is associated with comparatively small reductions in viable neuronal function (as measured by NAA). In contrast, it was found that brain *myo*-inositol (mI) concentration was only increased in the demented DS group (see Figure 48.1), suggesting that elevated brain *myo*-inositol modifies the risk of dementia in people with DS possibly by interacting synergistically with other risk factors for dementia in this vulnerable population[42]. Research is currently under way to determine if manipulation of brain *myo*-inositol in DS by the use of lithium could offer a novel target for intervention in the dementia process in DS.

OXIDATIVE STRESS

Free radicals produced by metabolic processes are kept in check by antioxidant defences and if this balance is disturbed, results in the highly reactive free radicals reacting with lipids in cell membranes to cause cellular damage, which contributes to neurodegeneration. The genetic locus for Cu,Zn-superoxide dismutase (SOD1), a key enzyme in free radical metabolism, is located on chromosome 21[43] and has been suggested to have particular relevance to neurodegeneration in DS[44].

NEUROINFLAMMATION

There is increasing evidence to suggest that cytokines have an important role to play in the development and/or progression of AD in the general population. The inflammatory component of AD is dominated by the presence of activated microglial cells[45]. Studies have shown some support for the hypothesis that cytokines may act as a risk factor for the development of dementia in DS[46,47]. A small study found positive correlations between serum IL-6 levels with age and severity of AD in people with DS[48], and there is preliminary evidence to indicate that serum TNF-α levels are elevated in DS persons with AD[49], suggesting a disease-stage-dependent general activation of the immune system.

NEUROIMAGING

Using magnetic resonance imaging (MRI) based measurements of grey matter atrophy as a surrogate marker of neuronal density,

various neuroimaging studies have described the macroscopic neuroanatomy of DS. More recent studies using sensitive quantitative measures of region-specific atrophy based on high-resolution MRI have suggested that age-specific atrophy in DS resembles the pattern of brain atrophy in the early stages of AD[50].

In DS persons, overall brain volume including the cerebellum and cerebral grey and white matter, ventral pons, mammillary bodies and hippocampus is reduced whereas the parahippocampal gyrus are enlarged[51]. Reductions in cerebral volume are prominent in the frontal and occipital lobes and there is relative preservation of parietal lobe grey and temporal lobe white matter[52].

As they age, non-demented DS individuals show volumetric reductions in most cortical brain regions[53], hippocampus, parahippocampal gyrus and corpus callosum. Demented DS individuals show volumetric reductions in total brain, total grey matter, frontal, temporal and parietal cortices, hippocampus and parahippocampal gyrus and enlarged ventricles when compared to non-demented DS individuals[50]. A recent study showed volumetric reductions of the hippocampus and caudate bilaterally, right amygdala and putamen in demented DS individuals. Hippocampal and caudate volumes both correctly categorized 92% of DS persons without AD as well as 75% and 80%, respectively, of DS persons with AD, suggesting that they may act as markers of clinical AD[54].

COGNITIVE AND BEHAVIOURAL FEATURES

Pre-Existing Cognitive Ability

Low education and low lifetime occupational attainment have been associated with increased risk of AD in the general population possibly by the lack of cognitive reserve, which hastens the onset of clinical manifestations[55]. In DS persons, higher cognitive functioning has been associated with fewer cases of dementia[56] and the rate of cognitive deterioration increased with age and degree of pre-existing cognitive impairment[57].

Executive Dysfunction

The presentation of the early stages of AD in persons with DS differs from that in the general population and is characterized by prominent personality and behaviour changes associated with executive dysfunction rather than declines in episodic memory, which may suggest impairments in frontal lobe functions[58].

Selective Attention

Progressive impairment in selective attention, as measured by cancellation tasks, has been detected in DS adults in the preclinical stage of AD and the performance in this group could be differentiated from their healthy DS peers who do not go on to develop AD[59].

CO-MORBIDITY

Physical Health

As in the general population, people with DS experience more health problems as they age. With the onset of AD, there is an increase in the frequency and severity of the co-morbidities. Visual and hearing impairments, gastric concerns, depression, epilepsy, lung disease and mobility problems have all been reported to be increased in DS with AD compared to those without AD and additionally have also been reported to be associated with the stage of AD, with the co-morbidities being more severe at the later stages of the dementia process[60]. Some of these co-morbidities are significantly more severe in the DS population with AD than those with AD in the general population who do not have DS, e.g. epilepsy[5].

Maladaptive Behaviours and Mental Ill Health

AD is characterized by progressive decline in cognitive and functional skills and is often accompanied by maladaptive behaviours and psychiatric symptoms. A recent longitudinal cohort study showed point prevalence of mental ill health in non-demented DS adults to be between 10.8% and 23.7% while the 2-year incidence varied from 3.7% to 14.9% depending on the diagnostic criteria used. The highest incidence was for depressive episode and dementia/delirium. Mental ill health was found to be lower in DS when compared with other adults with learning disability[61]. An earlier study found that most depressed DS persons were still symptomatic at one year and those with early onset depression were associated with better treatment outcomes[62].

Non-demented elderly DS persons show less initiative and more apathy compared to individuals with other causes of learning disability, and when compared to younger DS persons, showed more irritation, fear, restlessness at night, sadness, suspiciousness and loss of appetite[63]. In DS persons with AD, there was a higher prevalence of low mood, restlessness/excessive overactivity, disturbed sleep, being excessively uncooperative and auditory hallucinations, but they were less aggressive when compared to demented learning disabled individuals without DS[64]. In a more recent study, differences in maladaptive behaviours at various stages of dementia were found, with the non-demented DS individuals displaying fewer and less severe maladaptive behaviours than individuals in the early and mid-stages of dementia. Furthermore, those non-demented DS individuals who were transitioning into the early stages of dementia displayed increased aggression, fearfulness, sadness, sleep problems, social inadequacy, stealing and general regressive behaviours[65].

In a study on referral characteristics, it was found that DS individuals who were referred for specialist dementia assessment showed more behavioural excess, but not deficits, and lower socialization and coping skills when compared to those who were not referred. Their carers also reported the behaviours as having a greater impact on them than on the individual with DS[66].

DIAGNOSTIC ISSUES

There are significant difficulties associated with diagnosing AD in people with DS. The large intra-individual variability in cognitive functioning, lack of standard diagnostic and methodological procedures and difficulties with obtaining baseline cognitive function with which to assess cognitive and behavioural change in DS persons make early diagnosis of AD especially difficult in this population[67]. Further difficulties arise from the fact that many individuals with DS suffer from underdevelopment of social and cognitive skills and high rates of co-morbidity (e.g. depression and hypothyroidism).

The pre-existing learning disability often results in floor effects on many of the standard assessment tests used, and available screening instruments vary in their reliability[68]. Among the informant-rated instruments, the Dementia Questionnaire for Persons with Mental

Retardation (DMR)[69], later revised as the Dementia Questionnaire for people with Learning Disabilities (DLD), is widely used in people with learning disability but had variable sensitivity in single assessments and poor specificity in people with DS, while the Dementia Scale for Down Syndrome (DSDS) had good specificity but mediocre sensitivity. Of the direct assessment instruments, the Test for Severe Impairment (TSI) and Severe Impairment Battery (SIB) have been used but require further evaluation in people with DS. More recently, the CAMDEX-DS, a modified version of the Cambridge Examination for Mental Disorders of the Elderly (CAMDEX) informant interview, has been developed for assessing people with DS suspected of having dementia[70]. As to the different diagnostic criteria in use, the DSM-IV dementia criteria has been shown to be more inclusive than that of the ICD-10, which excluded DS persons with even moderate dementia[71].

TREATMENT

Established antidementia drug treatments for AD in the general population include the cholinesterase inhibitors donepezil, rivastigmine and galantamine as well as the NMDA antagonist memantine. There is limited evidence available on drug therapies for dementia in DS[72]. Recent Cochrane reviews on the subject found only one randomized controlled trial of suitable quality for donepezil, and none for galantamine, rivastigmine and memantine[73–76]. That study on donepezil suggested some limited benefit of donepezil treatment at 24 weeks[77], and an open label extension of that study showed that those continued on donepezil showed less deterioration at two years, which may suggest benefits of longer-term use[78]. Drug therapy should form part of the broader multidisciplinary management of persons with DS and AD, incorporating carer support, psychological and behavioural therapies and ongoing assessment of and management of physical and mental health.

CONCLUSIONS

There is considerable neuropathological, genetic and clinical overlap between the AD in DS and in the general population but also some subtle differences. The occurrence of dementia in people with DS is expected to rise proportionately with the increase in their life expectancy. This has implications for health and social care provisions both for them and their carers, and further research into better understanding the neurobiology of the disease in DS and potential treatments for them are warranted.

The Molecular Neuropathology of Alzheimer's Disease

Orly Lazarov

Department of Anatomy and Cell Biology, The University of Illinois at Chicago, IL, USA

INTRODUCTION

It is yet to be discovered what induces the high vulnerability exhibited by specific groups of neurons in Alzheimer's disease (AD), leading to their progressive degeneration. Vulnerable neurons are located in brain areas that are functionally linked to various forms and aspects of learning and memory, including the hippocampal formation, olfactory system and neocortex (for review see[1]). The parahippocampal regions are the earliest to be affected (Braak stages I and II). In particular, the entorhino-hippocampal circuit exhibits an early and significant neuropathology. Neuropathology in this region correlates significantly with degree of dementia. The hallmark lesions of the disease, most pronounced in the affected brain areas, are neurofibrillary tangles and amyloid deposits. Neurofibrillary tangles are intracellular aggregates of bundled paired helical filaments. The principal component of neurofibrillary tangles is hyperphosphorylated tau. The microtubule-associated group of tau proteins consists of alternatively spliced cytoplasmic proteins that bear either three or four microtubule-binding domains and co-assemble with tubulin onto microtubules, where they stabilize these organelles. As such, tau is implicated in numerous critical cellular processes, such as cell proliferation, neuronal maturation, process elongation and axonal transport. Thus, preceding neurofibrillary tangle formation, hyperphosphorylation of tau may interfere with crucial cellular and neuronal functions. The mechanism underlying hyperphosphorylation of tau in AD is not fully understood, as discussed below. Amyloid deposits are aggregates of β-amyloid (Aβ) peptides released from a large precursor termed amyloid precursor protein (APP) upon enzymatic cleavage. Upon increase production or fibrillogenic properties, Aβ undergoes conformational changes to form β-sheet structures that tend to form oligomers and subsequently insoluble aggregates. One form of amyloid aggregates is neuritic plaque, an extracellular core of amyloid fibrils surrounded by dystrophic dendrites, degenerating axons and reactive gliosis. Neuritic plaques are abundant in the molecular layer of the dentate gyrus of the hippocampus, the amygdala, the association cortices of the frontal, temporal and parietal lobes, and within certain deep brain nuclei that project to these regions. In addition to neuritic plaques, several other forms of Aβ aggregates exist, including abundant 'diffuse plaques' in the limbic and association cortices and even in non-conventionally affected regions, such as cerebellum. Increased fibrillogenesis and/or levels of Aβ is caused by either mutagenesis or ageing-linked unknown pathogenesis. In rare, familial, early onset form of AD (FAD), increased fibrillogenesis and/or levels of Aβ are caused by mutations in APP, presenilin-1 (PS1) and presenilin-2 (PS2). These mutations cause misprocessing and trafficking of APP by β-secretase or γ-secretase, the aspartyl protease of which PS is the catalytic core, yielding an increased amount and/or ratio of the fibrillogenic forms of Aβ (e.g. Aβ_{42}), that consequently aggregate in the form of amyloid deposits. Both hallmark lesions are the result of misfolding and polymerization of otherwise soluble proteins. The progressive emergence of altered conformations of originally soluble proteins and subsequently insoluble aggregates, intra- and extracellularly, is associated with profound neuronal dysfunction and death.

FAMILIAL ALZHEIMER'S DISEASE-LINKED CENTRAL PLAYERS

Amyloid Precursor Proteins

Amyloid precursor proteins encompass a family of membrane-anchored type I glycoproteins that are ubiquitously expressed and particularly abundant in the brain (for review see[2]). APP full length are 110–130 kDa proteins that are synthesized in the endoplasmic reticulum. *APP* maps to chromosome 21 in humans and is transcribed to three isoforms, APP_{695}, APP_{750} and APP_{771} with the former being predominantly expressed in neurons and the latter two in glia. APP_{770} is encoded by 18 exons, where exon 17 resembles the membrane-spanning domain. APP_{695} is lacking both exon 7 and exon 8, and is the most abundant APP transcript in the brain. APP_{751} (lacking exon 8), APP_{714} (lacking exon 7) and APP_{770} are expressed in the peripheral and central nervous system. Exon 7 encodes an amino acid fragment that exhibits substantial homology to the Kunitz-type serine protease inhibitor (KPI) while exon 8 shares some homology with the MRC OX-2 antigen. Two additional members of the APP family are amyloid precursor-like protein 1 and 2 (APLP1 and APLP2). They are truncated at the carboxyl terminus and lack the Aβ region. The APLPs map to chromosome 19 in humans. The APLP2 but not APLP1 contains a KPI domain. Nevertheless, neither mutations in APLP1 nor in APLP2 are causative of FAD, supporting the notion that Aβ plays a major role in the disease. Indeed, FAD-linked mutations introduce

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

amino acid substitutions within or flanking the Aβ region of APP, around the cleavage sites of α-, β- and γ-secretase. APP undergoes a complex set of tightly linked trafficking and processing. From the endoplasmic reticulum, APP is transported to the plasma membrane through Golgi apparatus. However, only a small fraction of APP molecules reaches the plasma membrane. During this journey APP undergoes multi post-translation modifications of *N*- and *O*-glycosylation, ectodomain and cytoplasmic phosphorylation, and tyrosine sulphation. The presence of the YENPTY internalization motif near the C terminus of APP enables APP endocytosis shortly after it reaches the plasma membrane. Then APP is delivered to endosomes, and a fraction of endocytosed molecules is recycled to the cell surface. Some of internalized APP undergoes lysosomal degradation. During its journey, APP is subject to a complex processing by multiple enzymatic activities (Figure 49.1), most of which are around the 4 kDa region of the Aβ peptide (for review see[1]). In the nonamyloidogenic pathway, APP is cleaved by α-secretase at amino acid 16–17 of the Aβ region, preventing the formation of Aβ. In the amyloidogenic pathway, APP is cleaved by the β-secretase enzymatic activity at the carboxyl terminus of the Aβ region, followed by a cleavage by γ-secretase enzymatic complex at the amino terminus of the Aβ region, leading to the release of Aβ. Following shedding of APP by α- and β-secretase, the soluble product (sAPPα and sAPPβ) is released to the extracellular space, while a membrane-anchored fragment is subject to an intramembranous cleavage by γ-secretase, releasing APP carboxyl terminus fragments (AICD) into the cytoplasm. AICD can form a transcriptionally active complex with Fe65 and Tip60. While the role of AICD in regulation of gene transcription is yet to be confirmed, several genes are thought to be regulated by AICD: *KAI1*, the Aβ-degrading enzyme neprilysin, *LRP1*, and epidermal growth factor (EGF) receptor. Many adaptor proteins with phosphotyrosine-binding domains, including Fe65, Fe65L1, Fe65L2, Mint1 (i.e. X11), Mint2, Mint3, Dab1, and c-Jun N-terminal kinase (JNK)-interacting protein family members bind this motif and the flanking region. Overexpression of these adaptors reduces Aβ production and deposition in the brains of transgenic mice, suggesting that these adaptors play a role in regulation of APP processing (for review see[3]). Interestingly, Fe65 serves as a functional linker between APP and LRP in modulating endocytic APP trafficking and Aβ production. Mutations within the YENPTY endocytosis motif inhibit APP internalization and decrease Aβ production, suggesting that APP is processed to yield Aβ following internalization.

The phenotype of mice with homozygous ablation of APP appeared rather mild compared to presenilin-1 knockout phenotype. Some

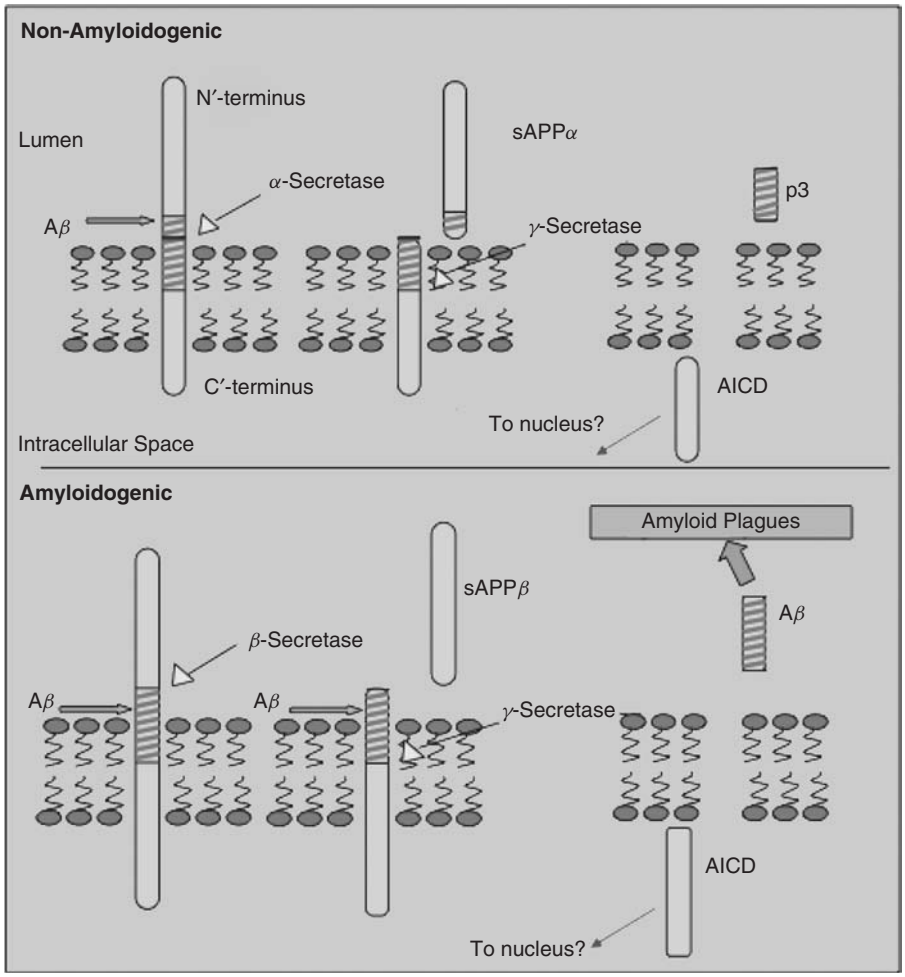

Figure 49.1 Schematic presentation of APP processing in its amyloidogenic and nonamyloidogenic pathways. AICD = APP carboxyl terminus fragments

synaptic markers are thought to be reduced in APP-deficient mice, and this reduction correlates with deficits in learning and memory and in synaptic plasticity. APLP2 knockout mice appear normal, while APLP1 knockout exhibit some growth impairments. This mild phenotype might be due to partial functional redundancy among the family members. In support of this notion, *APLP2/APLP1* and *APP/APLP2* double knockouts die right after birth, suggesting that APLP2 functionally overlaps with APP and APLP1. Examination of the central and peripheral nervous system of the double knockout mice confirmed significant deficits in synapse formation, deformed pre- and post-synaptic element distribution, reduced number of synaptic vesicles and aberrant localization of the choline transporter at neuromuscular junctions. Deficiency of all three *App* genes led to death shortly after birth, exhibiting cortical dysplasia suggestive of migration abnormalities of the neuroblasts and partial loss of cortical Cajal–Retzius cells. Taken together, these findings suggest that the *APP* gene family plays important roles in the development of the nervous system, such as synapse formation and regulation of neural progenitor cells.

Presenilins and γ-Secretase

Presenilins (PS1 and PS2) are multipass membrane proteins that are predominantly localized to the endoplasmic reticulum. PS undergo endoproteolysis by an unknown enzymatic activity termed Presenilase, and the resulting amino-terminal and carboxy-terminal fragments that remain closely associated, are thought to be the active form of the protein. PS are thought to play numerous roles in the cell, but are best known for their central role as the catalytic core of the intramembranous, γ-secretase aspartyl protease that cleaves numerous membrane proteins, including APP. γ-secretase is a unique membrane protease complex. Presenilin 1,2 are thought to be the catalytic subunit of γ-secretase. PS contain two essential aspartate residues in putatively adjacent transmembrane domains (for review see[4]). Substitution of either of the two aspartate residues buried within the sixth and seventh transmembrane domains of PS abolishes γ-secretase activity. The proteolytic cleavage, which takes place in the middle of the transmembrane region of the substrate, occurs after ectodomain shedding of the target protein and is amino acid sequence independent. Experiments using transition state analogue inhibitors suggest that γ-secretase has separate sites for substrate binding and catalysis. Another unusual characteristic of the γ-secretase cleavage is the multiplicity of the cleavage sites: one in the middle of the transmembrane domain that creates the carboxy-terminus of Aβ, and another one that liberates intracellular domain of the substrate into the cytoplasm, for example NICD (notch site-3 cleavage) or APP ICD (AICD ε-cleavage of APP). While the composition of the γ-secretase complex is still under intense investigation, three additional proteins, nicastrin, aph-1 and pen-2, have been identified so far as cofactors in the γ-secretase multicomponent complex[5]. Co-expression of these components with presenilin appears to be critical for γ-secretase activity. The first cofactor of the γ-secretase complex to be identified was nicastrin (NCT), a type I membrane glycoprotein comprising 709 amino acid residues in humans. Ablation of NCT in *Drosophila* resulted in embryonic lethality, and knockdown of NCT homolog aph-2 in *C. elegans* resulted in hypoplasia of the anterior pharynx. A point mutation in aph-1 gene identified in *C. elegans* caused an abnormality in anterior pharynx development, similar to that seen in aph-2 mutants. Disruption of the GXXXG motif within the fourth transmembrane domain of APH-1 caused by the mutation leads to failure in assembly and activation of the γ-secretase complex. Two homologues of aph-1 genes were identified in human aph-1a and aph-1b, both encoding membrane proteins predicted to span the membrane seven times. The identification of presenilin enhancer genes pen-1 and pen-2 revealed that pen-1 is identical to aph-1, while pen-2 encodes a membrane protein that spans the membrane twice. Experiments using RNAi established that suppression of the *Drosophila* homologues of nicastrin, APH-1 or PEN-2 result in the loss of Psn fragments and of γ-secretase activity, as indicated by lack of Aβ production. Based on systematic examination of downregulation of the different components of the γ-secretase using combinations of RNAi, it is thought that APH-1 and NCT team up to stabilize PS holoprotein, while PEN-2 induces PS endoproteolysis, eliciting maturation of the active form of the γ-secretase complex. Reconstitution of γ-secretase activity in yeast by over-coexpression of human PS1, NCT, APH-1a and PEN-2 in yeast, components which otherwise are not endogenously expressed in yeast, strongly suggests that these four cofactors are sufficient to the generation of γ-secretase activity. In contrast to other known proteases, γ-secretase is composed of a high molecular weight multicomponent complex. However, the stoichiometry of the γ-secretase is still under an intensive investigation. It is yet to be determined what other components are associated with the γ-secretase. γ-secretase regulates the second step in a two-step proteolytic cleavage event of membrane proteins known as regulated intramembrane proteolysis (RIP). This process starts with an ectodomain shedding resulting in the proteolytic processing of membrane proteins to their soluble counterparts. Ectodomain shedding is carried out by members of the ADAM family and matrix metalloproteases, and to a lesser extent by BACE1 and BACE2 (see below). Following shedding, the resulting membrane-bound CTF undergoes a second cleavage event within its transmembrane domain, called intramembrane proteolysis that is catalyzed by the γ-secretase complex.

β-Secretase

A decade ago, the enzymatic activity termed β-secretase that cleaves APP at the N′ of the Aβ region was identified as the aspartyl protease β-site APP cleaving enzyme I (BACE1; also known as memapsin and Asp2) (for review see[6]). A 501 amino acid type I membrane protein, BACE1 resides on the cell surface and in intracellular compartments of the secretory pathway, with its active site within the lumen of these compartments. BACE1 is predominantly expressed in neural tissues with the highest activity level exhibited in neurons. Genetic ablation of BACE1 provided an explicit evidence that BACE1 is the principal neuronal protease required for cleavage of APP at the +1 and +11 site of Aβ and the main β-secretase in the brain. BACE1 cleaves APP in its extracellular domain at a site close to the membrane surface, the Asp+1 residue, generating a secreted APP ectodomain, soluble APPβ (sAPPβ), and a membrane-bound APP C-terminal fragment of 99 amino acid residues (C99). This highly sequence-specific cleavage is a prerequisite for Aβ formation and is followed by endoproteolysis within the transmembrane domain of C99 by γ-secretase, yielding Aβ. BACE1 also cleaves the APP homologues, amyloid precursor-like proteins, APLP1 and APLP2. BACE1 exhibits classical characteristics of an aspartyl protease with two active site motifs. Mutating either aspartic acid inactivates the protease. A signal sequence (residues 1–21) and a pro-peptide domain (residues 22–45) are in its N-terminus, and are removed post-translationally. Near its C-terminus (residues 455–480) there is a single transmembrane

domain and a palmitoylated cytoplasmic tail. Possible regulators of BACE1 may include several stress-induced transcription factors that bind to its promoter, such as Sp1, GATA-1, AP1, AP2, CREB, oestrogen and glucocorticoid receptors, NFκB, STAT1, HIF-1 and HSF-1. Other potential regulators are several cytokines, such as IL-1, and Aβ itself (for review see[6]). BACE1 cleavage of APP is the first critical step for Aβ production. Therefore, alterations in BACE1 activity manifests in changes in levels of Aβ production. Indeed, FAD-linked Swedish mutation in APP causes enhanced BACE1 activity, leading to increased Aβ production and amyloid deposition. In that regard, age-dependent increase in BACE1 activity occurs in the brains of mammals, and correlates with levels of Aβ. Likewise, an increase in BACE1 activity is detected in AD and correlates with amyloid deposition and A$\beta_{1\text{-}x}$ and Aβ_{1-42} production. Apparently a mild increase in BACE1 expression results in a significant elevation in Aβ levels until a plateau is reached. In turn, increased levels or ratio of Aβ_{1-42} may trigger an upregulation in BACE1 activity. As BACE1 is primarily enriched in neurons, it is expected that amyloid plaque-induced elevated BACE1 level is manifested primarily in neurons. An additional contribution of increased BACE1 activity is expected from activated glia, especially at the stage of disease in which inflammation in the brain is upregulated. Intriguingly, reduced BACE1 activity ameliorates amyloidosis and memory impairments in FAD mice. Thus, cross-breeding BACE1 KO mice with FAD-linked mice exhibiting high levels of Aβ and amyloid deposition abolished any traces of Aβ formation or aggregation and learning and memory impairments. Nevertheless, it should be noted that BACE1 knockout mice exhibit some abnormalities in cognitive and emotional functions, such as spatial and reference memories and impairments in temporal associative memory, suggesting that BACE1 is required for some aspects of hippocampal memory, and that a complete inhibition of the enzyme may have unfavourable cognitive side effects. Recent studies show that APP is modulated by the interaction of BACE1 with the neurite growth inhibitor NOGO, a member of the reticulon protein family and a component of myelin, which may imply that BACE1 plays a role in myelination. In support of that, high BACE1 expression levels are observed in early postnatal stages when myelination takes place. Like APP, BACE1 cycles between compartments of the secretory pathway and BACE1 activity resides in both the endosomes and secretory pathway. The immature precursor of BACE1 is synthesized in the endoplasmic reticulum (proBACE1). Through the addition of complex carbohydrates and the removal of the propeptide domain, ProBACE1 rapidly matures into a 70 kDa form, which undergoes extensive post-translational modifications. The majority of BACE1 is produced as an integral membrane protein, while a minor portion of BACE1 undergoes ectodomain shedding. Inhibition of shedding does not influence processing of APP at the β-site. However, co-expression of APP and the soluble ectodomain of BACE1 in cells increase the generation of Aβ, suggesting the enhanced BACE1 ectodomain shedding may enhance amyloidogenic processing of APP. Mature BACE1 localizes largely within cholesterol-rich lipid rafts. BACE1 is capable of forming stable homodimers that exhibit enhanced catalytic activity.

α-Secretase

In its non-amyloidogenic cleavage pathway, APP is cleaved by α-secretase. This cleavage takes place within the Aβ domain at Leu+17, thus preventing Aβ formation. Evidence suggests that BACE2 cleaves APP at a novel θ-site Phe+19 and Phe+20 sites of APP, downstream of the α-secretase cleavage site[7].

α-secretase cleavage produces sAPPα ectodomain, and an APP-CTF, C83, which in turn is cleaved by γ-secretase to form a 3 kDa fragment, p3. While an increase in non-amyloidogenic APP metabolism was shown in some studies to be coupled to a reciprocal decrease in the amyloidogenic processing pathway, as α- and β-secretase compete for the same APP substrate, other studies show that these activities may not necessarily be coupled. The identity of α-secretase is unknown. Four putative enzymes were shown to have α-secretase activity: TACE (TNF-α converting enzyme), ADAM (a disintegrin and metalloprotease domain protein)-9 and ADAM-10, and BACE 2[8,9]. BACE2 is an aspartyl protease and a homologue of BACE1. The amino acid sequences of BACE1 and BACE2 are ~45% identical and 75% homologous. BACE2 is expressed at low levels in most human peripheral tissues, but very low or undetectable levels in the brain. *In vitro*, BACE2 can cleave APP at the β-secretase cleavage site[9]. However, it seems that BACE2 functions mainly as an alternative α-secretase and as an antagonist of BACE1. In support of that, BACE2 is not upregulated as a compensatory mechanism following downregulation of BACE1 and its overexpression reduces Aβ production in neuronal cultures.

Aβ MISFOLDING AND OLIGOMERIZATION, SYNAPTIC FAILURE AND MEMORY LOSS

γ-secretase can cleave APP in multiple sites, leading to the formation of numerous size forms of Aβ. The main form is Aβ_{40}, however, Aβ_{38-43} have been identified as well. While its physiological role is yet to be determined, it is important to note that under normal conditions, Aβ is secreted from neurons throughout life. The most abundant 40 amino acid species (Aβ_{40}) is not thought to be harmful, whereas the less abundant Aβ_{42} variant aggregates faster and is thus linked to disease neuropathology (for a review see[10]). It is not clear how the addition of the two amino acids at the C-terminus of Aβ changes the properties of the peptide in a way that makes it more aggregation-prone. However, it is thought that an increase in the Aβ_{42}/Aβ_{40}, an upregulation of Aβ levels and/or reduced Aβ degradation or clearance lead to neuropathology. Aβ_{42} tends to generate soluble oligomers that can range in size between dimers to dodecamers. These oligomers were found in human brains lacking amyloid deposits or fibrillary tangles, suggesting that accumulation of oligmeric species of Aβ occur early in the disease. Many studies have shown that FAD-linked transgenic mice with amyloid pathology have impairments in learning and memory paradigms including acquisition of long-term spatial memory, spatial reversal learning, utilization of spatial working memory, acquisition of social recognition memory, object recognition memory and contextual fear conditioning (for review see[11]). In some cases, the severity of the impairment has been correlated to Aβ levels in the brains of individual mice and treatments that reduce Aβ levels (e.g. immunization with Aβ or Aβ antibodies) can reverse learning deficits. Most of these tasks are dependent on the hippocampus and deficits in hippocampal synaptic plasticity, i.e. long-term potentiation (LTP) in the transgenic mice are possible causes for the learning impairments (for review see[11]). However, the cues used in these learning paradigms are complex and require processing in multiple brain networks before reaching the hippocampus. This makes it difficult to establish where and how in the brain learning breaks down in the affected animals. Several studies have reported impairments in hippocampal LTP in FAD-linked

transgenic mice. However, the role of Aβ deposition and the presence or absence of amyloid plaques remains unclear. Some studies have reported impaired synaptic function or LTP deficits prior to amyloid deposition, some deficits only after amyloid deposition, and some preserved LTP in the face of extensive amyloid deposition. These disparate results no doubt reflect strain-specific differences in transgene expression and other factors. Most studies agree that functional synaptic density, measured electrophysiologically, is reduced in hippocampus of mice with extensive Aβ deposits. This accords with other indicators of synaptic degeneration and the toxic effects of Aβ monomers, oligomers, protofibrils and fibrils on synapses. Compelling evidence for the role of soluble Aβ oligomers in memory loss was provided by studies showing that a single intraperitoneal injection of anti-Aβ antibodies can reverse memory impairments in APP transgenic mice without affecting amyloid deposition, suggesting that the antibodies target soluble Aβ. In support of that, recent evidence suggests that these are the oligomeric forms of Aβ that are cytotoxic, interfering with numerous cellular functions as well as interfering with aspects of learning and memory and synaptic function. Synaptic dysfunction takes place before synaptic loss, which precedes neuronal loss.

MEMORY LOSS, ALTERATIONS AND IMPAIRMENTS IN NEUROGENESIS

Neurogenesis and Alzheimer's Disease: Cross-Talk and Effects

The contribution of impaired neurogenesis to memory disorders and to AD in particular is increasingly acknowledged. In the adult brain there are two discrete areas where neural stem cells are maintained and differentiate into new neurons and glia throughout life: the subventricular zone (SVZ), adjacent to the walls of the lateral ventricle, and the subgranule layer (SGL) of the dentate gyrus. Both neurogenic areas are part of the olfactory-hippocampal and entorhino-hippocampal circuits that are most affected in AD. Neurogenesis in the adult brain plays a role in numerous aspects of learning and memory (for review see[12]). Numerous studies have suggested that the rate of neurogenesis in both SVZ and SGL declines with age, raising the possibility that reduced neurogenesis may account for, at least in part, impaired learning and memory and cognitive deterioration in the elderly (for example see[13]). Examination of neurogenesis in brain tissue of AD patients revealed increased expression of immature neuronal marker proteins. However, these observations have been challenged recently. Other reports suggest that in the aged and AD brain, there is a dramatic decline in both proliferative capacity of progenitor cells and in the pool of NSCs in the SGL, and that this decline may be attributed to loss in growth factors (for review see[14]). Information obtained using animal models of the disease reveals that the vast majority of studies using transgenic mice harbouring FAD-linked mutant PS1 report that neurogenesis is impaired on a steady-state level and upon enriched environment stimulation (for review see[15]). Nevertheless, the interpretation of observations obtained in transgenic mice harbouring FAD-linked APP variants is challenging. This may result in the fact that APP is processed to numerous metabolites, that convey different effects on neurogenesis as described below. It is important to keep in mind that the organization composition and dynamics in the neurogenic niches may change as AD progresses, according to the dynamics of neuropathological cues, such as oligomeric Aβ and amyloid deposition. Another fascinating aspect of the cross-talk between AD and neurogenesis, adding another level of complexity, is that players that cause FAD regulate neurogenesis, as discussed in the next paragraph.

PS1 Regulates Embryonic and Postnatal Neurogenesis

γ-secretase cleaves other membrane proteins in addition to APP, such as the receptor tyrosine kinases ErbB4, IGF-1R and insulin receptor, as well as of the neurogenic signals Notch1, L1 and E-cadherin (for review see[15]). A large number of these substrates are neurogenic signalling that regulate embryonic and postnatal neurogenesis, suggesting that alterations in PS1/γ-secretase expression, activity or function may directly affect neurogenesis. In support of that PS1 is a homologue of the *C. elegans* sel-12 – a protein that plays a major role in cell-fate decisions. Recent evidence suggests that PS1/γ-secretase acts as a tumour suppressor in epithelia and that epidermal growth factor receptor (EGFR) levels inversely correlate with PS1/γ-secretase activity. Intriguingly, EGFR signalling plays a major role in regulation of neural stem proliferation, migration and survival (for review see[16]). PS1 is further implicated in the Wnt/β-catenin signalling pathway that regulates adult hippocampal neurogenesis. The first indication that PS1 may play a role in neurogenesis has been provided by experiments in mice with genomic deletions of *PSEN1* exhibiting severely abnormal somitogenic and neurogenic processes in the brain. These mice die in late embryogenesis. This has hampered further studies of the role of PS1 in a natural brain setting in postnatal life. Some studies in transgenic mice harbouring FAD-linked PS1 variants reveal that expression of FAD-linked mutant PS1P117L, PS1M146V or conditional ablation of PS1 in the forebrain induce impaired hippocampal neurogenesis. In addition, experience of mice in an enriched environment does not upregulate neurogenesis in transgenic mice harbouring PS1 mutant variants. In contrast, other studies suggest that expression of FAD-linked PS1A246E enhances proliferation of progenitor cells in the adult DG. However, these animals express mutant PS1 ubiquitously, including in fully mature neurons. Further studies using mice expressing mutant PS1 in the neurogenic areas solely will be needed to determine the role of PS1 in postnatal neurogenesis.

TAU HYPERPHOSPHORYLATION, AXONAL TRANSPORT, KINASE AND PHOSPHATASE ACTIVITY

Another inevitable cause of synaptic degeneration is impaired communication synapse-cell body, which may result in dysfunctional axonal transport. APP is axonally transported by anterograde fast axonal transport (FAT) in both peripheral and central nerves (for review see[17]). Interference with the tightly regulated and complex trafficking of APP might have detrimental effects on its processing and consequently on neuronal homeostasis. A large body of evidence supports the notion that axonal transport is impaired in neurons harbouring FAD-linked mutant PS1 (for review see[18]). Thus, for example, budding of endoplasmic reticulum- and *trans*-Golgi network (TGN)-derived APP-containing vesicles is increased in PS1-deficient cells, or cells expressing a dominant negative PS1 D385A variant. In addition, increased steady-state levels of APP were observed on the surface of cells lacking PS1 or expressing PS1 D385A, while vesicle biogenesis and the extent of cell-surface APP is reduced in membrane preparations from cells expressing FAD-linked PS1 variants. Other recent studies show that the PS1-interacting protein phospholipase D1 plays a role in PS1-regulated APP trafficking in neuronal cultures. Significantly, FAT of both

APP and Trk receptors is markedly impaired in the sciatic nerves of transgenic mice expressing FAD-linked PS1 mutants, accompanied by a reduction in both steady-state levels and accumulation of kinesin-1 in nerves of mice expressing mutant PS1 relative to nerves of mice expressing human wild-type PS1[19]. These findings are consistent with and extend previous observations that expression of FAD-linked PS1 mutants in embryonic cultured neurons leads to increased glycogen synthase kinase 3 (GSK-3) activity and reductions in kinesin-1-based transport of selected membrane proteins[18]. Taken together, the evidence suggests that expression of FAD-linked PS1 variants leads to deficient supply of both neurotrophin receptors and presynaptic membrane components at nerve terminals, resulting in compromised neuronal function. This evidence further implies that misregulation of phosphatase and kinase activity might underlie impaired axonal transport. In that regard, misregulation of phosphatase and kinase activity may underlie hyperphosphorylation of tau. Tau is a multifunctional microtubule-associated protein that plays major roles in the assembly of microtubules, the stabilization of microtubules against dynamic instability, axonal transport and in polymer interaction with other cytoskeletal filaments. The equilibrium between phosphorylations and dephosphorylations of tau modulates the stability of the cytoskeleton and consequently axonal morphology and transport. Recent studies provide interesting information concerning the course of tau pathology in relation to amyloid pathology in the 3XTg-AD mice and shed new light on the pathological effects of tau hyperphosphorylation and aggregation (for review see[20]). Function-associated phosphorylation sites of tau are reportedly on serine and threonine, suggesting the role of serine and threonine kinases and phosphatases in AD. For example, the epitope at Ser-396/Ser-404 of tau, thought to be preferentially phosphorylated by GSK3, is hyperphosphorylated in AD. There are more than 10 serine/threonine protein kinases that have been shown to phosphorylate tau *in vitro*. According to the motif-specificity, these kinases can be divided into two major groups, i.e. the proline-directed protein kinases (PDPKs) and nonproline- directed protein kinases (NPDPKs). Among these kinases, GSK-3β is among the most implicated in the abnormal hyperphosphorylation of tau in AD brains. Glycogen synthase kinase 3 (GSK3) is a component of the WNT signalling pathway, which plays a major role in adult neurogenesis, microtubule dynamics and fast axonal transport[21]. GSK3 is inactivated by phosphorylation at serine 9 (Ser9) in its N′-terminus. Among GSK3's numerous substrates are PS1, β-catenin, tau and kinesin-I light chains (KLC) (for review see[22]). Previous studies suggest that FAD-linked PS1 mutations affect GSK3 kinase activity in transfected cell lines. Significantly, phosphorylation of KLC by GSK3 promotes the release of kinesin-I from membrane-bound organelles, leading to a reduction in fast anterograde axonal transport[21]. A separate study showed an interplay between cyclin-dependent kinase 5 (Cdk5), previously shown to be central for tau phosphorylation and GSK3β in mice overexpressing p25. While Cdk5 activity increases APP processing, GSK3β activity induces tau phosphorylation. Interestingly, inhibition of Cdk5 activates GSK3β activity. Cdk5 is activated by factors like p35 and p39, and is involved in tau phosphorylations in neurogenesis. Cdk5 activation is concomitant with degeneration of hippocampal neurons and tau hyperphosphorylation, while its inhibition is neuroprotective, suggesting that misregulation of Cdk5 activity plays a role in the formation of neurofibrillary tangles. Recent intriguing studies shed light on a possible role for casein kinase 2 (CK2) activation in the pathogenesis of the disease. Future studies will determine the sequence of events in these signalling pathways in the course of the disease.

PERTURBED CALCIUM HOMEOSTASIS AND INTRACELLULAR CALCIUM SIGNALING

As a primary resident of the ER, it may not be surprising that dysfunctional PS affect ER calcium dynamics on multiple levels, imposing mostly 'gain of function' effects on these processes (for review, see[23,24]). This effect on intracellular calcium homeostasis may also be associated with altered glutamate uptake, leading to neurotoxicity. Expression of FAD-linked mutant PS results in increased ER calcium release in fully mature neurons (for review see[23]). Mutant PS enhance IP_3-mediated calcium release from the ER stores, as well as perturb calcium entry through store-operated channels. In addition, it appears that ryanodine receptor (RyR) function is predominantly upregulated. IP_3R alterations or direct effects of mutant PS on endoplasmic reticulum store levels may play a role in the observed calcium dysregulation as well. Nevertheless, it should be noted that mutant PS have also shown a reduction in ER calcium load and ER release with SERCA inhibition. Thus it is not clear whether all mutations have the same effect on ER calcium regulation. Overexpression of mutant PS increases IP_3 channel activity in suboptimal and saturated IP_3 levels by prolonging the channel open time, while wild-type PS mildly affect IP_3 channel activity. PS physically interact with IP_3 receptors and thus modulate them directly. IP_3 receptors modulate gating activity and affect overall calcium dynamics. Indeed, fibroblasts derived from mutant PSKI1 mice exhibit increased sensitivity to IP_3 receptor agonists. A recent report suggests that mutant PS reduces endogenous calcium leak from the ER, which may result in an increased ER calcium load and overfilled ER stores. Presenilin knockout cells exhibit perturbed ER calcium stores. Overexpression of PS accelerates the sequestration of cytosolic calcium, an effect that can be blocked by pharmacological inhibition of SERCA, suggesting that PS modulate SERCA function. In support of that, PS1KO/PS2KO cells exhibit a phenotype similar to SERCA KO, suggesting that PS may interact and modulate calcium influx into the endoplasmic reticulum via SERCA, and calcium extrusion from the endoplasmic reticulum via interactions with the ryanodine and IP3 receptors as well as through endogenous leak channels. While a link to Aβ regulation is provided by studies suggesting that knocking out IP_3 receptor or SERCA results in a dramatic reduction in Aβ production further studies will be required in order to determine the intracellular sequence of events that lead to calcium imbalance and subsequently neuronal death.

OXIDATIVE STRESS

Oxidative stress refers to circumstances in which oxidant production surpasses the endogenous antioxidant capabilities of the cell, leading to damage of the tissue. Such conditions occur either following increased production of cellular oxidants and/or decreased concentrations of cell antioxidants including glutathione, vitamin E, ascorbate, the glutathione peroxidase system, superoxide dismutase (SOD) and catalase. Overproduction of reactive oxygen and nitrogen species such as superoxide, hydrogen peroxide, nitric oxide and peroxynitrite occurs in AD and is considered to mediate cell damage and subsequently death (for review see[25]). Studies suggest that Aβ induces the formation of high concentrations of oxygen and nitrogen-reactive species and a depletion of endogenous antioxidants. In brain tissue

from AD patients, there are increased levels of markers of oxidative stress including oxidized proteins, membrane lipids, DNA and nitrotyrosine immunoreactivity. Additionally, antioxidants including vitamin E, idebenone, uric acid and glutathione are effective in preventing Aβ neurotoxicity *in vitro*. Aβ induces the generation of reactive oxygen species, including the generation of hydrogen peroxide, peroxyl radical and superoxide that in turn may initiate a series of secondary reactions. As oxidative stress might have an accumulative effect that is environment and ageing linked, it may contribute to the initiation and development of neuropathology in sporadic AD.

GENETIC LINKS AND RISK FACTORS UNDERLYING LATE-ONSET SPORADIC AD

Ageing is the greatest risk factor for sporadic Alzheimer's disease, and the vast majority of AD cases are the sporadic late-onset form. The cause of late-onset AD is unknown. Several genetic loci have been identified that predispose individuals to late-onset AD (for review see[26]) and it has been suggested that some of the encoded polypeptides might play roles in modulating the clearance and/or degradation of Aβ peptides. For example, studies that have implicated the low-density lipoprotein receptor-related protein (LRP) in regulating the efflux of Aβ from the brain to plasma have received support from the identification of DNA variants in LRP, apolipoprotein E (ApoE) and α-2-macroglobulin (α2M) in late-onset AD. LRP was recently identified as a substrate of BACE1. Polymorphisms in the apolipoprotein E (apoE) gene show the most significant effects on relative genetic risk of sporadic AD. The ε4 isoform (Cyc112-Arg) of apoE is associated with increased risk of developing AD, while ε2 (Arg158-Cys) is associated with protection from the disease compared to the normal ε3 allele (for review see[27]). ApoE binds to members of the low-density lipoprotein receptor family (LDLR) (for review see[28]). These receptors are known to function in cholesterol and lipid transport and as signal transducers. Numerous reports established that LDLR linked cellular signalling pathways modulate AD pathology. Reelin and its homologue F-spondin are recognized by the very-low density lipoprotein receptor (VLDLR) and apolipoprotein E receptor-2 (apoE-R2), two members of the LDLR family. Interestingly, mice lacking reelin, double-knockouts lacking VLDLR and ApoER2 and mice lacking disabled-1 (Dab1) exhibit tau hyperphosphorylation. Based on that it was suggested that the reelin-ApoE receptor complex initiates a signalling cascade that regulates phosphorylation of tau by GSK3. F-spondin and reelin are thought to regulate APP processing through their interaction with APP and ApoER-2. ApoER-2 has also been shown to be neuroprotective during ageing, and F-spondin was reported to protect against Aβ toxicity. Other LDLR family members including LRP1, LRP1B and LR11/sorLA have also been shown to modulate APP processing. Furthermore, DNA variants have been identified in a gene on chromosome 10, encoding insulin degrading enzyme (IDE), a $\sim$110 kDa thiol zinc-metalloendopeptidase shown earlier to degrade several peptides, including insulin, glucagon, atrial naturetic peptide and TGFα. Interestingly, IDE-deficient mice exhibit increased levels of Aβ in the brain, and transgenic overexpression of IDE results in reduced Aβ burdens in brains of transgenic mice that develop Aβ deposits. Finally, numerous studies during the last 10 years have reported the beneficial effect of the experimental model 'enriched environment' on AD neuropathology, including reductions in Aβ levels and deposition and learning and memory (for review see[11]), suggesting that genetic environmental factors play in concert to induce or prevent sporadic AD.

Neurochemistry of Alzheimer's Disease

Paul T. Francis

King's College London, Wolfson Centre for Age-Related Diseases, UK

INTRODUCTION

Alzheimer's disease (AD) is characterized by gross and progressive impairments of cognitive function, which are often accompanied by behavioural disturbances such as aggression, depression, psychosis, apathy and wandering. Cell and synapse loss together with neuronal dysfunction affecting a number of neuronal systems are considered to result in the development of these typical symptoms of the disorder. In particular, non-cognitive behavioural symptoms are also considered to relate to structural and functional alterations in neurotransmission. Carers find behavioural disturbances difficult to cope with and the presence of such behaviours in AD patients often leads to the need for institutionalization[1]. The challenge has been to identify changes in specific neurotransmitter systems that underlie cognitive impairment and particular behavioural problems and to develop rational therapeutic strategies.

NEUROCHEMICAL CHANGES IN ALZHEIMER'S DISEASE

The majority of biochemical studies of AD have relied on information derived from postmortem brain, which typically represents the late stage of the disease (8–10 years after onset of symptoms). In these studies there is considerable evidence of gross brain atrophy, histopathological features and multiple neurotransmitter abnormalities affecting many brain regions. However, investigations of biopsy tissue taken from AD patients 3–5 years (on average) after the onset of symptoms indicate that a selective neurotransmitter pathology occurs early in the course of the disease[2].

Acetylcholine

Changes affecting many aspects of the cholinergic system in patients with AD have been reported since the initial discovery of deficits in choline acetyltransferase activity in postmortem brains[3–5]. In biopsy samples from AD patients, presynaptic markers of the cholinergic system were also uniformly reduced[2]. Thus, choline acetyltransferase activity, choline uptake and acetylcholine synthesis are all reduced to 30–60% of control values. The clinical correlate of this cholinergic deficit in AD was, until recently, considered to be cognitive dysfunction. Such a conclusion was supported by clinicopathological studies in AD and parallel experiments in non-human primates or rodents, which demonstrated disruptive effects of basal forebrain cholinergic lesions on cognitive functions. Furthermore, cholinergic deficits in AD occur to the greatest extent in cortical areas primarily concerned with memory and cognition – the hippocampus, adjacent temporal lobe regions and select frontal areas. Such studies led to the 'cholinergic hypothesis of geriatric memory dysfunction'[6].

Neuropathologically, loss of neurons from the nucleus of Meynert (nbM; Ch4 cholinergic nucleus) is well documented in AD, although the extent of the loss reported varies from moderate to severe, and it has been suggested that in AD cholinergic dysfunction exceeds degeneration[7]. Detailed analysis of subpopulations of cholinergic perikarya in the nbM have been reported by Mesulam and Geula[8], who identified selective cell loss in Ch4p (the posterior section projecting to temporal cortex). In the intermediate sector, Ch4id, which includes projections to the frontal cortex, neuron loss is not as extensive, consistent with the moderate loss of cholinergic enzyme activity.

On the basis of the above evidence, neocortical cholinergic innervation appears to be lost at an early stage of the disease and this is supported by a study in which the cholinergic deficit (reduced ChAT activity) has been related to Braak stageing[9]. Braak stages I and II are considered to represent the earliest presentation of AD, with neurofibrillary tangles in the entorhinal cortex, and a 20–30% loss of ChAT activity was reported in brains from patients at these stages of AD[10]. However, another study using the Clinical Dementia Rating Scale (CDR) suggests that the greatest reduction in markers of the cholinergic system occurs between moderate (CDR 2.0) and severe (CDR 5.0) disease, with little change between non-demented and the mild stage (CDR 0–2)[11]. Finally, tau and tangle pathology occurs in cholinergic neurons of the nbM during normal ageing and to a greater extent in patients with mild cognitive impairment (MCI), indicating functional changes in cholinergic neurotransmission[12].

There has been a recent shift of emphasis regarding the clinical significance of cholinergic deficits. Non-cognitive or neuropsychiatric, in addition to cognitive, symptoms also appear to have a cholinergic component[13]. For example, visual hallucinations relate to neocortical cholinergic deficits[14], such deficits (e.g. loss of ChAT) being greater in dementia of Lewy bodies (DLB), where hallucinations are common, than in AD, where they are less common[15]. Reductions in cortical ChAT activity in patients with dementia, in addition to correlating with cognitive decline, are also related to overactivity and aggressive behaviour[16].

Glutamate

Approximately 70% of cortical neurons use glutamate as a neurotransmitter and hence the glutamatergic system plays an important role in all regions of the cortex and hippocampus. Evidence for a pivotal role of glutamate in learning and memory is long-established[2]; indeed, it is likely that any function of a particular cortical region will depend on glutamate neurotransmission at some level. Loss of synapses and pyramidal cell perikarya (both considered to be markers of glutamatergic neurons) from the neocortex of AD patients correlate with measures of cognitive decline[2]. From a biochemical perspective studying the glutamatergic system is more difficult since the amino acid is present at high concentrations in all cells. However, certain proteins related to glutamatergic neurotransmission provide vital clues to the status of this system in AD. For example, reduced glial glutamate uptake is reported in AD[17], probably reflecting oxidative damage to the transporters[18,19]. Additionally, there is loss of the vesicular glutamate transporter (VGluT) in several cortical regions[20,21]. Such changes are likely to generate an elevated baseline level of glutamate at the synapse, triggering inappropriate Ca^{2+} influx. These raised background levels of glutamate impair the usual detection of physiological signals (low signal-to-noise ratio), disrupting normal cognitive processes[22]. Furthermore, the disruption of vesicular glutamate transport results in less glutamate being stored in presynaptic vesicles, reducing the level of signal upon neurotransmitter release[20].

In addition, soluble oligomers of beta amyloid ($A\beta$) can reduce glutamatergic transmission by inducing the internalization of NMDA receptors[23]. This pathological effect has been shown to disrupt NMDA-induced receptor currents, inhibiting long-term potentiation (LTP – synaptic plasticity) and signalling to downstream targets such as Akt (also known as protein kinase B)[23–25].

Other Neurotransmitters

Using biopsy samples from AD patients, serotonergic and some noradrenergic markers are affected, whereas markers for dopamine, γ-aminobutyric acid (GABA) or somatostatin are not altered. When postmortem studies of AD brain are considered, many neurotransmitter systems, including GABA and somatostatin, are involved or are affected to a greater extent[2]. Based on postmortem studies, however, changes in serotonergic neurotransmission may be linked to the behavioural disturbances of AD, such as depression, rather than cognitive dysfunction. For example, patients with AD who were also depressed had lower numbers of serotonin re-uptake sites in the neocortex than did patients without this symptom[26]. Furthermore, both reduced serotonergic[27,28] and increased noradrenergic activities and sensitivity[29,30] have been linked to aggressive behaviour.

Neurotransmitter Receptors

Many neurotransmitter receptors appear to be unaltered in AD; however, studies have demonstrated a reduction in the number of nicotinic and muscarinic (M2) ACh receptors, most of which are considered to be located on presynaptic cholinergic terminals. Despite continuing, often unconfirmed, reports of changes in one or more of the muscarinic receptor subtypes (M–M5), it is generally agreed, on the basis of autopsy studies, that the M1 subtype is unchanged until later in the disease, when it may decline, probably in relation to cholinoceptive (postsynaptic) neurodegeneration. The status of the other subtypes is not clearly established, primarily due to the lack of specific pharmacological labels. Results using antibodies against the different receptor subtypes, while specific, are complicated by discrepancies between the distribution and density of immunoreactive proteins and localized functional receptors. With respect to muscarinic receptor coupling to G-proteins, most studies using a variety of investigative procedures have identified some degree of uncoupling, especially to the M1 receptor[31,32] that correlated with cognitive decline.

A highly consistent receptor abnormality in AD is the loss of the nicotinic receptor[33,34], which appears to primarily reflect loss of the α4-containing subtype (generally associated with β2) as opposed to α3 or α7 subtypes[35]. Immunohistochemically, loss of α4 and β2 reactive fibres has been observed in temporal cortex, associated with reactive neuropil threads, tangles and plaques[36].

The density of 5-HT_{2A} receptors was reduced in AD patients compared to age-matched controls and this reduction also correlated with the rate of decline of Mini-Mental State Examination (MMSE) scores, suggesting that loss of neocortical 5-HT_{2A} receptors may predict for faster cognitive decline[37]. By contrast, density of $5HT_{1A}$ receptors in frontal cortex was negatively correlated with cognitive decline[38], consistent with an inhibitory action of these receptors on cortical pyramidal function[2]. It is interesting to note that in temporal cortex loss of 5-HT_{1A} receptors was associated with aggressive behaviour[39].

NEUROCHEMICAL BASIS FOR APPROACHES TO TREATMENT

Biochemical studies of postmortem brains from AD patients showing evidence of a substantial presynaptic cholinergic deficit, which correlated with cognitive impairment[40], together with the emerging role of ACh in learning and memory[6], clearly suggested a rational approach to treatment. However, more recent studies have identified a role for the cholinergic system in attentional processing rather than simply memory.

A prediction of the cholinergic hypothesis is that drugs that potentiate central cholinergic function should improve cognition in AD patients. There are a number of approaches to the treatment of the cholinergic deficit; however, the use of acetylcholinesterase inhibitors is the most well developed approach to the treatment of AD to date[41].

During the late 1980s and early 1990s, the first cholinomimetic compound, tacrine, underwent large-scale clinical studies and established clearly the benefits of cholinesterase inhibition treatment in patients with a diagnosis of probable AD. Tacrine was subsequently approved for use in some, but not all, countries. Statistically significant, dose-related improvements on objective performance-based tests of cognition, clinician- and caregiver-rated global evaluations of patient well-being and also quality of life measures have been reported[42]. Unfortunately, potentially serious adverse side effects have limited the use of this compound.

A so-called second generation of cholinesterase inhibitors has been developed, including donepezil, rivastigmine and galantamine[41]. Such compounds demonstrate a clinical effect and magnitude of benefit of at least that reported for tacrine, but with a more favourable clinical profile[43]. Furthermore, evidence is emerging from clinical trials of cholinomimetics that such drugs may improve the abnormal non-cognitive, behavioural symptoms of AD[44]. The cholinesterase inhibitors physostigmine, tacrine, rivastigmine and metrifonate have variously been reported in placebo-controlled trials

to decrease psychoses (hallucinations and delusions), agitation, apathy, anxiety, disinhibition, pacing and aberrant motor behaviour, and lack of cooperation in AD. The most recent studies indicate that cholinesterases inhibitors have the greatest effect on apathy and mood in AD, rather than agitation and aggressive behaviour[45,46].

Targeting the acknowledged glutamatergic deficit in AD has been more problematical since direct agonists would be expected to be toxic and there is no analogous enzyme (cf. cholinesterase) to inhibit. Indirect approaches such as AMPAKines, positive modulators of the AMPA glutamate receptor, have undergone clinical trials with mixed results[47,48]. The only licensed treatment targeting this system is the NMDA glutamate receptor antagonist memantine. In clinical trials this drug has been shown to improve cognition and activities of daily living[49,50] and some troublesome behaviours, in particular agitation and aggressive behaviour[51]. It is proposed that the cognitive benefits of this drug flow from improving 'signal-to-noise ratio' at NMDA receptors[52] while the improvement in behaviour may be because of inhibition of the hyperphosphorylation of tau[53].

CONCLUSIONS

In AD many different pathological manifestations, such as cortical and subcortical β-amyloidosis (plaques), abnormal tau (tangles and dystrophic neurites), neuronal and synapse loss and various transmitter deficits, provide an increasingly complex framework for clinical–neuropathological correlations. Based upon detailed knowledge of the neurochemical changes that occur in AD, two main symptomatic treatments have emerged, cholinesterase inhibitors and memantine. These drugs provide some benefit to patients and in particular the improvements in behaviour are important to carers. Such therapy is all that is available at present and may well still be required as new therapies designed to slow disease progression come into the clinic.

INTRODUCTION

It has become increasingly clear that the disease process of Alzheimer's disease (AD) is multifaceted. Because AD appears to be a complex disorder involving several genes interacting with environmental influences, it is difficult to single out any one factor as the root cause of the disease. Apart from the familial forms of the disease, in which the gene mutations have been elucidated, many post-translational factors are involved in the process of neurodegeneration, in the formation of plaques and tangles and in the development of an inflammatory state of the brain. Although some of these have been found to be altered in AD patients compared with controls, very few markers suitable for antemortem diagnostic purposes have emerged, since many of the alterations are not specific for AD, while others pertain only to subsets of AD[1].

While it has been argued that the most powerful antemortem marker in AD is a clinical diagnosis based on an adequate range of observations[2], such diagnosis is at present largely one of exclusion. An ideal biological marker would allow for greater specificity and sensitivity than a clinical diagnosis on its own, and be readily obtainable. While neuropathological biopsy diagnosis of AD allows high specificity and sensitivity, it is typically only available postmortem.

The neurobiological alterations present in AD may be reflected in changes in cerebrospinal fluid (CSF) neurotransmitters or neurochemicals, or changes in systemic tissues including blood constituents. It should be borne in mind, however, that CSF measurements are influenced by a variety of factors, including CSF gradients, age, gender, diurnal and seasonal variations, state of the blood–brain barrier, blood contamination, contributions from the spinal cord, phase of illness, psychomotor activity, stress and diet. Measurement of blood constituents may also reflect concentration differences due to diurnal rhythms and other factors.

In this chapter on antemortem markers, we will briefly review neurotransmitters, neurochemistry and systemic pathology. We will also briefly address findings in brain imaging, and genomic and proteomic methods.

NEUROTRANSMITTERS AND NEUROCHEMISTRY

The Cholinergic System

Cholinesterase inhibitors (ChEIs) were introduced for the treatment of AD following the discovery that cholinergic neurons were depleted, and that cholinergic function was significantly decreased in the basal forebrain of AD patients[3]. Interestingly, the latter research group recently reported that ChEIs increased the phosphorylation of tau protein[4], resulting in a possible decrease in long-term clinical responsiveness to ChEIs. The depletion of membrane choline may also play a role[5]. CSF markers of cholinergic function, as well as erythrocyte and plasma choline, have been studied as biomarkers for AD, but have not yielded consistent results[6]. Studies, however, indicate differences in the dynamics of RBC choline uptake, consistent with a vulnerability of cholinergic neurons in patients with AD[7].

The Noradrenergic System

Autopsy studies of AD brains demonstrate that loss of cells in the locus coeruleus (LC), the major nucleus of origin of noradrenergic fibres, may undergo even greater degeneration than the nucleus basalis of Meynert[8]. This raises the question whether the degeneration of the noradrenergic system would provide markers for AD. Reduced noradrenaline (norepinephrine; NE) in autopsy samples of AD brains has been a fairly consistent finding, although it may be hypothesized that increased activity and turnover of the noradrenergic system may compensate for cell loss and that a limited number of NE cells remain highly active in AD patients. Loss of NE innervation would in addition lead to peripheral effects, such as decreased control of vasoconstriction[8]. Some patients with advanced AD have biochemical and physiological indices of noradrenergic hyperactivity, including higher heart rate and blood pressure. Severe neuronal loss in advanced AD may lead to a compensatory increase in LC firing rate, contributing to symptoms such as pacing, agitation, insomnia and weight loss. Haglund *et al*.[8] developed a scale for the evaluation of LC degeneration in patients with AD, vascular dementia

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

and non-focal ischaemic deep white matter disease (WMD), as part of the ongoing Lund Longitudinal Dementia study. They found that LC degeneration was significantly higher in AD than in vascular dementia cases, and that there was a significant correlation with white matter pathology severity. However, there was no correlation between the degree of LC degeneration and duration of dementia or AD pathology[8].

The Serotonergic System

Numerous autopsy studies of AD brains have suggested a serotonergic deficit. Although there have been reports that the major serotonin metabolite, 5-hydroxyindoleacetic acid (5-HIAA), is unchanged in the CSF of AD patients, most studies indicate a reduction in CSF 5-HIAA. In a study by Stuerenburg *et al*., CSF 5-HIAA correlated with CSF Aβ42, but not with CSF tau. There was also a significant positive correlation between CSF 5-HIAA and homovanillic acid (HVA) in AD, but neither 5-HIAA nor HVA could differentiate between mild cognitive impairment (MCI), depression and AD[9].

Although CSF measures of monoamines have not proven sufficiently specific and sensitive for clinical diagnosis, the degree of pineal calcification (DOC) can be used as an intra-individual melatonin deficit marker[10]. Melatonin, the pineal hormone biosynthesized from serotonin, declines with age and more so in AD patients due to calcification of the pineal gland. Mahlberg *et al*.[10] measured the DOC, as well as the size of uncalcified tissue, with computed tomography (CT) in 279 consecutive memory clinic outpatients. The DOC was significantly higher in AD than in patients with other types of dementia, depression or controls, while the size of uncalcified pineal tissue in AD patients was significantly smaller than in patients of the other three groups[10].

Wu and Swaab found that pineal melatonin secretion and pineal clock gene oscillation were disrupted in AD patients, as well as in non-demented controls with early signs of AD neuropathology (neuropathological Braak stages I–II), in contrast to non-demented controls without AD neuropathology[11]. Furthermore, a functional disruption of the suprachiasmatic nucleus (SCN) was observed from the earliest AD stages onwards, as shown by decreased vasopressin mRNA, a clock-controlled major output of the SCN.

Taken together, measures of neurotransmitter systems have not provided sufficient sensitivity and specificity to be used for diagnostic purposes in the clinic. Nevertheless, such work has been useful in investigating the pathophysiology of AD.

SYSTEMIC PATHOLOGY

It is possible to view AD as a systemic illness. Thus, if AD were a genetic disorder, then disturbances at the molecular level may be expressed in non-neural tissue, with systemic effects. Using blood cells for biomarkers has the added advantage of being relatively non-invasive, and techniques such as flow cytometry provide a convenient platform for such analyses. Uberti *et al*. found that the expression of a conformational mutant of p53 in mononuclear cells was significantly higher in AD patients compared to non-AD subjects. The expression of mutant p53 did not, however, correlate with the duration of illness or disease severity[12].

Zainaghi *et al*. found that an alteration of amyloid precursor protein (APP) fragments in platelets, as measured by Western blot analysis, correlated with cognitive decline in patients with AD[13]. Platelets contain more than 95% of circulating APP and enzymatically produce both soluble APP and amyloid-beta peptides. It was found that the ratio of 130- to 110-kDa APP fragments in platelets from patients with AD was significantly lower compared to patients with mild cognitive impairment and elderly controls. There was no difference between the latter two groups. The alteration in APP also correlated with membrane fluidity of the platelets[13].

Membrane fluidity of platelets as a biomarker for AD has been extensively studied. Increased fluidity was demonstrated in patients with AD compared to patients with vascular dementia and elderly controls. Only about 50% of AD patients, however, demonstrate this abnormality. Increased platelet membrane fluidity (PMF) appears to be a familial trait, and the subgroup of AD patients in whom it manifests suffers from an earlier onset and a more rapidly progressive decline. In a prospective longitudinal study evaluating PMF as a putative risk factor for AD, 9 of 330 people with increased PMF (initially asymptomatic first-degree relatives of probands with AD) developed AD after 7.5 years[14]. On a biochemical level, it was found that free radical induced lipid peroxidation increased the fluidity of platelet membranes, providing a possible mechanism underlying increased PMF[15]. This putative marker of AD would hence also be subject to modulation by environmental factors such as a diet rich in antioxidants.

In fibroblasts, abnormalities in enzymatic activity, glucose metabolism, abnormal calcium metabolism, impaired DNA repair as well as potassium channel dysfunction[16] have been observed. While studies on blood cells and fibroblasts have advanced our understanding of the mechanisms relevant to AD, they are not sufficiently sensitive or specific for clinical use, once more raising the question of environmental influences.

Protein Abnormalities

The hallmark lesions of Alzheimer's disease are neurofibrillary tangles, which contain tau protein, and the plaques with deposition of β-amyloid (Aβ). Given that the clinical phase of AD may be preceded by a 15–30 year period of deposition of amyloid and tau protein, markers to predict the development of AD should ultimately be obtainable. Several studies have found increased levels of tau protein (total tau as well as phosphorylated tau) and decreased levels of Aβ(1–42) in CSF[17], while the ratio of these two measures has been found to be a highly sensitive discriminator of AD from normal ageing. Maddalena *et al*. found that the ratio of CSF phospho-tau to Aβ42 was significantly increased in patients with AD and provided high diagnostic accuracy in distinguishing patients with AD from healthy control subjects (sensitivity, 86%; specificity, 97%), subjects with non-AD dementias (sensitivity, 80%; specificity, 73%), and subjects with other neurological disorders (sensitivity, 80%; specificity, 89%)[18].

Inflammation

Neuropathological findings in AD brains demonstrate an inflammatory response, including activated microglia. Several studies have measured concentrations of inflammatory markers such as C-reactive protein (CRP) and cytokines in the blood and CSF of AD patients. In the Framingham study, peripheral blood mononuclear cell (PBMC) cytokine production was related to the risk of incident AD. It was concluded that higher spontaneous production of IL-1 or TNF-alpha by PBMCs may be a marker for the future risk of AD in older

individuals. These data strengthen the evidence for a pathophysiological role of inflammation in the development of clinical AD[19]. Although these markers are too non-specific for AD diagnosis, drugs aimed at diminishing inflammation and the activity of microglia are currently still being investigated.

A range of other research areas in AD can conveniently be mentioned in this section. These include studies of visual system dysfunctions, olfactory deficits, extrapyramidal dysfunction, atypical dermatoglyphic patterns, altered sweat response, abnormal glucose tolerance and vitamin B12 deficiency. Such work, although interesting, has not yet led to a sensitive and specific antemortem marker.

Environmental Factors in Alzheimer's Disease

Although AD has been linked to a genetic aetiology, studies with monozygotic twins revealed variability in age at onset of as much as 9, 15 or 20 years[20]. This led to the suspicion that some environmental factor(s) ingested from food and water, or a deficiency of some protective element, or increased oxidation status resulting from stress[21] may accelerate disease expression in susceptible individuals. Several metals have been investigated in AD in the hope of finding a marker for the disease. Iron metabolism is altered and levels of the iron transport protein transferrin are decreased in the serum of AD patients. Previous reports of elevated levels of the iron binding protein p97 (melanotransferrin) in AD patients were not confirmed in a later study[22]. Blood mercury levels are significantly raised in AD patients[23] and zinc and copper are decreased in AD compared to controls. Decreased activity of the copper-containing protein ceruloplasmin may be linked to iron deposition in the brains of patients with AD[24]. Although CSF diagnostic markers Aβ42, tau and phospho-tau correlate with lower plasma copper and ceruloplasmin levels in AD patients, supplementation with copper has not improved cognition in AD[25], whereas in our experience supplementing AD patients with zinc improves cognition, especially if augmented by vitamins A and D[26].

Wu *et al*. investigated the effect of infantile exposure to lead on markers of AD-like pathology in monkeys, and found that epigenetic imprinting in early life influenced the expression of AD-related genes with the effect that a causative environmental marker could be undetectable by the time of disease expression[27]. Indeed, to date environmental markers have insufficient sensitivity and specificity to serve as useful in the diagnosis of AD.

BRAIN IMAGING

There has been considerable interest in the use of brain imaging in the diagnosis of AD and follow-up during drug trials. Initial promising neuroimaging candidate markers obtained from CT scans and MRI have been confirmed and extended with new techniques, such as measuring hippocampal and entorhinal cortex volumes, basal forebrain nuclei, cortical thickness, deformation-based and voxel-based morphometry, as well as the use of diffusion tensor imaging tractography and functional MRI[28].

There are ongoing attempts to validate MR and PET imaging and other biomarkers for use in clinical trials to distinguish between elderly controls, subjects with mild cognitive impairment, and subjects with AD[29]. C-11 Pittsburgh compound B (PIB) PET (amyloid imaging) represents a particularly promising avenue of exploration, potentially providing a direct window on the pathological processes that underlie AD. A combination of PET, MRI and mutation analysis of APOEε4 has been found to be effective in determining grey matter volume and quantification of Aβ plaque load for patient inclusion and follow-up in anti-amyloid therapy trials[30]. High-resolution PET also allows *in vivo* visualization of changes in amyloid after administration of Pittsburg Compound-B, and microglial activation after administration of [18F]fluoroethyl-DAA1106[31].

GENOMICS AND PROTEOMICS

Advances in genomic and proteomic methods raise the question of whether these may provide clinically useful antemortem markers. The greatest potential impact arguably lies in the detection of early stages of the disease, monitoring of AD progression, and assessment of response to existing and future active and preventative treatments.

Genomics has to date not been helpful in providing accurate diagnostic markers for AD. Structural genomic studies indicated that more than 200 genes may be involved in the pathogenesis of AD. Mutations in the *APP, PSEN1* and *PSEN2* genes directly associated with the amyloid cascade account for AD in much less than 5% of affected patients. The most consistent susceptibility factor for late-onset AD[32], the ε4 allele of the *APOE* gene, underlies dementia in 40% of Caucasian patients with late-onset disease; however, the APOEε4 allele does not (yet) influence dementia progression in sub-Saharan Africans[33]. Could this indicate that effects of the environment on individuals may change their susceptibility to AD and the expression of genes involved with AD predisposition, causing divergent results when putative markers are compared in different populations? Notably, alcohol consumption increases the risk of dementia specifically in those individuals carrying the APOEε4 allele[34].

Another genetic marker, a genetic variant of transferrin, TfC2, has an increased allele frequency in AD in some populations[35,36], but not in others, such as a French population of the Bordeaux region[37]. TfC2 is associated with diseases attributed to free radical damage, therefore it could be hypothesized that increased dietary intake of antioxidants in certain populations would be protective against the effects of the oxidative allele. The predominantly Mediterranean diet and red wine, which is consumed in the Bordeaux region of France, is known to be antioxidative. Robson *et al*. found that carriers of TfC2 and the C282Y allele of the haemochromatosis gene were at a five times greater risk of AD, while co-inheritance of APOEε4 conferred an even higher risk of AD in cases from the OPTIMA cohort in the UK[38]. In the Bordeaux study, in contrast, such an effect was not observed.

While genomics may not at present provide a reliable diagnostic marker for AD, it is estimated that genetic variation accounts for between 20% and 95% of the variability in therapeutic response in AD patients. The pharmacogenetic response in AD depends on the interaction of genes involved in disease pathogenesis (such as APOEε4) and genes involved in drug metabolism (such as the cytochrome P450 [CYP] system). The CYP2D6 enzyme isoforms affect the metabolism of more than 20% of drugs used to treat CNS disorders, and gene variation may cause drug side effects. Of the four genotype-related metabolizer types defined by CYP2D6, the extensive and intermediate metabolizers are the best responders, while the ultra-rapid and poor metabolizers are the worst responders to pharmacologic treatments in AD.

Genetic markers not suitable for diagnostic purposes may therefore still be useful in providing knowledge of the disease process, for disease prognosis and to guide treatment, e.g. to detect responders to

treatment with ChEIs by testing for the *APOE* genotype. The incorporation of pharmacogenetic protocols into AD research and clinical practice potentially helps to optimize therapeutics by developing cost-effective pharmaceuticals and improving drug efficacy and safety.

Gene expression profiling with microarrays has also yielded some useful evaluations of pathomechanisms and systemic manifestations in AD, using blood mononuclear cell (BMC) transcriptomes of sporadic AD subjects and aged-matched controls. The AD BMCs exhibited a significant decline in the expression of genes concerned with cytoskeletal maintenance, cellular trafficking, cellular stress response, redox homeostasis, transcription and DNA repair, as well as those genes which may impact on Aβ production and the processing of tau. The microarray results also revealed gender differences in the levels of altered gene expression[39].

Proteomic research has not fared better than genomics when it comes to providing markers for the diagnosis of AD. Several markers that were initially promising (such as complement factor H precursor and alpha-2-macroglobulin) did not provide the specificity and sensitivity required for biomarkers[40]. In a European task force consensus document, it was also stated that no marker had been validated to reliably measure a change in response to therapy, not even the rate of change in hippocampal volume[41]. It was recommended that future trials should include assessment of biomarkers in order to advance our knowledge about their usefulness. Proteomics is an attractive technique for prospecting protein biomarkers, since it involves plasma proteins and peptides that are readily obtained.

Ravid has commented that although plasma could be a useful source of markers, it is also one of the most complex media to work with[17]. Dealing with sample-to-sample variations, variations among individuals, and separating 'noise' from a true signal require the processing of thousands of samples. Moreover, only 13% of peptides reproducibly change significantly with the changes in the patient's disease state. Some new technologies that are being used to deal with the complexities of the plasma proteome include a combination of mass spectrometry, affinity chromatography and liquid chromatography to produce unbiased identification and quantification of signature peptides. This author has confirmed that the gap between discovery and diagnostics is still wide. Some of the outstanding issues include finding ways to reduce the costs associated with the validation of biomarkers or proteomic platforms, demonstration of biomarkers' clinical significance, minimizing technical complexity, gaining regulatory approvals, and reaching pharmaceutical levels of reproducibility and sensitivity. He also emphasized the need for collaboration between different disciplines.

Zellner *et al*., on a more optimistic note, have predicted that the constraints on proteomics will be overcome by developing more advanced technologies, including the design of AD-related protein panels, on which established markers such as tau and Aβ42 will be used in combination with novel markers. Laser capture microdissection and fluorescence saturation labelling will overcome the limitations of homogeneous sample collection[42].

CONCLUSION

It is clear that a number of difficulties face the researcher interested in finding an antemortem marker for AD. Many of the techniques used in this search have important limitations: for example, CSF measurements are influenced by a variety of factors; brain imaging findings often show group differences only; and genetic and proteomic studies reveal multiple small effects. Diagnosis of AD, even at autopsy, may not always be definitive, leading to heterogeneity of patient samples. In addition, AD may be a heterogeneous disorder, certainly with different manifestations in the older age group. A marker may be present in a control with the AD trait who has not yet developed AD; and if a marker is related to the severity of AD, it may not distinguish between mild cases and controls. Other dementias may overlap with AD not only in phenomenology but also in pathogenesis, and therefore display similar markers. There are also mixed cases, where patients, for example, have both AD and vascular dementia. In addition, biomarkers are currently only of value when they form part of the clinical diagnostic work-up of the patient, emphasizing the expertise of the clinician and collaboration between disciplines.

Nevertheless, the work discussed here does suggest that some combination of measures may ultimately correlate strongly with biopsy diagnosis. Measures from molecular and genetic biology and brain imaging seem particularly promising and are consistent with our growing knowledge of neurochemistry and neuropathology. Genomic and proteomic advances have the potential to ultimately translate into clinically meaningful biomarkers and to result in advances in patient care.

Pharmacological Therapies in Alzheimer's Disease

Martin Steinberg and Constantine G. Lyketsos

Johns Hopkins Bayview Medical Center, Baltimore, MD, USA

INTRODUCTION

Alzheimer's disease (AD) is a progressive neurodegenerative disorder that causes deterioration in cognition and functioning and is associated with a high frequency of neuropsychiatric co-morbidity. The emotional and financial costs of AD for patients and their caregivers are enormous. To date, no treatment is available to cure the disease or halt its progression, nor is any disease-modifying. Available symptomatic therapies, which include cholinesterase inhibitors and memantine, attenuate cognitive and functional decline and may also improve neuropsychiatric symptoms. This chapter will review the rationales for these therapies, summarize research pertaining to their cognitive, functional and neurobehavioural efficacy, and discuss current prescription and monitoring guidelines. Available evidence concerning the use of unapproved therapies such as vitamin supplementation and *Ginkgo biloba* will also be discussed.

RATIONALE FOR CHOLINERGIC THERAPIES

The deteriorations in cognition and function that occur in AD have been linked to the degeneration of numerous neuronal systems. Evidence is especially strong, however, for an association between these symptoms and the loss of cholinergic neurons. Therefore, increasing available levels of brain acetylcholine may be expected to attenuate decline in AD. Three approaches to increasing cholinergic transmission have been subject to research: increasing availability of the chemical precursors of acetylcholine (e.g. lecithin), enhancing cholinergic transmission by direct receptor stimulation, and inhibiting the breakdown of acetylcholine at its receptor site[1,2]. Early studies involving the use of acetylcholine precursors were not encouraging. Lecithin, phosphatidylcholine and acetyl-L-carnitine were ineffective, with the former also causing significant body odour[1,2]. While modest cognitive and behavioural benefits were demonstrated in trials of two cholinomimetic agents, milameline and xanomeline, the frequent occurrence of sweating, gastrointestinal symptoms and syncope limited their usefulness[2]. While the first two strategies have to date been unsuccessful, both efficacy and safety have been established for cholinesterase inhibitors, which increase the availability of acetylcholine for neurotransmission by inhibiting the enzyme acetylcholinesterase. Four cholinesterase inhibitors are currently approved by the FDA for the treatment of AD. Three of these are discussed in detail below. The fourth, tacrine, is now rarely used due to both its complex titration schedule and risks of hepatotoxicity.

DONEPEZIL

Cognitive Benefits

A reversible acetylcholinesterase inhibitor, donepezil has been FDA-approved since 1997 for the treatment of mild to moderate Alzheimer's disease. In one double-blind, placebo-controlled study of 468 participants with mild to moderately severe Alzheimer's disease[3], those in the donepezil group improved significantly compared to placebo on a 70-point cognitive battery. The improvement, however, was modest: 2.5 points in the 5 mg/d group and 3.1 in the 10 mg/d group. On the 30-point Mini-Mental State Examination (MMSE), this improvement was 1.0 and 1.3 points respectively. On a scale of global impression of function, 32% and 38% respectively in the donepezil group improved, compared to only 18% with placebo. Correlation was found between clinical improvement and the degree of red blood cell acetylcholinesterase inhibition. Comparable benefits were found in additional trials up to 24 weeks[4]. In an open-label extension trial of two 15–30 week studies[5], benefits were observed to possibly persist for up to 2.8 years. Donepezil's benefits have been demonstrated in the nursing home setting[6], and in one study[7], treatment delayed nursing home placement by 18 months. A one-year, double-blind study[8] found donepezil to be both cost effective and to reduce the time caregivers spent providing care by 400 hours annually. The sustained benefits of long-term treatment remain controversial, however. One study suggested no significant benefits compared to placebo persisting after three years[9], while another study[10] did demonstrate sustained benefits over three years, particularly in participants who began treatment immediately, as opposed to receiving placebo for the first year.

Donepezil's benefits have been found to extend to the severe stages of AD as well. In one six-month, placebo-controlled, double-blind study of participants with MMSE scores less than or equal to 10[11], those receiving donepezil performed better on measures of cognitive function and activities of daily living. In 2006, donepezil received FDA approval for the treatment of severe AD and is currently the only acetylcholinesterase inhibitor approved for treatment during all disease stages.

Side Effects

Donepezil's side-effects profile and those of the other marketed cholinesterase inhibitors are similar. Gastrointestinal symptoms

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

Table 52.1 Common and less common side effects of cholinesterase inhibitors and memantine

Medication class	*Common side effects*	*Less common side effects*
Cholinesterase inhibitors	Nausea Vomiting Diarrhoea	Anorexia Muscle cramps Insomnia Nightmares Bradycardia Syncope
Memantine	None	Dizziness Constipation Headaches

(e.g. nausea, loose stool) are most common and usually mild and transient, though in some cases these symptoms can be severe. Patients sometimes experience vivid nightmares; discussion of this with patients and caregivers is important as they may not automatically associate these unpleasant experiences with a medication side effect. Muscle cramps and diaphoresis may also occur. Due to its cholinergic properties, caution should be used in patients with pre-existing bradycardia. These cholinergic effects are the likely cause of the most serious side effect, syncope, which may occur in 1% of patients. Table 52.1 displays common and less common side effects for donepezil and other approved AD therapies.

Dosing

The starting dose of donepezil is 5 mg/d. The dose is usually increased to 10 mg/d after four weeks. Side effects are dose dependent and should be monitored. Some clinicians have found doses of 15 mg and 20 mg/d to be tolerated and to confer additional benefit; however, these doses have not been systematically studied and are unapproved. Table 52.2 displays typical dosing guidelines for donepezil and other approved AD therapies.

GALANTAMINE

Cognitive Benefits

Galantamine was FDA approved in 2001 for the treatment of mild to moderately severe AD. A reversible, competitive inhibitor of acetylcholinesterase derived from the snowdrop variety of daffodils, galantamine is also an allosteric modulator of nicotinic acetylcholine receptors. Although nicotinic receptors may increase cholinergic transmission, any additional cognitive benefits specifically conferred by this mechanism remain theoretical. In one six-month, double-blind, placebo-controlled study[12] of 636 participants with mild to moderate AD, those treated with galantamine at doses of 24 mg/d and 32 mg/d scored 3.9 and 3.8 points higher on the 70-point ADAS-Cog scale than those in the placebo group. At the end of a 6-month, open-label extension with all participants receiving 24 mg/d, ADAS-Cog scores for those treated for the entire 12 months with 24 mg/d remained stable, with less benefit seen in those who started on 32 mg/d and then decreased to 24 mg/d, possibly due to a rebound effect. Although the six-month, double-blind phase showed no benefit on the Disability Assessment for Dementia (DAD) measurement of activities of daily living (ADLs), at the end of the open-label extension, ADL scores for participants receiving galantamine remained at pre-treatment baseline. A later double-blind, placebo-controlled study of 653 participants demonstrated the benefit of galantamine on DAD scores[13]. In a 36-month, open-label trial of galantamine[14], the 194 participants with mild to moderate AD were assessed as experiencing 50% less cognitive decline than would be expected without treatment. An extended-release form of galantamine was FDA approved in late 2004, and has been shown to have similar bioavailability to the immediate-release galantamine. The benefits of galantamine in severe AD are less certain than is the case for donepezil. In a recent placebo-controlled, double-blind study of 407 participants with severe AD, those treated with galantamine demonstrated improvement in cognitive function, but not in activities of daily living. Galantamine remains approved for treatment of mild to moderate AD only. Galantamine is also currently the only acetylcholinesterase inhibitor available in generic form.

Table 52.2 Starting and optimal treatment doses for cholinesterase inhibitors and memantine

Medication	*Starting dose*	*Optimal dose*
Donepezil	5 mg daily	10 mg daily
Galantamine	4 mg bid immediate release	12 mg bid immediate release
	8 mg daily extended release	24 mg daily extended release
Rivastigmine	1.5 mg bid immediate release	6 mg bid immediate release
	4.6 mg/24 hours for patch	9.5 mg/24 hours for patch
Memantine	5 mg daily	10 mg bid

Dosing

The starting dose for immediate-release galantamine is 4 mg twice daily. This is increased after one month to 8 mg twice daily. Depending on response, patients can remain at this dose, or increase to 12 mg twice daily after one month. Extended-release galantamine is begun at 8 mg/d and is increased to 16 mg/d after one month, with the option after at least one month to increase to 24 mg/d. Galantamine should be taken with food to reduce gastrointestinal side effects.

Side Effects

The side effects of galantamine are essentially identical to those of donepezil (see above). Gastrointestinal side effects may be slightly more frequent with galantamine than donepezil. For many patients, however, the cost savings due to its availability in generic form may offset this minor disadvantage.

RIVASTIGMINE

Rivastigmine was approved in 2000 and, unlike donepezil and galantamine, is a reversible inhibitor of both acetylcholinesterase and butyrylcholinesterase. Although research suggests that butyrylcholinesterase plays a role in acetylcholine breakdown in AD, as is the case for the allosteric nicotinic properties of galantamine, the clinical significance of this additional mechanism of action remains

unclear. Like galantamine, rivastigmine is currently approved for the treatment of mild to moderate AD. In a placebo-controlled, double-blind study of 725 participants with mild to moderate AD[15], the treatment group was randomized to either 1–4 mg/d or 6–12 mg/d, and more participants in the 6–12 mg/d group improved by ≥ 4 points on the ADAS-Cog; improvement compared to the other groups was also seen in a scale of progressive deterioration. Nearly a quarter of participants discontinued the higher dose treatment due to side effects, however, mostly gastrointestinal. In a study demonstrating similar clinical outcomes[16], only 55% tolerated the 12 mg/d dose. In a 26-week, open-label extension of a 26-week, double-blind study of rivastigmine at 6–12 mg/d[17], participants treated with rivastigmine for the entire 52-week study duration had improved cognition compared to those initially receiving placebo. Open-label data suggest benefit for rivastigmine over even longer durations. Using a baseline-dependent mathematical model, Small *et al*.[18] demonstrated that patients treated with rivastigmine for up to five years experienced less decline on the MMSE than would be expected in a modelled untreated group.

Since 2007, a rivastigmine 24-hour transdermal patch has also been approved by the FDA for the treatment of mild to moderate AD. The efficacy of the transdermal patch appears to be similar to that of 12 mg/d oral rivastigmine, with three-fold *fewer* gastrointestinal side effects[19].

Side Effects

While oral rivastigmine has been associated with a high occurrence of gastrointestinal side effects, with the 24-hour transdermal patch, these side effects now appear comparable to those of donepezil and galantamine. Side effects otherwise are similar to donepezil (see above) and galantamine. Rare cases of oesophageal rupture have been reported, and restarting rivastigmine at higher than the minimum dose after several weeks or more off from the medication may place patients at increased risk for this. Oral rivastigmine should be taken with food.

Dosing

Oral rivastigmine is usually begun at 1.5 mg twice daily. At minimum two-week intervals, the dose is gradually increased in 1.5 mg twice-daily increments up to a maximum dose of 6 mg twice daily. Increasing the dose titration intervals from two weeks to four weeks may decrease side effects, and rivastigmine should be taken with food[2]. The rivastigmine 24-hour transdermal patch is started at 4.6 mg/24 hours, and after one month can be increased to 9.5 mg/24 hours. Switching from oral rivastigmine to transdermal patch typically does not require delay, and most patients taking 9–12 mg of oral rivastigmine daily can immediately switch to the 9.5 mg/24 hours patch[2].

COMPARATIVE EFFICACY AND TOLERABILITY

Several studies have compared the efficacy and tolerability of cholinesterase inhibitors in the treatment of AD. In one 12-week, open-label study of donepezil and oral rivastigmine in the treatment of mild to moderate AD[20], similar improvements were noted in both groups on the ADAS-Cog. Tolerability favoured donepezil. Only 47% of the rivastigmine group remained on the maximum dose (6 mg twice daily), compared to 88% for donepezil (at 10 mg/d). The rivastigmine group was also twice as likely to discontinue treatment due to side effects (22% vs. 11%). Another study compared donepezil to oral rivastigmine in 994 participants with moderate to moderately severe AD over a two-year period[21] and found that while cognitive benefits were similar, the rivastigmine group performed better in activities of living and daily functioning, though only in the intention-to-treat population. Although adverse events, especially gastrointestinal, were more frequent with rivastigmine during the titration phase, no difference was evident in the maintenance phase, and serious adverse events were nearly identical at 32%.

In a 52-week comparison of donepezil and galantamine in 182 AD participants[22], galantamine treatment trended to fewer declines in MMSE score and, in the subgroup of participants with MMSE scores between 12 and 18, fewer declines on the ADAS-Cog. Although no difference was found in performance of activities of daily living, caregivers from the galantamine group reported larger reductions in burden. In contrast, a recent meta-analysis of comparison trials among acetylcholinesterase inhibitors found that, while cognitive profiles among the three were similar, the relative risk of global response favoured donepezil and rivastigmine over galantamine (relative risks 1.63 and 1.42 respectively). Adverse events were lowest for donepezil and highest for rivastigmine, although with the introduction of the rivastigmine transdermal patch, which has improved tolerability, this difference may be less relevant. In interpreting the above inconsistent research, clinicians would be wise to consider Farlow and Boustani's[2] observation that the companies sponsoring comparison trials often have conflicts of interest, and the results 'must be judged with caution'.

SWITCHING ACETYLCHOLINESTERASE INHIBITORS

Given the similar mechanisms of action among acetylcholinesterase inhibitors, it might be anticipated that patients failing to benefit from one of these agents would be unlikely to benefit from switching to another. Research, however, has suggested that non-responders may benefit from such a medication change. Most studies have focused on a switch from donepezil or galantamine to rivastigmine and have been open label, which limits interpretation of results. In one recent study[23], 270 participants with mild to moderate AD who had not adequately responded to donepezil were immediately switched to rivastigmine and followed for 26 weeks. Seventy percent of these donepezil non-responders either improved or showed no deterioration in global functioning, although only 69% completed the trial and 54% experienced at least one adverse event, mostly gastrointestinal. One hundred and forty six of these participants entered a 26-week, open-label extension[16] in which rivastigmine was generally well tolerated, and 80% completed the trial. Similar results have been found in other studies of non-responders who switch from donepezil or galantamine to rivastigmine[24]. Unfortunately, no published research has evaluated switching from another acetylcholinesterase inhibitor to donepezil or galantamine; nor has any study evaluated the benefits of a medication change for rivastigmine non-responders.

PRESCRIBING AND MONITORING ACETYLCHOLINESTERASE INHIBITORS

When to Begin

All acetylcholinesterase inhibitors are approved for the treatment of mild AD. Some research points to the benefits of starting treatment as early as possible after the diagnosis is made; in several

clinical trials, participants who began on placebo and switched to a cholinesterase inhibitor were never able to 'catch up' to study peers who received treatment all along[25]. In patients who do not yet meet criteria for dementia but are diagnosed with mild cognitive impairment (MCI), evidence does not support the use of cholinesterase inhibitors. Potential benefits have been described as 'minor, short-lived and associated with significant side effects'[26]. If a clinician chooses to begin a cholinesterase inhibitor in an MCI patient (e.g. at the patient's request), disclosure to the patient about the limited known benefits as well as side-effect risks is essential.

Which Cholinesterase Inhibitor to Choose

As reviewed above, limited comparison data are available and research suggests that the three medications are roughly equivalent in efficacy. Most clinicians decide which drug to use based on side-effect profile and patient convenience. For a patient vulnerable to gastrointestinal upset, for example, donepezil may be preferable as gastrointestinal symptoms are likely mildest. If cost is a concern, galantamine is currently the only cholinesterase inhibitor available as a generic. The rivastigmine 24-hour transdermal patch might be an appropriate choice for patients who do not wish to or have difficulty taking oral medication. Because oral rivastigmine is associated with frequent gastrointestinal symptoms and confers no benefit over the patch, it is now uncommonly prescribed.

How Long to Continue Treatment

Guidance in this regard is limited. Most studies demonstrating benefit after six months of treatment have been open label; instead of placebo-controlled, participant outcomes are compared against the expected outcomes of a theoretical untreated cohort. Many clinicians, including the authors, recommend a trial of at least six months, with use of at least one and preferably several outcome measures (e.g. MMSE, opinion of caregivers)[1]. If no clear improvement or stabilization is evident after six months, a trial off the medication should be strongly considered, with close observation for decline and a plan to reinitiate treatment if such occurs. Reinitiation should occur promptly, as some research suggests that after a washout of more than several weeks, patients may not regain full treatment benefits after restarting the drug[27]. If no difference is seen off the medication, consideration should be given to switching to another cholinesterase inhibitor. As reviewed above, most available evidence supports the benefit of switching to rivastigmine from another cholinesterase that has not provided benefit.

MEMANTINE

Rationale

Glutamate excitotoxicity may play an important role in the death of neurons in AD. It is hypothesized that injured glutamate-producing neurons release excessive amounts of glutamate, resulting in injury and death to downstream neurons. This likely occurs via glutamate's activation of calcium channels, leading to influx of calcium into downstream neurons. Memantine, a non-competitive antagonist of the *N*-methyl-D-aspartate (NMDA) receptor of glutamate, is believed to protect these neurons by preventing the glutamate-mediated cascade of neuronal damage.

Cognitive Benefits

Memantine has been FDA approved since 2003 for the treatment of moderate to severe Alzheimer's disease. In one 28-week, placebo-controlled, double-blind trial of memantine at 20 mg/d in 252 participants with moderate to severe AD[28], participants treated with memantine had improved outcomes compared to placebo on measurements of global assessment of change, activities of daily living and cognitive functioning. Another placebo-controlled, 12-week study in participants with moderately severe dementia (either AD or vascular dementia) found memantine use to be associated with a significant decrease in care dependence[29]. A 24-week, open-label extension of the above-mentioned 28-week study[30] demonstrated benefits both in participants who remained on memantine for the entire study duration and those who switched from memantine to placebo. One study suggests that the addition of memantine to donepezil may confer additional advantages in cognition, activities of daily living, global outcome and behaviour[31]. A more recent study suggests that addition of memantine to a cholinesterase inhibitor delays time to nursing home admission[32]. A third study of memantine addition to a cholinesterase inhibitor, however, found no benefit over placebo[33]. Although some evidence suggests benefits in mild AD, memantine is not FDA approved for this purpose.

Side Effects

Memantine is well tolerated by most patients and side effects are uncommon. These can include dizziness, constipation and headaches. The presence of severe renal impairment is a contraindication, and the dose should be reduced in the presence of moderate renal insufficiency.

Dosing

Memantine is started at 5 mg/d and the dose is increased by 5 mg/d weekly until a total dose of 20 mg/d is reached, typically using a commercially available 'titration starter pack'. After initial titration, memantine is administered in a divided dose of 10 mg twice daily.

Prescribing and Monitoring Memantine

A memantine trial should be considered in patients with moderate to severe AD who are able to tolerate such. Memantine can be prescribed in combination with a cholinesterase inhibitor which, as indicated above, may confer additional advantages. Negligible guidance exists as to how long to continue a memantine trial. Most clinicians, including the authors, recommend re-evaluating use every six months, as with the cholinesterase inhibitors. Because cognitive measures (i.e. MMSE) are less useful in advanced dementia, increased emphasis should be placed on the report of caregivers, including professional providers in the assisted living and nursing home setting.

NEUROPSYCHIATRIC EFFECTS OF CHOLINESTERASE INHIBITORS AND MEMANTINE

Neuropsychiatric symptoms (e.g. apathy, agitation, delusions) are nearly universal in patients with Alzheimer's disease, with over 90% experiencing at least one such symptom over the illness course. While these symptoms are often distressing to patients

and caregivers, conventional treatments such as antipsychotics, antidepressants and mood stabilizers are often inadequately effective or cause significant side effects. Studies reporting positive neurobehavioural effects of cholinesterase inhibitors and memantine are therefore of particular interest. In a study by Holmes *et al*.[34], 134 participants with mild to moderate AD and significant neuropsychiatric co-morbidity (defined as a neuropsychiatric inventory (NPI) score >11) were randomized to donepezil or placebo for 12 weeks (following a 12-week, open-label donepezil trial). At the end of 12 weeks, NPI scores were 6.2 points lower in the donepezil group compared to placebo. Similar improvement has been demonstrated in trials of galantamine[35] and rivastigmine[36]. Another 12-week study of 272 AD patients with significant agitation[37], however, showed no benefit with donepezil treatment compared to placebo. In studies showing positive benefits of donepezil, apathy and mood symptoms appear most likely to respond. The addition of memantine to a cholinesterase inhibitor may confer additional benefit. In a 24-week, placebo-controlled, double-blind study of 404 participants with moderate to severe AD[38], those treated with memantine and donepezil demonstrated improvement on the NPI compared to those treated with donepezil alone. Memantine's benefits were most pronounced on agitation, eating behaviour and irritability.

Despite the above encouraging findings, cholinesterase inhibitors and memantine currently have at best a limited role in the treatment of neuropsychiatric symptoms in AD. Although most clinical trials report positive treatment effects, these effects are typically modest. Heterogeneity among studies also exists regarding which symptoms are most likely to respond[38], making decisions to target a specific neuropsychiatric symptom with an antidementia drug difficult. Another factor limiting the applicability of these findings to clinical care is that, in most published studies, improvement of neuropsychiatric symptoms was a secondary outcome. A review by Cummings *et al*.[39] notes that of 13 placebo-controlled, double-blind trials, only 4 included behavioural change as a primary outcome. For these reasons, the authors do not recommend cholinesterase inhibitors as first-line treatment for any neuropsychiatric symptom causing severe distress. However, in situations where symptoms are mild to moderate in severity and an immediate intervention is not required, a trial of a cholinesterase inhibitor or memantine is a reasonable first step before resorting to pharmacotherapy (e.g. antipsychotics, mood stabilizers) that carries higher side-effect risks. An antidementia drug trial may be particularly appropriate for apathy and irritability both because studies suggest that these symptoms may be most responsive and because alternative effective pharmacotherapy options are especially limited.

ALTERNATIVE THERAPIES FOR ALZHEIMER'S DISEASE

The cholinesterase inhibitors and memantine are currently the only FDA-approved treatments for AD. Various unapproved alternative treatments which have been proposed include vitamin B12, folic acid, vitamin E, *Ginkgo biloba* and serotonergic augmentation with serotonin-specific re-uptake blockers (SSRIs). None of these treatments are supported by sufficient evidence to be recommended by clinicians. Patients and caregivers often inquire about these, however, and they are reviewed below.

Vitamin B12 and Folate

Elevated homocysteine levels have been linked to Alzheimer's disease, and studies have demonstrated an association between high levels of homocysteine and cognitive dysfunction even in the non-demented elderly. Because vitamin B12 and folate are linked to reduction in homocysteine levels, they have been proposed as treatments for AD. Unfortunately, trials to date do not support clinical benefit. A recent double-blind trial of 409 participants with mild to moderate AD randomized to placebo or high-dose vitamin supplementation (folate, B6 and B12)[40] demonstrated that, although vitamin supplementation was associated with decreased homocysteine levels, no clinical improvements were evident. This is consistent with prior studies showing no cognitive benefit from folic acid supplementation with or without vitamin B12[41]. Vitamin supplementation in the above study was also associated with an increase in depression reaching marginal significance. Thus, vitamin B12 or folate cannot be recommended as treatments for AD.

Ginkgo Biloba

Oxidative stress has been linked to the neuropathological changes in AD, and *Ginkgo biloba* has been proposed as a putative therapy due to its antioxidant properties; recent evidence suggests some anti-amyloid aggregation effects as well. Despite these theoretical rationales, clinical benefits are unclear. One placebo-controlled, double-blind study of 513 participants with mild to moderate AD[42] found no difference between placebo and treatment groups. However, the authors note that this study may have been compromised by the negligible decline observed in the placebo group. Also, participants with neuropsychiatric symptoms did appear to benefit cognitively compared to placebo. A recent Cochrane review[43] of 36 trials describes the evidence for ginkgo as 'inconsistent and unreliable'. Ginkgo is generally well tolerated, but carries a small risk of intracranial bleeding. The authors do not recommend use of ginkgo to treat AD, but would not strongly discourage patients who wish to take it[1].

Vitamin E

Similar to *Ginkgo biloba*, vitamin E has antioxidant properties hypothesized to be of benefit in treating AD. One placebo-controlled, double-blind trial suggested that high-dose vitamin E (2000 international units daily) may slow functional decline in moderate AD[44]. These findings have been considered controversial because clinical significance was found only after adjustment for higher MMSE score in the placebo group. More recent findings have suggested that high-dose vitamin E may be associated with a small increased mortality risk in the elderly. The authors therefore do not recommend vitamin E supplementation in AD, but would not discourage patients wishing to start vitamin E in doses of 1000 international units daily or less.

SSRI Augmentation

Although acetylcholine is the neurotransmitter most highly linked to the cognitive deficits of AD, other neurotransmitters are presumed to play important roles as well. Despite uncertainty about the relationship between serotonin and cognition in AD, some clinicians have observed a modest increase in functional performance in patients treated with SSRIs[2]. In a study by Mowla of 122 participants with mild to moderate AD[45], cognition improved equally whether subjects were treated with rivastigmine or rivastigmine plus fluoxetine. However, those treated with the combination therapy performed better in activities of daily living and global functioning.

Some of the functional improvement clinicians report with SSRI treatment may actually reflect improvement in underlying depression; Lyketsos *et al*.[46], for example, found functional decline to be attenuated in depressed AD participants who responded to antidepressant therapy.

FUTURE THERAPIES FOR AD

To date, only symptomatic pharmacotherapies are available for the treatment of AD. Despite the consistently demonstrated efficacy of these medications, their benefit remains frustratingly modest in degree. Current research focuses on the development of novel therapeutic strategies which are disease modifying. Although the pathological mechanisms leading to neuronal loss in AD remain only partially understood, abnormal amyloid processing appears to be a crucial early step. When amyloid precursor protein (APP), which is normally cleaved by alpha secretase, is instead cleaved by beta and then gamma secretase, insoluble extracellular amyloid plaques occur. These plaques have been implicated in neuronal death. Some treatments under development therefore aim to either inhibit beta or gamma secretase, or to enhance alpha secretase activity. Other proposed treatments target the aggregation of amyloid into plaques. Neprolysin, an amyloid-degrading enzyme, is one such target under study. Immunotherapies have also been designed with the intent to clear abnormally processed amyloid from the brain. Although an early clinical trial of an active amyloid-beta vaccine was discontinued after several participants developed meningoencephalitis, modified versions of this vaccine believed less likely to have this adverse effect have since been developed and are being tested.

Neurofibrillary tangles of phosphorylated tau protein are another hallmark AD pathology. These tangles are hypothesized to cause neuronal death by interfering with microtubule function. Proposed therapies to promote microtubule stability include tau kinase inhibitors and the anticancer compound paclitaxel. Although still in early development, viral vectors to deliver genes to modify AD neuropathology are another hopeful area of research.

The results of recent clinical trials for novel AD therapies have unfortunately been discouraging. The failure to demonstrate benefit may at least in part reflect that some AD therapies will work best in certain 'subtypes' of the disease, in certain stages of severity, or in individuals with specific characteristics (e.g. gender, apolipoprotein E status). Increasing attention has therefore focused on biomarkers, which may differentiate which patients are most likely to benefit from different therapies. Such biomarkers may also assist in determining drug response in pre-symptomatic patients, serve as outcome measures in clinical trials of symptomatic patients, and aid in determining whether further development of a treatment is warranted[47].

CONCLUSION

Although a cure for AD remains elusive, available symptomatic therapies may slow cognitive and functional decline, delay the need for a higher level of care and decrease caregiver burden. Donepezil is currently approved for the treatment of all AD stages, galantamine and rivastigmine for mild to moderate AD, and memantine for moderate to severe. These medications are typically well tolerated. Severe side effects are more common with cholinesterase inhibitors and are mostly gastrointestinal in nature. Although none of the available pharmacological treatments can presently be recommended as a first-line therapy for any neuropsychiatric symptom, some patients may experience behavioural benefits, especially in regards to mood and apathy. Negligible evidence exists for vitamin supplementation, *Ginkgo biloba* or SSRI augmentation as treatments for AD. When a patient or caregiver inquires about beginning an unapproved therapy, a careful discussion of the available evidence and potential risks is warranted. Current research focuses on the development of treatments which are disease-modifying. The investigation of valid biomarkers for AD may be pivotal in determining which treatments are most promising, and in which subgroups of AD patients they are most likely to be effective.

INTRODUCTION

Behavioural symptoms are common in patients with Alzheimer's disease (AD) and contribute substantially to morbidity[1–3]. As many as 80% of Alzheimer's patients develop behavioural changes, typically with increasing frequency as the disease progresses[4]. Estimates range from between 30–50% for delusions or hallucinations and up to 70% for agitated or aggressive behaviors[5]. Behavioural symptoms have long been known to contribute to caregiver distress[5,6]. More recent work has found that 46% of caregivers cite dementia-related behaviours as a primary reason for institutionalization[7]. Behavioural symptoms in patients with AD significantly increase direct costs of care, a cost which may be lessened by appropriate psychopharmacological management[8,9]. In this chapter, descriptions of the most common behavioural disturbances observed in AD and other dementias are provided, followed by examples of common measurement tools used in research to study these symptoms. The currently available pharmacological options for treating the behavioural symptoms of dementia are then reviewed, highlighting areas in which data can help guide targeted treatment of specific symptoms. This chapter concludes with a discussion of general treatment principles, intended to aid clinicians in an era when there are not clearly benign and beneficial treatment options available to address the ongoing severe and complex behavioural symptoms of dementia[10].

The psychosis of AD typically consists of delusions, misidentification syndromes and, less frequently, visual or auditory hallucinations[3,11]. Delusions of dementia tend to be simple, non-bizarre and often reflective of misinterpretation of the environment. The delusion of stealing is most prevalent, followed by persecutory delusions, delusions of reference, infidelity, grandiosity and somatic delusions[12]. Delusions are more common in moderate stages of the illness and are associated with greater cognitive impairment. Likewise, hallucinations are rare in the early stages of AD and become more common in the later stages[13]. The most common misidentification syndromes include failure to recognize one's home ('this is not my home' phenomenon), the belief that strangers are living in the home (phantom boarder syndrome) and imposter loved ones (Capgras phenomenon)[14]. Psychosis in AD clearly represents a syndrome distinct from schizophrenia in elderly patients, with only rare presence of first-rank Schneiderian symptoms and a higher rate of eventual remission of psychosis. In contrast to treatment of older adults with schizophrenia, antipsychotic treatment of psychosis in AD, described in detail below, is characterized by lower doses of medication, shorter duration of treatment and greater vulnerability to extrapyramidal symptoms (EPS).

Agitation in dementia has been defined as inappropriate verbal, vocal or motor behaviours not judged by an outside observer to result directly from the needs or confusion of the agitated individual. Increasing agitation is associated with advanced dementia, pre-morbid aggression and rapid decline. AD patients often also develop depression and anxiety, which in general are managed with antidepressant medications. While these topics will not be addressed in depth during this chapter, it is important to note that, similar to the contrast between schizophrenia and the psychosis of AD, substantial differences exist between primary mood and anxiety disorders versus dementia-related psychological symptoms in terms of aetiology, manifestations and treatment response.

Several standard neuropsychiatric symptom rating scales are used, primarily in research settings, to categorize the common behavioural and psychological symptoms in dementia (BPSD) (Table 53.1). Four of the most widely used general rating instruments include the Neuropsychiatric Inventory (NPI), the Brief Psychiatric Rating Scale (BPRS), the Neurobehavioral Rating Scale (NBRS) and the Cohen–Mansfield Agitation Inventory (CMAI). The NPI measures the frequency and severity of 12 psychiatric symptoms on the basis of caregiver report[15]. The items are delusions, hallucinations, agitation/aggression, depression/dysphoria, anxiety, elation, apathy/indifference, disinhibition, irritability/lability, aberrant motor behaviour, sleep disturbance, and appetite and eating disorder. The BPRS measures the severity of 18 psychiatric and behavioural symptoms, typically scored by a trained clinician after a semi-structured patient interview and collection of additional information from caregivers[16]. The NBRS has 28 items, covering areas including agitation (aggression, agitation, hostility) and psychosis (suspiciousness, hallucinations, delusions) and is completed by an observer on a 7-point scale[17]. The CMAI rates the frequency of 29 agitated behaviours in four factors on 7-point scales[18].

Table 53.1 Neuropsychiatric symptom rating scales

Agitated Behavior Inventory for Dementia (ABID)
Agitation-Calmness Evaluation Scale (ACES)
Alzheimer Disease Assessment Scale, non-cognitive portion (ADAS–noncog)
Bech–Rafaelsen Mania Scale (BRMS)
Behavior Observation Scale for Intramural Psychogeriatric Patients (GIP)
Behavior Rating Scale for Dementia (BRSD)
Behavioral Pathology in Alzheimer Disease Rating Scale (BEHAVE–AD)
Brief Psychiatric Rating Scale (BPRS)
Caregiver Burden Questionnaire (CBQ)
Clinical Global Impression of Change (CGIC)
Clinical Global Impression Scale (CGIS)
Clinicians Interview Based Impression of Change plus caregiver input (CIBIC–plus)
Cohen–Mansfield Agitation Inventory (CMAI)
Hamilton Rating Scale for Depression (HAM–D)
Iowa Caregiver Stress Inventory (CSI)
Neurobehvaioral Rating Scale (NBRS)
Neuropsychiatric Inventory (NPI)
Neuropsychiatric Inventory–Nursing Home version (NPI–NH)
Neuropsychiatric Inventory minus 5 'mood' items (NPI–NM)
Overt Aggression Scale (OAS)
Positive and Negative Syndrome Scale–Excited Component (PANSS–EC)
Revised Memory and Behavior Problem Checklist (RMBPC)
Screen for Caregiver Burden (SCB)
Social Dysfunction and Aggression Scale (SDAS–9)

When approaching behavioural disturbances in dementia, the overall preferred approach to management includes: (i) assessing to characterize the specific psychiatric or behavioural symptoms; (ii) developing an appropriate set of nonpharmacological behavioural interventions; and (iii) considering medication treatment if there are immediate safety concerns or insufficient response to behavioural interventions. To date, there are no FDA-approved medications for behavioural management of AD. The largest amount of available evidence studying psychosis and/or agitation associated with dementia suggests a modest efficacy of antipsychotic medications in symptom reduction, in the context of these medications now carrying a 'black box' warning regarding use in elderly patients with dementia. What follows is a review of the options available for pharmacological management of behavioural symptoms of dementia. See Tables 53.2 and 53.3 for dosing and side-effect information for agents discussed below.

ANTIPSYCHOTIC MEDICATIONS

Efficacy Trials

The majority of data examining the psychopharmacological management of behavioural symptoms in dementia exist for the use of antipsychotic medications. Historically, short-term (6–12 week), double-blind, placebo-controlled, randomized controlled trials (RCTs) were completed using standardized neuropsychiatric symptom rating scales. These trials have been reviewed in depth in prior publications; here, the reader is referred to Table 53.4 for a summary of published trial results.

In total, efficacy trials of antipsychotic medications have demonstrated a modest benefit for treatment of agitated behaviour and psychosis in AD and other dementias. However, there is heterogeneity of these findings, with multiple studies also showing no benefit of antipsychotic treatment on primary or secondary outcome measures. Efficacy trials in this arena have typically had high placebo response rates, underscoring the likely importance of several general effects, including the passage of time, increased attention and the expectation of therapeutic intervention. Medication benefit has further been counteracted by adverse events.

As discussed in more detail at the end of this chapter, the decision to use medication and antipsychotic medications in particular should be made in parallel to the process of ongoing optimization of the social and environmental setting of each patient. Concerning results from meta-analyses and a recent large effectiveness trial underscore the importance of completing a thorough individualized risk–benefit analysis prior to initiating psychopharmacological management of behavioural disturbances in dementia with antipsychotic or other medications. However, despite the potential risks involved, antipsychotic medications continue to be used to manage particularly severe and persistent symptoms in patients with dementia, due in large part to a lack of available alternative with substantial supporting evidence.

Meta-Analyses

Schneider *et al*. reported a meta-analysis of RCT data on the efficacy and adverse effects of atypical antipsychotic medications for dementia[19]. Using a combination of published and drug company data, they reported on 15 RCTs (three on aripiprazole, five on olanzapine, three on quetiapine and five on risperidone) with a total of 3353 patients assigned to active treatment versus 1757 patients treated with placebo. The majority of patients had AD (87%), were female (70%) and averaged 81 years of age. Mean MMSE score was 11. Eleven trials were conducted in nursing homes and four were completed on outpatients. While approximately half of included trials were designed to recruit subjects with psychosis and the other half agitation, the authors found that most studies had a mixture of

Table 53.2 Dosage and adverse effects of atypical antipsychotics in dementia

Medication	*Initial dose (mg/day)*	*Usual dosage range (mg/day)*	*Sedation*	*Hypo-tension*	*Anti-cholinergic*	*EPS*	*Weight gain*
Risperidone	0.5	0.5–2	++	++	+/–	+	++
Olanzapine	2.5–5	5–10	+++	++	+	+	+++
Quetiapine	25	25–250	++	++	+/–	–	++
Aripiprazole	5	5–15	+	+	+/–	–	+/–

Table 53.3 Dosage and adverse effects of other agents in dementia

Medication	*Initial dose (mg/day)*	*Usual dosage range (mg/day)*	*Common adverse effects*	*Precautions*
Cognitive enhancers				
Donepezil	5	5–10	Nausea, diarrhoea	Bradycardia
Galantamine	8	16–24	Nausea, diarrhoea	Bradycardia
Rivastigmine	3	6–12	Nausea, diarrhoea	Bradycardia
Memantine	5	10–20	Sedation	Dose reduction with kidney impairment
Antidepressants				
Citalopram	10	10–40	Nausea, diarrhoea	Hyponatremia, EPS
Sertraline	25	50–200	Nausea, diarrhoea, insomnia	Hyponatremia, EPS
Trazodone	25	50–200	Sedation, orthostasis	Priapism (rare)
Mood stabilizers				
Divalproex sodium	125–250	250–1000	Nausea, sedation	Liver function abnormalities, thrombocytopenia, pancreatitis
Carbamazepine	50–100	200–1000	Nausea, sedation, ataxia	Hyponatremia, pancytopenia, drug interactions

patients with psychosis and agitation, a subject pool likely to reflect typical clinical populations.

After combining the trials, symptomatic efficacy was observed for aripiprazole and risperidone while olanzapine was not associated with efficacy overall. The available quetiapine trials used different selection criteria and outcomes and thus could not be statistically combined. In general, there was heterogeneity of findings across trials. Larger effect sizes were seen in patients without psychosis (vs. with psychosis), for those in nursing homes (vs. outpatients) and in patients with more severe cognitive impairment (MMSE less than 10). Approximately one-third of subjects dropped out of the trials, without significant difference between drug and placebo groups. The most common adverse events were somnolence and urinary tract infections or incontinence; increased incidence of extra-pyramidal symptoms and gait abnormalities were seen with risperidone and olanzapine. The authors noted a significant risk for cerebrovascular events, especially with risperidone. In addition, an increased risk for overall death was observed, which will be discussed in more detail below.

Two meta-analyses of typical antipsychotic medications found that neuroleptics are significantly more effective than placebo for behavioural disturbances in dementia, albeit with a small effect size and without differential efficacy between particular agents. For example, results from a meta-analysis of six studies comparing thioridazine with another neuroleptic and five studies comparing haloperidol with another neuroleptic, did not show that these two medications differed significantly from comparison medications[20]. In another meta-analysis, Lonergan *et al*. examined five RCTs comparing haloperidol to placebo and found that aggression decreased among patients with agitated dementia treated with haloperidol; other aspects of agitation were not affected significantly in treated patients, compared with controls[21].

A recent meta-analysis of patients with psychosis of AD from four large placebo-controlled clinical trials of risperidone in dementia demonstrated that risperidone significantly improved scores on the BEHAVE-AD Psychosis subscale and CGI scale compared with placebo[22]. Secondary analyses demonstrated that patients with more severe symptoms showed a more pronounced response to treatment with risperidone compared with placebo than those patients with less severe symptoms. Extra-pyramidal symptoms and somnolence were more frequent with risperidone than placebo ($p = 0.04$). Cerebrovascular adverse events and all-cause mortality were observed more frequently, although not statistically significantly, with risperidone versus placebo.

Effectiveness Data: NIMH CATIE-AD Trial

The National Institute of Mental Health (NIMH) Clinical Antipsychotic Trials of Intervention Effectiveness–Alzheimer's Disease (CATIE–AD) project compared the effectiveness of antipsychotic medications versus placebo in treating AD-associated psychosis or agitated/aggressive behaviour[23]. CATIE–AD included outpatients in usual care settings and assessed treatment outcome on several clinical measures over nine months. Initial CATIE–AD treatment (olanzapine, quetiapine, risperidone or placebo) was randomized and masked, yet the protocol allowed medication dose adjustments or a switch to a different treatment at any time on the basis of the clinician's judgement. The primary CATIE–AD phase 1 outcome was time to discontinuation of the initially assigned medication for any reason, which was intended as an overall measure of effectiveness that incorporated the judgements of patients, caregivers and clinicians about therapeutic benefits in relation to undesirable effects.

The two primary hypotheses were that (i) there would be pair-wise differences between the three antipsychotic treatment groups and the placebo group in the time to discontinuation for any reason and (ii) among antipsychotic medications that were different from placebo, none would be inferior to the others. The results revealed no pair-wise treatment differences in all-cause discontinuation. The benefits of olanzapine and risperidone, i.e. longer times to discontinuation for lack of efficacy in comparison to placebo (Kaplan–Meier estimate of median time: olanzapine, 22.1 weeks; quetiapine, 9.1 weeks; risperidone, 26.7 weeks; placebo, 9.0 weeks), were offset by shorter times to discontinuation due to adverse effects in the antipsychotic groups (discontinuations due to intolerability: olanzapine, 24%; quetiapine, 16%; risperidone, 18%; placebo, 5%)[24]. The mean last prescribed medication dose was 5.5 mg/day olanzapine, 56.5 mg/day quetiapine and 1.0 mg/day risperidone.

A secondary data analysis of phase 1 in CATIE–AD found that some clinical symptoms improved with atypical antipsychotic

Table 53.4 Published randomized double-blind, placebo-controlled trials of atypical antipsychotics for dementia related psychosis or agitation

Study	*Medication(s)*	*Sample size*	*Length (weeks)*	*Primary outcome(s)*	*Secondary outcomes*	*Primary outcome significance*	*Results/Comments*	*Adverse events (AEs)*
Katz *et al.*[65]	Risperidone (0.5–2 mg/d)	625	12	BEHAVE-AD (50% reduction)	BEHAVE-AD psychosis subscale, CMAI, CGIS	Yes	Significant primary outcome (50% or more reduction of BEHAVE-AD in 45% of risperidone 1 mg group and 50% of 2 mg group compared to 33% of placebo group)	More EPS with risperidone 2 mg; dose-dependent increase in somnolence
De Deyn *et al.*[66]	Risperidone (mean dose: 1.1 mg/d), haloperidol (mean dose: 1.2 mg/d)	344	13	BEHAVE-AD (30% reduction)	BEHAVE-AD, CMAI	No	Negative primary outcome – no difference between groups; several positive results for secondary outcomes of risperidone vs. haloperidol and placebo	More somnolence with risperidone than placebo; more EPS with haloperidol than risperidone or placebo
Street *et al.*[67]	Olanzapine (5, 10 or 15 mg/d)	206	6	Sum of NPI-NH agitation/ aggression, hallucinations, delusion scores	NPI-NH, BPRS	Yes	5 mg and 10 mg but not 15 mg had a significant effect on the primary outcome; only 5 mg yielded improved NPI-NH total score	Somnolence and gait disturbance were increased significantly; not EPS
Meehan *et al.*[59]	Olanzapine (2.5 or 5 mg IM), lorazepam (1 mg IM)	204	24 h	PANSS-EC	CMAI, ACES	Yes	Significant mean change in primary outcome at 2 and 24 h for both olanzapine doses; lorazepam with significant effect at 2 h but not 24 h	Not significantly different across groups
Brodaty *et al.*[68]	Risperidone (mean dose: 1.0 mg/d)	345	12	CMAI total aggression score	CMAI, BEHAVE-AD, CGIS, CGIC	Yes	Risperidone improved CMAI-aggression subscale more than placebo (4.4 point difference, $P < .001$); similar results for other outcomes	Sedation, urinary tract infections with risperidone

Table 53.4 (*continued*)

Study	*Medication(s)*	*Sample size*	*Length (weeks)*	*Primary outcome(s)*	*Secondary outcomes*	*Primary outcome significance*	*Results/Comments*	*Adverse events (AEs)*
De Deyn *et al.*[69]	Olanzapine (1–7.5 mg/d)	652	10	NPI-NH psychosis subscale, CGIC	NPIH-NH total and item scores	No	No significant difference on primary outcome between any olanzapine dose and placebo	Weight gain, anorexia and urinary incontinence
Ballard *et al.*[70]	Quetiapine (50–100 mg/d), rivastigmine (6–12 mg/d)	93	26	CMAI	SIB (Severe Impairment Battery)	No	Rivastigmine, quetiapine and placebo equivalent	Statistically significant negative effect on cognition with quetiapine
Deberdt *et al.*[71]	Risperidone (mean dose: 1.0 mg/d), olanzapine (mean dose: 5.2 mg/d)	494	10	NPI, CGIS		No	Improvement regardless of treatment group	EPS with risperidone, weight gain and higher rate of discontinuation due to AEs with olanzapine
De Deyn *et al.*[72]	Aripiprazole (5, 10 or 15 mg/d)	208	10	NPI psychosis subscale, BPRS	BPRS	No	No difference in NPI psychosis subscale decline between aripiprazole (–6.5) and placebo (–5.5). BPRS psychosis and core subscale scores improved significantly with aripiprazole vs. placebo	Mild somnolence, not associated with falls or injury; no increase in EPS
Mintzer *et al.*[73]	Risperidone (mean dose 1.0 mg/d)	473	8	BEHAVE-AD psychosis subscale, CGIC		No	Both placebo and risperidone improved without significant difference	Somnolence occurred significantly more with risperidone
Tariot *et al.*[74]	Quetiapine (mean dose 97 mg/d), haloperidol (mean dose 1.9 mg/d)	284	10	BPRS total, CGIS	BPRS factors, NPI	No	All groups improved without significant differences on primary outcomes	Somnolence with quetiapine and haloperidol; EPS with haloperidol

Table 53.4 (*continued*)

Zhong *et al.*[75]	Quetiapine (100 mg/d or 200 mg/d)	333	10	PANSS-EC	NPI-NH, CMAI	Yes	No significant effect on primary outcome with 100 mg group alone or when combined with 200 mg group, but a significant effect with the 200 mg/day group alone; no effect of quetiapine on CMAI	
Kurlan *et al.*[76]	Quetiapine (mean dose 120 mg/d)	40	10	BPRS score		No	No significant difference in primary or secondary outcomes	Quetiapine did not worsen Parkinsonism; trend towards decline on a measure of daily functioning
Mintzer *et al.*[77]	Aripiprazole (2, 5 or 10 mg/d)	487	10	NPI-NH psychosis subscale	NPI-NH total; CGIS, BPRS, CMAI	Yes	Aripiprazole 10 mg/d but not 2 or 5 mg/d significantly improved the primary outcome	CVAEs were present with aripiprazole ($N = 7$) but not placebo ($N = 0$)
Paleacu *et al.*[78]	Quetiapine (mean dose 200 mg/d)	40	6	NPI, CGIC		No	Reductions in NPI did not differ between placebo and quetiapine; CGIC did decrease significantly in the quetiapine ($P = 0.009$) but not placebo ($P = 0.48$) group	No differences between groups
Streim *et al.*[79]	Aripiprazole (mean dose 9 mg/d)	256	10	NPI-NH psychosis subscale, CGIS	NPI-NH total, BPRS total, CGIC, CMAI	No	No significant difference in co-primary outcomes; improvements in several secondary outcomes	Somnolence increased (14% vs. 4% placebo), no increase in EPS

medications[25]. Data from the last phase 1 observation indicated greater improvement with olanzapine or risperidone on NPI total scores and the BPRS hostile suspiciousness factor, as well as for risperidone alone on the BPRS psychosis factor and the CGIC. There was worsening with olanzapine on the BPRS withdrawn depression factor. Among patients continuing phase 1 treatment at 12 weeks, there were no significant differences between antipsychotic medications and placebo on functioning, care needs or quality of life, except for worsened functioning on an activities of daily living (ADL) scale with olanzapine compared to placebo. These results suggest that specific symptoms, rather than global changes, may be more realistic treatment targets for antipsychotic medications when used in dementia and that anger, aggression and paranoia may improve preferentially with treatment. These and other treatment guidelines will be discussed in more detail at the conclusion of the chapter.

Analysis of the entire 36-week trial revealed that, metabolically, atypical antipsychotic use was associated with a significant weight gain (0.08 lb/week) and increase in BMI (0.02 kg/m^2 per week), with the likelihood of weight gain increasing with longer use of antipsychotic medication[26]. In sub-group analysis, change in weight reached significance for olanzapine (0.12 lb/week) and quetiapine (0.14 lb/week), but not risperidone (0.10 lb/week); similar findings were present for BMI. When examined by gender, these changes in weight and BMI were significant in women (0.14 lb/week and 0.02 kg/m^2 per week, respectively), but not in men (−0.02 lb/week and −0.003 kg/m^2, respectively). Further analysis revealed unfavourable overall changes in HDL cholesterol (−0.19 mg/dl/wk) and waist circumference (0.07 inches/wk) with olanzapine.

Cognitively, patients declined significantly over the course of the trial (e.g. mean total decline in MMSE 2.4 points); a decline apparently increased by antipsychotic treatment[27]. Patients on antipsychotic medications declined more than patients on placebo on all 11 cognitive measures completed in the study, though the majority of differences between active treatment groups and placebo were non-significant. Statistically significant differences included greater decline on the MMSE in the olanzapine group, greater decline on the BPRS cognitive subscale in the quetiapine group and greater decline on a cognitive summary score in the risperidone and olanzapine groups.

Safety Issues with Antipsychotic Medications

Usual side effects of antipsychotic medications include sedation, hypotension, anti-cholinergic effects, extrapyramidal symptoms and weight gain. The general frequency of these side effects varies based on the dose and agent used, as listed in Table 53.2.

Two major safety issues concerning antipsychotic use in dementia, namely cerebrovascular adverse events (CVAEs) and risk of death, have come into focus over the last several years. In 2003, the FDA issued a warning about CVAEs (e.g. stroke, transient ischaemic attack), including fatalities, in patients (mean age 85 years; range 73–97) in trials of risperidone in elderly patients with dementia-related psychosis. In placebo-controlled trials, there was a significantly higher incidence of CVAEs in patients treated with risperidone compared to patients treated with placebo: in combining data from three controlled trials of risperidone, 12 of 744 (1.6%) risperidone-treated patients compared to 4 of 562 (0.7%) placebo-treated patients developed serious cerebrovascular events. Risperidone prescribing information was adjusted to include this risk. A similar warning was issued for olanzapine and aripiprazole by the manufacturers based on similar data. For example, in a pooled analysis of five controlled trials of olanzapine in patients with dementia, 15 patients of the 1178 randomly assigned in the trials to receive olanzapine suffered CVAEs (1.3%), compared with 2 out of the 478 randomly assigned to placebo (0.4%). For the subgroup of patients who had vascular dementia, there was a five-fold higher likelihood of experiencing a CVA. Overall, a meta-analysis found that pooled rates of CVAEs were 1.9% in atypical antipsychotic treated patients versus 0.9% in placebo-treated patients, yielding an odds ratio of 2.1 (95% CI, 1.2–3.8)[19]. Typical antipsychotics appear to be similar to atypical antipsychotics in stroke risk[28,29].

Regarding risk of death, in 2005 the FDA reported that atypical antipsychotic medications were associated with a significantly (1.6–1.7 times) greater mortality risk compared with placebo, based on several analyses of 17 RCTs of 5106 elderly patients with dementia[30]. Most deaths were due to either cardiac or infectious causes, the two most common immediate causes of death in dementia in general. A meta-analysis of 15 RCTs found a risk of death with atypical antipsychotics of 3.5%, compared to 2.3% for placebo, resulting in an odds ratio of 1.5 (95% CI, 1.1–2.2)[31]. Data on typical antipsychotic medications demonstrated a similar elevated risk of death[31,32]. In 2008, the FDA required manufacturers of typical antipsychotic drugs to make safety-related changes to prescribing information to warn about an increased risk of death associated with the off-label use of these drugs to treat behavioural problems in older people with dementia[33].

These safety concerns are highlighted in warnings now on all antipsychotic medications stating that these drugs are not approved for treatment of dementia-related psychosis. This has resulted in efforts to re-evaluate the prescription of antipsychotic medications to patients with dementia. In addition, there is a renewed level of interest in the discovery and development of alternatives to the use of antipsychotic medications in treating the behavioural disturbances found in dementia, as discussed below.

Antipsychotic Withdrawal Trials

In AD patients initially prescribed antipsychotic medications for treatment of behavioural disturbance for at least three months, the DART–AD trial found no significant difference between those randomized to receive continued treatment and those receiving placebo (antipsychotic medication discontinued) in the change of global cognitive function on the Severe Impairment Battery (SIB) or behavioural symptoms (as measured by the NPI) after six months follow-up[34]. A later analysis of this same population found a significantly increased risk of mortality in the patients who continued to receive antipsychotic medications compared to those who received placebo[35]. A similar lack of negative impact on NPI scores with stopping antipsychotic drug therapy in demented nursing home patients was observed in the briefer four-week BEDNURS trial[36].

COGNITIVE ENHANCERS

Cholinesterase Inhibitors

Given the high proportion of patients with advancing dementia placed on cholinesterase inhibitors, several recent studies have examined the possible clinical utility of cognitive enhancers in ameliorating emergent behavioural symptoms. A meta-analysis of

26 trials to quantify the efficacy of cholinesterase inhibitors for neuropsychiatric and functional outcomes in patients with mild to moderate AD found at best a very modest beneficial impact of these drugs[37]. For neuropsychiatric outcomes, six used the NPI and 10 of the trials used the ADAS-noncog. Compared with placebo, patients randomized to cholinesterase inhibitors improved 1.72 points on the NPI (95% CI, 0.87–2.57) and 0.03 points on the ADAS-noncog (95% CI, 0.00–0.05). For functional outcomes, 14 trials used activities of daily living (ADL) and 13 trials used independent-ADL (IADL) scales. Compared with placebo, patients randomized to cholinesterase inhibitors improved 0.1 SDs on ADL scales (95% CI, 0.00–0.19) and 0.09 SDs on IADL scales (95% CI, 0.01–0.17)[37]. There was no difference in efficacy among the various currently available cholinesterase inhibitors. Importantly, these trials did not specifically seek to include patients with behavioural disturbance and the findings may best apply to patients with very mild symptoms.

In contrast, a notable recent negative study was the 2007 CALM-AD trial examining donepezil treatment of agitation in AD[38]. Howard *et al*. examined the potential benefits of cholinesterase inhibitors for behavioural disturbances in 272 patients with AD who had clinically significant agitation and no response to a brief psychosocial treatment programme. There was no significant difference between the effects of 12 weeks of donepezil (128 patients) versus placebo (131 patients) on scores of the Cohen–Mansfield Agitation Inventory (CMAI). Twenty-two of 108 patients (20.4%) in the placebo group and 22 of 113 patients (19.5%) in the donepezil group had a reduction of 30% or greater in the CMAI. Likewise, there were also no significant differences between the placebo and donepezil groups in scores for the NPI, the Neuropsychiatric Inventory Caregiver Distress Scale or the CGIC. An earlier nursing-home study of 208 patients with advanced AD also failed to show a significant benefit of donepezil on total NPI scores, although there was benefit of donepezil on the agitation measure specifically[39].

Memantine

Data investigating the behavioural effects of memantine on behavioural disturbances in dementia are limited. A recent exploratory analysis of a 24-week, double-blind, placebo-controlled trial comparing memantine (20 mg/day) with placebo in subjects with moderate to severe AD on stable donepezil treatment was completed[40]. Authors used NPI measurements at baseline, week 12 and week 24, to assess the effects of memantine on behaviour. Treatment with memantine reduced agitation/aggression, irritability and appetite/eating disturbances. While the studies did not seek to include patients with behavioural symptoms and mean rating scores suggested mild symptoms, memantine reduced agitation/aggression in patients who were agitated at baseline and delayed its emergence in those who were free of agitation at baseline.

ANTIDEPRESSANTS

Available data on antidepressants and behavioural disturbance in dementia are limited, but do show some possible benefit. The findings discussed below need to be replicated in expanded study populations before antidepressants can be confidently recommended as alternatives to antipsychotic medications for the treatment of agitation or psychotic symptoms associated with dementia. Adverse effects may be more benign than with antipsychotic treatment, although there is very little comparison data and more complete understanding of the antidepressant side-effect profile in this population will require larger trial samples.

Citalopram

In a moderately sized study, citalopram was found to be more efficacious than placebo in the short-term hospital treatment of psychotic symptoms and behavioural disturbances in non-depressed, demented patients[41]. This study also included a treatment arm with perphenazine, which did not differ from citalopram or placebo groups. In a later study, when citalopram was compared to risperidone, agitation symptoms (aggression, agitation or hostility) and psychotic symptoms (suspiciousness, hallucinations or delusions) decreased in both treatment groups, but the improvement did not differ significantly between the two groups[42]. There was, however, a significant increase in side-effect burden with risperidone but not with citalopram.

Sertraline

An initial small trial of sertraline showed a 38% overall response rate, which was equivalent to placebo and a trend for decreased aggression ($P = 0.08$)[43]. A later trial of sertraline, in this case added to donepezil treatment, in outpatient AD patients with behavioural problems found no primary effect, but post hoc analyses demonstrated a modest but statistically significant advantage of sertraline over placebo augmentation in mixed-model analyses and in a subgroup of patients with moderate-to-severe symptoms as measured on CGI and NPI scales[44].

Fluvoxamine

The initial published trial on fluvoxamine use in dementia did not show significant benefit on cognitive functioning or behavioural changes in elderly dementia patients[45]. However, given that fluvoxamine can increase antipsychotic blood levels, another small trial examined fluvoxamine augmentation of perphenazine in AD patients and found that perphenazine plus fluvoxamine was better than perphenazine plus placebo on lowering total BPRS scores[46].

Trazodone

Sultzer *et al*. 1997 found that trazodone was equally efficacious as haloperidol in reducing agitation and aggression in a small mixed population of inpatient dementia subjects over a 9-week trial period[47]. Further analysis found that the presence of delusions did not predict a greater behavioural improvement with haloperidol treatment than in subjects without signs of psychosis, while mild depressive symptoms were associated a with greater improvement in trazodone-treated patients[48]. However, a larger ($n = 149$) randomized, placebo-controlled, multicentre trial comparing the efficacy of trazodone, haloperidol, behavioural management and placebo found modest but non-significantly different improvement in all four groups of the study[49]. Post hoc analysis of placebo responders demonstrated that the reduction observed was of the same magnitude as predicted by regression to the mean; patients exhibiting greater improvement had more severe baseline behavioural disturbances[50]. A small ($n = 26$) study of frontotemporal dementia patients found trazodone to be effective in reducing behavioural disturbances; 10 of the trazodone treated patients had a greater than 50% reduction of NPI scores[51].

MOOD STABILIZERS

Valproate/Divalproex Sodium

Despite preliminary promise, results from controlled trials published to date essentially show very limited effect of valproate/divalproex sodium over placebo in the treatment of behavioyral disturbances in dementia. The first RCT published using divalproex sodium in nursing-home patients with agitation and dementia ($n = 56$) found the drug/placebo difference in BPRS agitation scores at the threshold of significance ($P = 0.05$), while differences in CGI did not reach significance ($P = 0.06$)[52]. In a second trial, in aggressive demented inpatients ($n = 42$), there was no primary effect of valproate[53]. Secondary improvement was shown on restless, melancholic and anxious behaviours – with the caveat that no correction was made for multiple comparisons. A third study of divalproex in nursing-home patients with AD associated agitation ($n = 153$), found no difference from placebo over six weeks of treatment[54]. More recently, Herrmann *et al*. found that valproate was poorly tolerated and significantly worsened agitation and aggression on NPI and CMAI measures in a small population ($n = 14$) of institutionalized AD patients, when compared with placebo treatment for six weeks[55].

Given the negative results in trials targeting existent behavioural symptoms in dementia, the Alzheimer's Disease Cooperative Study (ADCS) has been conducting a clinical trial to address whether chronic valproate treatment can delay emergence of behavioural symptoms in outpatients with AD. Divalproex sodium has been shown to be better tolerated in these AD patients in doses less than 1000 mg/day, with doses of 1500 mg/day causing worse cognitive performance[56].

Carbamazepine

Two small positive efficacy trials have been published using carbamazepine to treat behavioural symptoms of dementia. The first involved nursing-home patients with dementia with agitation who showed improvement on BPRS and CGI measures over six weeks when compared to a parallel placebo group[57]. The second examined outpatient AD patients who had failed treatment with antipsychotic medications and again found relatively greater improvement in carbamazepine-treated patients compared to placebo but also a trend for worsened hallucinations[58].

Other Medications

A few small studies have examined other pharmacological approaches for treatment of behavioural disturbances in dementia, including oral or intramuscular benzodiazepines[59,60], diphenhydramine[61], propranolol[62], buspirone[63] and transdermal oestrogen[64].

GENERAL PRINCIPLES FOR PHARMACOLOGY OF BEHAVIOURAL DISTURBANCES

At the current time, no uniform treatment algorithm can be applied to elderly patients with behavioural disturbance in dementia. However, some general treatment guidelines for medication use can be discussed. Medications should be prescribed only for specifically defined target signs and symptoms. Prior to initiating psychopharmacological management, one must identify underlying contributing factors. Modifiable causes, such as environmental issues or co-morbid medical conditions, should be addressed and corrected prior to medication treatment. A review of the patient's medication regimen should be undertaken to discontinue unnecessary drugs and those that may dull cognition, such as sedative-hypnotic, opiate and anti-cholinergic medications. Superimposed delirium due to acute change in medical condition or medications is common in patients with dementia and often promotes behavioural disturbances.

Behavioural interventions (see related chapter in this book) should be initiated prior to medication use and monitored for effectiveness and modification throughout the treatment process. Given the known risks of medication use in patients with dementia, only behavioural symptoms that are recurrent and severe should be considered for pharmacological treatment. Examples of such behaviours would include those which put patient or caregiver safety at risk, such as psychosis contributing prominently to behavioural disturbance. Medication management may also be considered for psychotic symptoms that are prominently distressing to the patient or for behaviours that interfere with basic care needs.

The treatment plan should be guided by an individualized assessment of specific symptoms and the possible benefits and potential risks to the individual of a particular intervention. Clinicians should recognize the value of evidence from controlled clinical trials that is derived from studies of specific patient groups and settings, yet must also consider the individual patient's particular circumstances, needs and goals in developing a personalized treatment plan. When initiating psychotropic drug trials, micro-doses may be a good starting point but this needs to be monitored, as some patients respond well to low doses but may need increases over time. In general, the minimally effective dose should be used over the shortest duration of time possible to address the target symptom being treated. Medication effects need to be monitored over time and the treatment adjusted to match ongoing goals. This should include regular attempts at dose reduction and medication discontinuation trials. Lack of improvement or presence of significant adverse effects may require medication discontinuation or switching to another agent within or between classes of psychotropic agents.

Psychopharmacological management works best when coordinated with caregivers and treatment team members in an active collaboration. The consultant model of treatment has been found to be least effective when compared to alternative models such as interdisciplinary treatment teams which include active input not only from treating specialists, but internists, nurses, social workers, therapists and other care partners.

Following the above guidelines, one can typically look for improvement within 2–4 weeks of treatment initiation and if not observed, this requires re-evaluation of target symptoms and treatment goals. Such goals should typically be shared decisions, based on the patient and family values expressed regarding quality of life and other relevant matters. Documented sharing of information regarding known risks and benefits of proposed drug treatments should be completed with patients and caregivers. Information should be delivered in a manner appropriate to each familiy's education level and knowledge base.

Behavioural Management: Non-Pharmacological

Jiska Cohen-Mansfield

George Washington University Medical Center and School of Public Health, Washington DC, USA
Tel Aviv University Herczeg Institute on Aging and Sackler Faculty of Medicine, Tel-Aviv, Israel

The discussion of non-pharmacological interventions to treat dementia has increased in recent years. Such interventions can be used to reduce agitation and problem behaviours, enhance affect, cognition and activities of daily living (ADL), and reduce delusions and hallucinations. These interventions most often change the physical and social environment of the person with dementia by improving the level and quality of stimulation in the environment, providing social contact, or adapting the environment to increase comfort and ease in daily activities. In this way, non-pharmacological interventions can address unmet needs of persons with dementia and enhance their quality of life.

THEORETICAL FRAMEWORKS

Several theoretical frameworks describe the manifestations of the behavioural, affective, cognitive and psychotic impairments associated with dementia from an environmental and psychosocial perspective. Three such theories that explain behaviour problems are the behavioural model, the environmental vulnerability model and the unmet needs model. Some of the theories that explain affect include the learned helplessness model and the reduced reinforcement model. There are also various theories relating pain and loneliness to affect. Each theoretical framework has different implications for intervention.

Behaviour

The behavioural model states that a problem behaviour is controlled by its antecedents and consequences. Antecedents include triggers that initiate the behaviour, such as the view of the exit door eliciting an attempt to exit the institution; consequences refer to the reaction to the behaviour, such as when screaming is followed by attention from staff members, a response that reinforces the screaming behaviour. Alternatively, the environmental vulnerability model asserts that dementia results in an increased vulnerability to the environment, which leads to a lower threshold at which stimuli affect behaviour. A stimulus that may elicit an appropriate response in a person without cognitive impairment, such as a movie or magazine, may overwhelm a person with cognitive impairment and therefore generate an inappropriate behaviour. This model is based on the concepts of person–environment congruence[1] and the environment-behavioural model, which suggest that, for optimal functioning, a match is needed between the person's needs and abilities and the demands of the environment as they relate to those needs and abilities. A related concept is that dementia results in a progressively lowered stress threshold[2]. Accordingly, persons with dementia progressively lose their coping abilities, and therefore perceive their environment as increasingly stressful. Since their threshold for tolerating this stress is also decreasing, anxiety and inappropriate behaviour can result as environmental stimuli exceed the person's stress threshold.

According to the unmet needs model, a person with dementia has difficulty meeting his/her needs because of a decreased ability to communicate needs and provide for oneself. The loss in the ability to communicate and perform tasks. The combination of the loss of ability to communicate and perform tasks, inability to effectively utilize the environment, and deficiencies in individualizing care results in unmet needs[3,4]. Problem behaviours emerge as an attempt to meet or to communicate those needs.

The different models are not mutually exclusive and may be complementary. An environmental vulnerability may make the person who suffers from dementia more susceptible to environmental antecedents and consequences. The environmental vulnerability may also produce an unmet need when normal levels of stimulation are perceived as over-stimulation. Furthermore, different models may account for different behaviours in different people.

Affect

Depressed affect has been conceptualized as resulting from lack of control and a sense of helplessness, from insufficient level of control over one's environment[5], or from an insufficient level of reinforcing activities, i.e. pleasurable experiences[6]. Depressed affect has also been linked to loneliness[7] and to physical pain.

Delusions/Hallucinations

Delusions can represent a misinterpretation of reality, which may stem from actual environmental changes for which the person is not adequately prepared. This may be the case when an older person becomes frightened by a caregiver who comes to get her dressed, and whom the older person may perceive as a total stranger. Hallucinations have been associated with visual impairments, and may therefore represent a natural reaction to sensory deprivation[8].

INTERVENTIONS

The following describes non-pharmacological interventions used for alleviating behavioural, affective, cognitive and psychotic symptoms of dementia.

Behavioural

Interventions for behavioural problems that are based on the unmet needs model most often focus on three types of unmet needs: need for social support and contact, need for stimulation and activities, and need for relief from discomfort. At the most basic level, providing social support and contact involves talking to persons with dementia, even if the caregiver conducts the majority of the conversation. One-on-one interaction is a potent intervention that can be performed by relatives, paid caregivers or volunteers. Alternatively, simulated social interventions can be useful when live social contact is not available; such interventions include videotapes of family members[9], simulated presence therapy[10], in which an audiotape of a family member's side of a telephone conversation is played repeatedly to the person with dementia, or commercially produced interaction videos for persons with dementia, in which viewers are invited to sing along to familiar music or to remember past events. Training staff members to view all interactions with those in their care (such as during ADL) as opportunities for social contact is also an opportunity to provide social support.

Pet therapy is another option[11], which may include visits with dogs, cats or fish, or simulated pet therapy using plush stuffed animals or robotic pets[12]. In addition to interaction with the animal, pet therapy provides a topic for interaction with other people. Dolls have also been used to simulate companions/babies, and massage may be an effective mechanism for social contact with non-verbal persons with advanced dementia.

In order to address the need for activity or stimulation, many different types of activities or stimuli have been used. Stimulation includes music, aromatherapy, touch therapy, 'Snoezelen' programmes, massages and white noise. Structured activities, such as manipulation of objects, sorting, cooking, sewing and sensory interventions, may be helpful. Montessori-based activities are a set of activities based on Maria Montessori's principles[13], such as task breakdown, immediate feedback, and use of everyday, real-world materials. Other options for activities include exercise, art therapy, including drawing and painting, where participants can express themselves by choosing colours and themes, and adaptations of ADL, like setting the table or cooking.

Activities can include cognitive tasks that can be done individually or within a group. Group examples include 'Question Asking Readings', in which a group reads a script accompanied by questions typed on cards that encourage participants to discuss related topics. Another group memory task is memory bingo, a game in which participants match beginnings and endings of popular sayings, which can also stimulate group discussion[14]. Individual cognitive tasks involve sorting cards or objects by category.

An alternative to addressing the need for stimulation by providing stimuli is to accommodate the behaviour that provides activity and stimulation. For example, interventions for accommodating pacing or wandering behaviour include outdoor walks[15] and the use of wandering areas[16]. Inappropriate handling or the constant manipulation of objects can be accommodated by providing appropriate materials, such as books and pamphlets for handling, or activity aprons (aprons that have buttons, zippers and other articles sewn on) as appropriate and safe items for persons to handle. Similarly, rocking chairs and gliding swings have been used to accommodate restless behaviour and provide more acceptable stimulation.

Regarding relief of discomfort, interventions such as pain management, light therapy to improve sleep, and reduction of discomfort by improved seating or positioning and removal of physical restraints have all been related to improvement in behaviour. Changes in the methods and environment of providing ADL have also been associated with reduction in inappropriate behaviours. For example, tape recordings and pictures of birds, flowing water and small animals in baths as well as offering food during bathing have been associated with a decrease of agitated behaviours during bathing. Person-centred showering and towel baths resulted in decreased agitation in comparison with usual bathing routines[17].

In order to provide for the unmet needs of the person with dementia, caregivers need to understand the needs and how to address them. Staff training is a category of non-pharmacological interventions, which includes training in skills such as communication and providing assistance in ADL, or in techniques to handle inappropriate behaviours. Many such programmes focus on improved understanding of the older person and the impact of dementia. Person-centred care and the use of dementia-care mapping are care principles that have been associated with decreased levels of behaviour problems[18]. Changing caregiver behaviour through training is, however, a complex and difficult challenge, and often requires ongoing instruction, modeling, monitoring, feedback and support of the caregiver. Therefore, in institutional settings, staff training is closely tied to management.

The most common intervention based on the behavioural theoretical framework is differential reinforcement, which changes the contingencies that are supposed to maintain or reinforce the behaviour. This consists of positive reinforcement contingent on non-agitated behaviour, such as moving the person to a quiet area when agitated for time out, or restriction, where the person is denied goods (e.g. cigarettes), activities or access to a location or another person when agitated. In contrast, reinforcement is provided when not agitated.

The interventions based on the environmental vulnerability theoretical framework include reduced stimulation units, which aim to eliminate the stimuli that, according to the theory, activate the low stress threshold and result in the problem behaviours. These units have been modified to appear less obstructive to those with dementia. They typically have small group sizes at tables for eating and small groups for activities, neutral colours on pictures and walls, no televisions, radios or telephones (except for emergencies), an educational programme for staff and visitors concerning the use of touch, eye contact and slow, soft speech, use of quiet voices by staff at all times, and a consistent daily routine[19].

Affect

Based on the theoretical model of learned helplessness, interventions to decrease depressed affect focus on increasing the older person's sense of control, such as allowing the person to make his/her own decisions about meals or clothes or to care for a plant. The intervention approach based on the alternative theoretical framework of reduced reinforcing events is that of providing older persons with pleasant activities, individualized to the preferences of each person[20]. Loneliness is highly correlated with depressed affect, and social interventions described above, including both live and simulated social

activities, are also appropriate for improving affect. Group activities can also be used as vehicles to promote social contacts. Additionally, combined interventions that merge outdoor experience with social contact, such as combining a wheelchair bicycle with small-group activity therapy and one-to-one bike rides with a staff member, have been applied to reduce depression in nursing home residents[21].

Self-affirming interventions also target improving affect. These include reminiscence therapy, which encourages persons with dementia to talk about their pasts, and may utilize audiovisual aids, such as old family photos and objects. Reminiscence can enhance individuals' sense of identity, sense of worth or general well-being[22], and may also stimulate memory processes. Validation therapy, in which a therapist accepts the disorientation of a person with dementia and validates his or her feelings, can improve affect by acceptance rather than rejection of the experiences of the person with dementia[23].

Cognition

Several cognitive principles underlie cognitive interventions for persons with dementia. These include: (i) long-term memory is usually maintained better than short-term memory; (ii) procedural memory remains more intact than declarative memory; and (iii) new learning is possible in dementia and is achieved through the same principles as other memory, but often requires more aids or repetition. Cognitive interventions have been used to improve general cognitive function or the performance of specific tasks. Interventions for improving general cognitive function include memory training[24], maintaining lifelong habits that have been over-learned through long-term practice, general problem solving, use of mnemonic devices, word games and puzzles, computer programs with cognitive exercises, and/or the use of external memory aids such as notebooks, lists, calendars or alarms. Computer-based memory training has the advantage of adapting to the level of the older person and to the type of cognitive stimulation most needed[25]. Physical exercise has also been shown to have a positive effect on cognitive performance in older adults with dementia[26]. For persons with more advanced cognitive impairment, reality orientation has been used, where staff members present orienting information such as information about time, place and person, usually in a group setting[27].

The use of cognitive interventions for more specific procedures often includes procedural memory training, using spaced-retrieval (a procedure where a task, such as placing the walker in a specific location, is learned through repetition over increasingly longer retention intervals[28]), cueing and similar techniques. In the later stages of dementia, memory books, which contain autobiographical, daily schedule and problem resolution information, can assist with communication[29]. Technological aids, such as the use of electronic memory devices or environmental sensors[30], are expected to play an increasing role in the future as prostheses for cognitive losses.

FUNCTION

Non-pharmacological interventions to improve function often include environmental interventions and task simplification. These are used to optimize the performance of activities of daily living by adjusting the surroundings (including physical access, temperature, colour, furniture, wall design and cues) to facilitate the activity for both patient and caregiver. The extent of environmental adaptation varies, from decreasing clutter to providing grab bars or handrails. As a means to decrease the risk of falling, lowering bed height, placing mattresses on the floor, using hip protectors, improving light on the way to the bathroom, and improving call systems have been used. Enhanced visibility of toilets increased their utilization[31], and eating behaviour improved with better light and increased contrast between plates and the table[32].

An alternative intervention is task simplification or cognitive prosthesis, which utilizes task breakdown, enhanced instruction, modeling, rehearsal, cueing and gradual approximations of a task. The notion of simplifying tasks can also be applied across daily activities, such as by providing consistency in caregiver assignment, which helps orient older persons across different tasks. A combination of these interventions and others has been included in occupational therapy interventions to enhance function in dementia[33].

Delusions/Hallucinations

Non-pharmacological interventions for psychotic symptoms are based on the understanding of the aetiology of the symptom.

- *Misinterpretation of stimuli or reality*. At times, the diagnosed 'delusion' or 'hallucination' is triggered by an environmental stimulus. For example, a loudspeaker system may sound like voices from outside or an image seen through a mirror may be interpreted as someone being in the room. This is facilitated by the combination of sensory deficits and cognitive limitations that occur with dementia giving rise to an incorrect interpretation of an initially vague or unclear stimulus. Interventions to minimize this confusion would most often remove or change the stimulus so as not to elicit the mistaken interpretation. Delusion can also be a representation of reality. Examples are delusions of theft, as theft is common in many nursing homes, or the delusions of abandonment that may occur when a person enters a nursing home. Whether this feeling reflects reality from the point of view of the caregiver is irrelevant, as the move into a strange environment represents abandonment from the point of view of the person with dementia. The goal of interventions to alleviate this feeling is to re-establish trust in the relationship. Older persons may eventually change their perceptions when they become comfortable with their care and when they sense consistent caring by the family, such as with social contact (real or simulated, described above), which may provide a sense of love and familiarity, thus countering the feelings of abandonment and betrayal.
- *Delusion as confabulation in the face of memory loss*. Many delusions are misinterpretations of actual events in the environment. When a person with dementia complains that an object has been stolen, she may be forgetting where she has placed her personal belongings and interpreting her inability to find them as theft. A number of potential solutions can be offered to older persons, including marking personal belongings in clear ways so that they are easily identifiable, attaching a finder such as a KeyRinger™ to a personal belonging, or purchasing multiple inexpensive copies of personal articles so they may be easily replaced when necessary. Similarly, the delusion that a caregiver is an impostor is often the result of an individual's inability to recognize the caregiver. In that case, an intervention should work toward improving the individual's relationship with the caregiver.
- *Other reasons*. Delusions have at times been reported to result from delirium associated with acute medical conditions that should be treated, or from bright light therapy, which, in those cases, should be removed. Delusions have also been linked to depressed

affect in many studies[34,35]. It is unclear whether the delusions lead to depression or the depression leads to delusions (e.g., through inactivity and isolation), or if both are caused by other factors. Depression may be controlled by treating the depression non-pharmacologically, as described above.

- *Pleasant 'psychotic symptoms'*. At times hallucinations are pleasurable. Some people talk with deceased relatives and derive happiness from these encounters. If a person seems to enjoy such hallucinations and does not suffer any ill effects, an optimal intervention may be to explain this situation to caregivers in a manner that will make the practice acceptable to them.
- *Visual and auditory problems/sensory deprivation*. Hallucinations are more likely to occur in persons with visual problems[8,35,36], and may be linked to sensory deprivation[37]. Additionally, there is evidence that in the absence of the stimulation of sensory areas by external objects, people may experience hallucinations[38]. Correction of visual problems through medical intervention or through aids such as eyeglasses, enhanced contrast, larger type/object or improved lighting is a first step in addressing hallucinations among persons with visual impairments. To the extent that sensory deprivation may be a contributing cause of hallucinations, sensory stimulation, such as music, massage and aromatherapy, may be beneficial.
- *Cultural differences between caregivers and persons with dementia*. Some behaviours perceived by caregivers as psychotic symptoms may actually be culturally based, such as 'talking' to the dead or singing, or praying in a loud voice.

INDIVIDUALIZATION OF INTERVENTIONS

A crucial principle in applying non-pharmacological interventions to persons with dementia is that of individualizing these interventions to fit the person's needs and abilities. Some of the dimensions to consider in tailoring interventions are listed below:

1. Current and past sense of identity, which usually include some retained aspects of previously held identities, such as work role, family relationship or preference for a certain type of leisure activity.
2. Current sensory abilities, which include visual, auditory, smell and touch modalities. Mechanisms for augmentation of sensory abilities should be explored, including simple ones, such as better fitting eyeglasses, an auditory amplifier, better fitting hearing aids etc.
3. An enhanced understanding of current needs, including social contact of any kind, longing for family, for daytime activity, for stimulation, for physical exercise or for a specific meaningful activity, such as helping or working.
4. Cognitive and communication abilities.

EFFICACY OF INTERVENTIONS

Many reviews have tried to clarify the evidence regarding the efficacy of non-pharmacological interventions, despite many methodological and other difficulties in the research in this area[39–43]. Many non-pharmacological approaches resulted in a statistically and clinically meaningful improvement in the manifestation of behaviour problems, function and affect. With few exceptions, most studies are small and have methodological problems, often due to insufficient funding. There are, however, some larger studies that used valid comparison groups and showed the efficacy of non-pharmacological approaches[44]. For some areas, however, such as delusions and hallucinations, no studies were found regarding the efficacy of non-pharmacological approaches. While results vary, non-pharmacological approaches to intervention are a promising option when treating specific symptoms and when aiming to improve quality of life in dementia.

PREREQUISITES AND BARRIERS TO THE PRACTICE OF INTERVENTIONS

The actual utilization of non-pharmacological interventions in dementia falls far short of its potential. A number of systemic issues are responsible for this gap. Funding is lacking both for the practice of non-pharmacological interventions and for the acquisition of knowledge about these through systematic research. The commonly used alternative intervention of psychoactive medication is reimbursed, and the underlying structure for its delivery, including physicians, medicine aids, pharmacies, and monitoring and quality control systems, is largely in place. In contrast, the provision of non-pharmacological interventions is generally not reimbursed, and a system for providing them is often absent. Similarly, funding for non-pharmacological research is limited, because, unlike pharmacological interventions, there is no financial entity that is likely to benefit financially from this knowledge. Such limited funding results in many of the studies on these interventions having small samples and other methodological limitations, further limiting the faith in this approach and the willingness to fund it.

Yet, the most obvious barrier to the implementation of the non-pharmacological approaches described is that the current structure of care does not promote such non-pharmacological assessment and intervention. In most cases, the physician prescribes antipsychotic or antidepressant medication based on informant reports. No one in the care system is currently responsible for assessing, observing and analysing inappropriate behaviour or psychotic symptoms in order to determine their aetiology and their impact on individuals' lives. Thus, clinicians most often do not witness the event and do not have the ability to verify or question the interpretation of the diagnosis. The ability of caregivers to provide non-pharmacological interventions is further limited by lack of staff member knowledge, insufficient staffing levels and insufficient support within and outside the care situation. In order to provide non-pharmacological interventions for dementia, the system of care needs to promote an atmosphere and practice of caring that goes beyond what is currently available in most care settings. Attentive listening and observation are needed to differentiate between the various needs expressed by behavioural and psychotic symptoms. Knowledge of the disease, as well as of specific symptoms and their aetiology, meaning and management, will allow caregivers to better understand the individual's behaviours rather than attributing them to resistance, difficult personality, malicious intent, craziness or indifference. Compassion and empathy by caregivers allow them to better understand the needs of the person with dementia and to clarify appropriate avenues for interventions. In order to allow alternative interventions, the system of care needs to promote autonomy and respect for the person with dementia and to maximize flexibility in procedures for caregiver and care-receiver alike. A transformation in the system of care is therefore needed in order to allow an optimal use of non-pharmacological interventions to promote quality of life for persons with dementia.

Emerging Applications of Gene and Somatic Cell Therapy in Geriatric Neuropsychiatry

Eric Wexler

David Geffen School of Medicine at UCLA, Los Angeles, USA

'Men do not quit playing because they grow old; they grow old because they quit playing.'

Oliver Wendell Holmes

INTRODUCTION

Startling advances in medicine have extended our lives and given us healthier bodies, but not healthier minds. The mere fact that we are living longer consigns more of us to enduring our final years ravaged by diseases like Alzheimer's or stroke, and suffering all the psychiatric manifestations that are part and parcel of these diseases. Currently available treatments do little. Therapies that replace the damaged brain tissue, either by regeneration or by transplantation, are needed. Unfortunately, both a poor theoretical understanding of neuronal generation/regeneration, and a lack of practical tools to effectively deliver these genes to the right cells, in the right amounts, continue to hamper the field of regenerative medicine. Similarly, harnessing the therapeutic potential of stem cell transplants remains a promise unfulfilled because neural stem cells (NSCs) simply do not function properly when transplanted into regions other than those that normally support adult neurogenesis. Worse yet, even those few privileged environments that normally support neurogenesis are rendered inhospitable to newly implanted NSCs by many of the same conditions that make someone a candidate for neural transplantation in the first place.

The idea of transplanting neurons to repair damaged brain is not new; the first trials, using foetal tissue, in Parkinson's patients were performed more than two decades ago. Initial optimism gave way to the harsh reality that this was not the cure many had hoped for. Many hypothesized that more mature cells simply had lost the ability to learn how to adapt to their new host environment. Naturally, waves of enthusiasm have heralded discoveries from foetal NSCs to human embryonic stem cells (hESCs), with their uncanny pluripotency. Still, somatic cell therapy remains an elusive prospect because transplanted cells do not properly engraft, either failing to properly differentiate, dying or not integrating into the local circuitry. Developing therapies that provide real clinical improvement requires leveraging our newfound appreciation of the microenvironment within which neurons normally develop.

Since the field of neural repair remains in its infancy, any review of this field (including this one) must contain a fair degree of educated guessing about the future, some of which will turn out to be wrong. To minimize the impact this might have, we will focus on communicating the essentials of current thinking in the field, rather than trying to divine what approach(es) will ultimately be successful. To this end we have broken this chapter down into three sections. The first section aims to supply the reader with a historical understanding of early clinical repair trials, highlighting some of their limitations and questions raised. The second section provides a primer on the regenerative capacity of the adult brain. In this section we introduce the concept of an adult stem cell niche. To the clinician, some of these sections may seem technically dense; we have made every attempt to minimize the use of unnecessary jargon. However, the reader should recognize that an under-appreciation of the importance of the niche goes a long way towards explaining the shortcomings of previous trials. Conversely, understanding how disease or ageing alters the functioning of these microenvironments will be absolutely critical for understanding the rational of any future neuroregenerative therapy trials. The third section introduces the clinical reader to some of the current and emerging tools at the gene therapist's disposal. Finally, we will provide some plausible scenarios where the discussed concepts and tools can be integrated to produce workable future clinical trials. In sum, this chapter should empower the reader with the necessary framework for understanding ongoing developments, rather than trying to divine which approaches will ultimately be successful.

BIRTH OF REGENERATIVE MEDICINE

Molecular strategies for functionally repairing the damaged brain fall into one of three categories: (i) replace/repair circuitry; (ii) potentiate function of remaining cells; and (iii) halt disease progression[1]. The cell replacement strategy has the longest track record with the first foetal neuron transplants being reported in 1989[2]. The lion's share of transplantation trials was performed on patients suffering from either Huntington's or Parkinson's disease. However, the technique has also been applied to patients with macular degeneration, stroke and, most recently approved, children with Batten's disease. More recently, there has been some forays into gene-therapy-based approaches. Below we will review the finding from these previous transplantation trials, with an emphasis on calling out those features that are amenable to improvement in future studies.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar

Parkinson's Disease

Parkinson's disease (PD) is characterized by relatively selective loss of the dopaminergic neurons in the nigrostriatal tract, though all brain regions are ultimately affected in later stages. Nigrostriatal degeneration results in a well-characterized syndrome of progressive rigidity, bradykinesia, tremors, poor gait/balance, and later dementia in many patients. The first human neural transplants involved unilateral stereotactic injection of mesencephalic dopamine neurons, obtained from 7 to 9 weeks gestational age human foetuses, into the putamen of long-term Parkinson's patients[2–11]. These trials delivered initially encouraging results. Imaging studies (PET or MRI) revealed graft viability and recipients exhibited motor improvement, with reduced medication doses.

Because initial trials were all unblended, concerns over the placebo effect prompted more sophisticated trials. These included sham surgery and blinded rating of imaging results. In a larger trial reported by Freed and colleagues[12] 40 PD patients, ranging in age from 34 to 75 years old, received either embryonic mesencephalic neuroblasts/neurons or sham surgeries and were followed, double-blind, for the succeeding 12 months. They found that although the transplanted cells survived transplantations, the procedure only seemed to clinically benefit younger (younger than 60 years of age) PD patients. Unfortunately, the more carefully this promising therapy was evaluated, the less 'promising' it appeared[13]. Some patients developed uncontrollable dyskinesia, presumably due to aberrant axon regrowth; many showed limited improvement. However, this approach has fallen out of favour because it neither slows disease progression, not is it more effective than aggressive medication, and probably less effective than deep brain stimulation.

With a guide to designing future therapies, it is interesting to note that on analysis some transplanted neurons developed Lewy bodies[14,15]. This finding suggests that merely placing new tissue into an inhospitable (deteriorating) brain is not a viable solution. The most recent regenerative trials for PD have focused on changing this environment by providing additional trophic support. Specifically, there have been attempts to augment glial-cell-derived growth factor (GDNF) levels in the striatum, as this protein has shown a significant ability to protect dopaminergic neurons from a variety of experimental insults. The farthest along trial involved direct infusion of GDNF into the putamen[16]. The preliminary results of these studies are again promising, but only time will tell[16–18]. The current trend in PD trials is towards use of adeno-associated virus (AAV) to deliver and induce production of the therapeutic factor (neurturin, a GDNF-like ligand[19]) or enzyme (glutamic acid decarboxylase[20]; aromatic l-amino acid decarboxylase[21]).

Alzheimer's Disease

In constrast to PD, only one group has made any progress towards applying regenerative medicine to Alzheimer's patients. The two trials differed in their technical approach, but shared the goal of delivering nerve growth factor (NGF), a survival factor for cholinergic neurons, to the brain regions suffering cholinergic neuron loss. Using an *ex vivo* gene therapy approach, they implanted fibroblasts that were engineered to secrete NGF[22]. The other study used *in vivo* gene therapy, utilizing AAV to induce local NGF production[23]. The initial results seem promising, but the long-term benefit and safety is an open question.

Huntington's Disease

Huntington's disease (HD) serves as a model neuropsychiatric disorder, despite being a relatively rare disease (7 per 100 000 persons). A toxic gain-of-function mutation (polyglutamine trinucleotide repeat expansion) in the huntingtin protein causes this dominantly inherited movement disorder. Huntingtin is widely expressed throughout the brain, resulting in personality changes or other psychiatric manifestations that may precede overt motor symptoms by almost a decade. However, it is the striking degeneration of the striatum that burdens patients with its characteristic choreoathetoid movements. Eventually, all patients will suffer major psychiatric symptoms, and if they live long enough, dementia will ensue (DSM-IV; 294.1 Dementia Due to Huntington's Disease).

Transplantation trials in HD were contemplated soon after the purported 'success' of foetal neural transplant in PD patients. These open label trials (i.e. no sham surgery) entailed transplantation of committed neuroblasts from foetal human striatum into the brains of moderately affected HD patients[24,25] (and later[26,27]). The results of these trials appeared mixed. Bachoud-Lévi and colleagues reported that on two-year follow-up, three out of five transplant recipients exhibited improvement of both motor and cognitive symptoms[28,29]. These improvements correlated recovery of metabolic activity in the specific striatal location of the transplants, as well as connected regions of the cortex. In contrast, another group following seven patients used PET to examine graft survival. They found evidence of poor graft survival/function. Moreover, they could not demonstrate a significant relationship between changes in PET and clinical function, forcing them to conclude that there was no benefit from transplantation[30].

On longer-term follow-up, Bachoud-Lévi and colleagues found mixed results with regard to improvements in motor symptoms. Among those patients who displayed an improvement at two years, chorea remained stable at an improved level for the following four years[31]. While chorea was improved, dyssomnia became steadily more prominent, paralleling the results in PD transplant trials. More encouraging were their observations of limited cognitive decline among initial responders. They showed no worsening on the Mattis dementia rating scale and only slight worsening on the Trails A. Although the relatively small numbers of these follow-up studies makes it difficult to draw any major conclusions, they suggest that transplants in HD may be more beneficial than in PD. Unlike PD, there are very few pharmacological interventions for HD, making an invasive procedure like cell transplant more appealing. Still, it seems apparent that transplantation is not going to become more pervasive until concomitant neuroprotective treatment becomes available. On a more general cautionary note, there are at least two documented cases of tumour formation among patients who have received cell transplants[32,33], raising the spectre of additional safety concerns.

REGENERATIVE CAPACITY OF ADULT BRAIN

A Brief History of Adult Neurogenesis

For nearly the entire twentieth century the regenerative capacity of the adult brain was considered to be almost nil. It was dogma that the number of neurons in the adult mammalian brain was fixed near birth. This sentiment was reflected by the great neuroanatomist Santiago Ramón y Cajal, who wrote, 'Once development was ended, the fonts of growth and regeneration of the axons and dendrites dried up irrevocably. In adult centers, the nerve paths are something fixed,

and immutable: everything may die, nothing may be regenerated'[34]. As early as 1897 there was evidence for undifferentiated cells in the adult brain that had the potential to become either neurons or glia; however, this view was not accepted for almost another century. (Charles Gross provides a fascinating historical accounting of this cautionary tale of scientific sophistry and denial[35].)

In the early 1990s, Reynolds and Weiss demonstrated that one could easily isolate multipotent progenitors from the adult mouse striatum. These precursors expanded in culture by application of epidermal growth factor (EGF) and then directed towards differentiating into neurons or glia[36,37]. More than anything, the ease with which other laboratories could replicate their findings ushered in the acceptance of adult neurogenesis. Subsequently, Eriksson and colleagues examined the postmortem brains of cancer patients who received BrdU as part of their chemotherapy regimen. They found that this thymidine analogue, which is incorporated into replicating DNA, was present in adult borne hippocampal neurons[38]. This elegant study was later extended and replicated, demonstrating a similar neurogenic zone in the subventricular zone (SVZ), neatly paralleling previous animal studies[39–41].

The lingering question of why all mammals retain this form of plasticity has yet to be answered satisfactorily. That the hippocampus plays a critical role in short-term memory formation and is implicated in emotional regulation suggests that adult neurogenesis plays an evolutionarily conserved role in these processes. The most straightforward evidence suggests that adult neurogenesis plays a role in memory formation. For example, the two most potent stimulators of adult neurogenesis, exercise and environmental enrichment, increase hippocampal neurogenesis and improve performance on cognitive tasks like the Morris water maze, even among aged animals. These improvements are only seen with tasks that are hippocampus-dependent (e.g. the water maze), but not with hippocampus-independent learning (e.g. active shock avoidance or delayed eye blink) (reviewed by [42–45]).

Neural Stem Cells and Their Environment

What is a neural stem cell?

Throughout our lifetime new neurons are generated from nascent precursors termed neural stem cells. 'Stem cells' have garnered tremendous popular and scientific attention over the past several years, but this raises the question of what is a neural stem cell? Since the discovery and acceptance of adult neurogenesis over 10 years ago, the field has been mired by confusing language and inconsistent definitions of what it means to be a neural stem cell[46]. In order to avoid such confusion, the following definitions will apply throughout this chapter: a neural stem cell is one that self-renews and has the potential to give rise to multiple cell lineages. Precursors (e.g. adult hippocampal precursor; AHP) are proliferating multipotent cells that do not self-renew. It is often difficult to experimentally distinguish NSCs from multipotential precursors. Therefore, in the absence of data showing that a cell truly self-renews, it is more conservative to refer to multipotent cells as precursors, and not stem cells. In contrast, lineage committed progenitors (e.g. neural progenitors) are rapidly proliferating cells whose differentiation potential is limited to one cell type.

Emergence of adult NSCs

The earliest NSCs begin their life as a thin layer of symmetrically dividing neuroepithelium lining the neural tube. In later embryonic development, these neuroepithelia become radial glia, which support the migration of migrating neuroblasts. These radial glia persist in the neonatal brain and ultimately transform into an astrocytic subtype with the properties of an NSC[47]. These NSC appear to constitute two preserved germinal centres in the adult mammalian brain, one in the SVZ and the other in the subgranular zone (SGZ) of the hippocampal dentate gyrus. The former migrate through the rostral migratory stream (RMS) to take up residence in the olfactory bulb, while the latter migrate a short distance to form the dentate granule cells[47].

Neurogenic stem cell niche

The anatomy of these two neurogenic region shares many similarities. Both constitute thin strips containing small clusters of proliferating cells (types A/G, B, C/D) in close opposition to vascular endothelium[48,49]. The type B cells are slowly proliferating, self-renewing astrocytes that are the real NSCs in these regions. The C (SVZ) and D (SGZ) cells are more rapidly dividing neural progenitors (transit amplifying), while the A (SVZ) and G (SGZ) cells are the immature neurons. The intricacies of the anatomy and the developmental process are far too complex for this discussion and are reviewed extensively elsewhere[47,49]. What is important is to recognize that the NSCs, their progeny and their blood supply reside in close opposition, creating a somewhat self-contained microenvironment. This specialized milieu is termed the stem cell niche[50].

Three compartments comprise this niche: ultrastructure, cells and milieu. (i) Ultrastructure: extracellular matrix and other cellular scaffolding maintain the gross cytoarchitecture of specific brain regions. Since guidance molecules are immobilized on these scaffolds, their loss can cause aberrant dendritic arborization and impaired axonal pathfinding of transplanted/regenerating neurons. (ii) Cellular components include NSCs, astrocytes (supportive and immunological), neurons, oligodendrocytes, microglia, and vascular endothelium and smooth muscle. (iii) The milieu is a metastructure composed of the many dynamically regulated, diffusible factors released by the constituent cells. Gradients of these factors are responsible for coordinating: (i) homing of immune cells; (ii) migration of neuroblast during foetal development (or transplanted neural stem cells); and (iii) neuritogenesis and synaptogenesis.

Niche Function

The niche, like a womb, creates a uniquely nurturing environment to support the birth and development of NSCs into full-fledged neurons. In addition to this supportive function, it serves to insulate the NSCs from the greater milieu. The constituent cells create this environment and generate the milieu, and in turn, each is impacted by it. Therefore, no cell is an island (with apologies to John Donne), the fate of each intimately affected by its neighbours. *In toto*, the niche preserves the delicate balance between NSC maintenance and differentiation and directs lineage decisions.

How is the niche regulated?

The SVZ/SGZ niche contains cells in various stages of development, from stem cells to committed progenitors to maturing neurons, as well as vasculature and ependyma (SVZ). As such, the developing NSCs are subjects to a host of intrinsic (e.g. neighbouring

Table 55.1 Niche targets for future gene therapy trials

Secreted proteins	*Niche effects*
Bone morphogenic protein4 [BMP4]	Astroglial differentiation
Brain derived neurotrophic factor [BDNF][a]	NPC/neuron survival
Ciliary neurotrophic factor [CNTF][a]	Astroglial differentiation
CCL5 (Rantes)	NSC quiescence
CXCL12 (SDF1α)	NPC chemoattractant, NSC
CX3CL1 (Fractaline)	NPC differentiation
Epidermal growth factor [EGF]	NSC/NPC survival and proliferation
Erythropoietin[b]	NPC differentiation
Fibroblast growth factors [FGF-2/FGF-20][a]	NPC proliferation
Glial-derived neurotrophic factor [GDNF][a]	Neuron survival
Granulocyte macrophage colony stimulating factor [GM-CSF][b]	Neuronal differentiation
Hepatocyte growth factor (HGF)[a]	NPC/neuron survival
Insulin-like growth factor 1 [IGF-1][b]	NPC proliferation, neuron survival
Leukaemia inhibitory factor [LIF]	NSC proliferation and survival
Neurotrophin 3,4/5 [NT3, NT4/5]	Neuron survival
Nerve growth factor [NGF[a]][a]	Neuron survival
Platelet-derived growth factor [PDGF][b]	OPC proliferation and survival
Progranulin [PGRN]	Neuronal survival (?), anti-inflammatory(?)
R-spondin [RSPO[a]]	NPC proliferation (?)
Transforming growth factor beta [TGFβ]	Neuronal differentiation, anti-inflammatory
Vascular endothelial growth factor [VEGF][a]	Angiogenesis, NPC/neuron survival
Wnt3,Wnt7a, Wnt8b	NSC/NPC proliferation and survival
Wnt5a, Wnt7b	Neuronal differentiation

NSC, neural stem cell; NPC, neural progenitor; OPC, oligodendrocyte progenitor.
[a] Used in clinical trials.
[b] FDA approved (alternate indication).

cells) and extrinsic (e.g. from blood or CSF) cues. These 'niche players' represent the prime targets of proposed gene therapy protocols. Formally, there are three forms of signalling at play: (i) externally derived signals conveyed via the blood (endocrine) or CSF (exocrine); these include diffusible factors like muscle-derived IGF-1 or VEGF, or inflammatory cytokines (e.g. interleukin-6, IL-1β or tumour necrosis factor alpha; TNFα); (ii) paracrine factors produced by local astrocytes or neurons (e.g. BDNF, FGF-2, Wnt, neurotransmitters); and (C) cell-autonomous signalling, which includes autocrine factors like Wnt or PDGF as well as genetically preprogrammed differentiation[51–53].

Table 55.1 summarizes some of the most prominent modulators of the adult NSC niche; however, the full panoply of secreted factors influencing the niche is far too extensive for the confines of this chapter (for review see[54–62]).

'Normally' aging niche

Neurogenesis reduces by more than 50% with advancing age. Some of the non-mutually exclusive hypotheses put forth to explain this observation include (i) functional, active downregulation[63]; (ii) inflammation[64]; (iii) burnout/depletion of stem cells (e.g. secondary to reduced Wnt[61]); (iv) niche changes that directly suppress trophic support[65]; (v) reduced circuit activity, which in turn could decrease BDNF/trophic support[66]; (vi) elevated cortisol, which accompanies normal ageing[63]; (vii) reduced physical activity, which reduces IGF-1, again, limiting trophic support[67–71]; and (viii) less intellectual stimulation might functionally reduce need for neurogenesis or might limit circuit activity indirectly (intellectual reserve hypothesis[72]). Intriguingly, exercise, environmental enrichment, cortisol reduction and inflammatory blockade all improve neurogenesis in older animals to near youthful levels and improve cognition[73–76]. Therefore, even though the aged brain exhibits lower baseline plasticity, it retains the capacity for regeneration, if properly stimulated. These provide additional scientific unpinning for ongoing trials of their efficacy in patients with cognitive impairment. (The reader should consult[77] for a systematic review of neurogenesis and ageing. However, for a more general review of age-related plasticity changes, consider[78,79].)

Neurogenesis and psychiatric illness

There is conflicting evidence about whether aberrant hippocampal neurogenesis underlies the aetiology of major depression or anxiety disorder. However, there is mounting evidence that neurogenesis is required for the beneficial effects of antidepressants. Without exception, all effective treatments for depression, including all classes of antidepressants, lithium and electroconvulsive therapy, stimulate neurogenesis, while chronic stress, which predisposes depression suppresses neurogenesis in animal models. Similarly, infusion of neurogenic stimulators like BDNF, IGF-1, FGF-2 and VGF produces antidepressant/anxiolytic effects, with the expected delay in onset. More recently, it was shown that ablation of neurogenesis blocks the beneficial effects of antidepressants on mood and cognition[80–85].

Niche and neurodegenerative disease

A host of pathologies, many associated with older age, can comprise niche function. Broadly, they do so in three ways: (i) generation of

an actively toxic environment by inflammation, increased expression of trophic antagonists or neurotoxins (e.g. soluble Aβ); (ii) development of a passively non-permissive environment through loss of trophic support (e.g. reduced BDNF, WNT, IGF-1, VEGF etc.) or vascular insufficiency; and (iii) structural damage from trauma or stroke. Because each neuropsychiatric disease differs in its underlying pathology, lesions to the neurogenic niche will differ as well. Since any cellular replacement/repair strategy requires recreating the niche (see below), an understanding of how the niche is compromised is an absolute prerequisite for the development of effective treatments.

Alzheimer's is the most common progressive neurodegenerative disease. It is characterized by early loss of short-term memory. Hippocampal involvement occurs early in the disease course, unlike PD or HD. As recently reviewed[86], there are conflicting reports in the literature as to whether hippocampal neurogenesis is increased or decreased early in the disease course[87–89]. The emerging picture suggests that early on modest cell loss triggers a compensatory increase in neurogenesis, probably via increases in FGF-2. However, the underlying pathology prevents survival of sufficient neurons to have a clinical impact. Later on, neurogenesis is uniformly impaired, paralleling the clinical picture. From the perspective of future therapies, it is interesting to note that exercise and environmental enrichment improve neurogenesis and cognitive performance, despite equal β-amyloid plaque loads[90,91].

A common feature of patients with AD, PD, HD and even non-specific mild cognitive impairment (MCI) is that they exhibit significantly impaired olfaction before the onset of more defining features (e.g. abnormal movements in PD)[92–96]. It is tempting to speculate that the cause is alterations in the SVZ niche, since the primary role of adult SVG neurogenesis is to supply new neurons to the olfactory bulb. Interestingly, when one examines the SVZ in patients with these three diseases, each displays a unique cytoarchitectural pathology. In AD, there is diffuse cell loss in regions with Aβ accumulation. In contrast, in PD, there is an SVZ thinning and 30% reduction in NSC proliferation, primarily reflecting a loss of type C (transit amplifying) progenitors and type A (immature) neurons. Examination of the SVZ in HD provides us with the most illuminating observation. The SVZ in HD is more than twice as thick as in age-matched healthy brains, even though AD, PD and HD are all characterized by profound neuronal loss. This increase is due almost exclusively to a doubling in the number of type B cells (radial glia/NSCs). Unlike in stroke patients, it appears that these cells never mature enough to leave the niche, hence never migrating to the lesioned area (i.e. striatum)[97].

Neurogenesis and stroke

Stroke represents a physiologically unique aetiology of cognitive impairment and mood dysregulation in the elderly. Up until the time of the ischaemic event, baseline regenerative mechanisms are unimpaired, unlike progressive neurodegenerative diseases like AD or PD. For this reason, the post-insult neurogenesis is far more robust than in AD, PD or HD. Initially, neural progenitors from the striatal SVZ migrate towards the area of inflammation created by the infarct. Neurogenesis in the region of the infarct can persist for upwards of four months in both humans and animal models[98–101], while the damage in younger patients can be mitigated by administration of erythropoietin[102] or GM-CSF[103] (as reviewed in[104]).

ADVANCED THERAPEUTIC TECHNOLOGIES

The terminology used for describing new technique or technologies can often be confusing; regenerative medicine is no exception. For simplicity's sake, let us define a few of these terms. *In vivo* gene therapy is the introduction of a novel gene into the patient. Most often, the goal is to raise above baseline the endogenous levels of some beneficial protein (e.g. infecting the striatum with a virus that overexpresses GDNF: see above). Somatic cell therapy is where primitive cells are engrafted into a region with the hope that they will integrate and subserve some function. The early foetal tissue transplants were an example of this type of therapy. *Ex vivo* gene therapy is a hybrid of the gene and cell therapy. In this model, cells (e.g. stem cells, fibroblasts) are engineered to express and release the protein of interest. In other words, they serve as living, implantable minipumps. Finally, there are advanced pharmaceuticals, which includes just about everything else. These can be engineered proteins (e.g. recombinant IGF-1 which is FDA approved for use in children with growth defects), small molecules (classic drugs), therapeutic antibodies, vaccines, interfering RNAs etc. In this section we will introduce cutting edge reagents and vectors that are being deployed in the coming generation of neural-repair trials

Cell-based Therapy

Cell-based therapy has received tremendous attention in recent years, as judged by both the volume of published review articles extolling its virtues and the volume of political debate regarding its use. People conceive of these cells as a ready source of spare parts that could be used to replace the damaged tissue. This conceptual simplicity belies quite significant technical challenges.

Newer transplantation trials propose using one of the following types of stem cells: (i) neural stem cells (NSC): possess the ability to differentiate into neurons, astrocytes or oligodendrocytes, but no other tissues; (ii) embryonic stem cells (hESC): blastocyst-derived pluripotent cells can give rise to any cell type in the body (in theory); and (iii) induced pluripotent stem cells (iPSC): pluripotent cells derived from a more mature cell type by genetic reprogramming with a panel of transcription factors. Since iPSCs can be derived from living patients, they hold great prospective value for modelling disease, as well as holding therapeutic potential. However, they are a less than two-year-old technology and many clinicians may be unfamiliar with them. Smith and colleagues provide a fuller discussion comparing and contrasting iPSCs and hESCs[105].

Even though no successful stem cell trial has been completed, the reader should already have a sense that no type of stem cell is the 'magic bullet' many had hoped for[106]. Each has significant limitations, as well as advantages, some of which are summarized in Table 55.2. Any pronouncement on which prove to be therapeutically useful would be mere speculation. Instead, the clinician and translational researcher should focus on what it would take to make any therapeutically useful.

First, we need to understand what we expect of these transplanted cells. (i) The transplanted stem cells must differentiate into the proper cell type and subtype (e.g. dopaminergic neurons, rather than glia); (ii) they must migrate into the correct position to integrate with the intact circuitry; (iii) they must survive in an environment already compromised by the underlying disease (i.e. survive immune attack, inflammation, apoptosis secondary to inadequate trophic support etc); and (iv) they need to remain differentiated and not

Table 55.2 Resources for cell-based therapy

	Source	*Application*	*Advantages*	*Disadvantages*
Foetal neural stem cells	Abortus	Replacement	Large expansion capacity	Heterologous donor
			Steady supply of tissue	Difficult to sort tissue
			Low transformation potential	
			High differentiation potential	
Adult NSC	Postmortem brain, biopsy (?)	Replacement	Autologous (potentially)	Limited expansion capacity
			Limited tissue supply	
Embryonic stem cell	Derived from discarded blastocycts	Replacement	Pluripotent	High teratoma risk
				Heterologous donor
				Chromosomal instability
				Religious/political complications
				Few available lines
Induced pleuripotent stem cells	Skin biopsy or hair samples (fibroblast-keratinocyte)	Replacement	Autologous	Potential transformation
Hematopoetic stem cell	Blood sample	Create vascular niche, anti-inflammatory	Easily purified	May be useless
			Easily acquired	
			Autologous grafing	
Engineered fibroblast-keratinocyte	Skin biopsy or hair samples	Ex-vivo gene therapy (minipumps)	Autologous	May not migrate sufficiently
Immortalized cell-lines	Mixed	Replacement	Easy to grow	Poor function
				High tumour risk
				Archaic technology

NSC, neural stem cell.

malignantly transform as occurred in several early gene therapy and foetal cell trials[32,107].

Second, getting transplanted stem cells to differentiate and integrate in non-neurogenic regions represents the greatest technical hurdle that must be overcome (points i and ii above). When foetal NSCs, and later hESCs, were first derived, there was a fanciful belief that being fully plastic (i.e. pluripotent) meant that they could be engrafted into a brain region. Once there they would grow into the region, as the native cells had done during foetal development. Since this was another case of wishful thinking, a limitation common to all three stem cell types is that they will require cellular programming prior to engraftment. As a field, we have made the greatest strides towards converting stem cells into dopaminergic neurons[1,108,109]. However, even here the programming efficiencies are low, and the developmental programme traversed is poorly understood. (The reader wishing a better understanding of these complexities should consult the following recent reviews[110,111].) Unfortunately, even less is known about coaxing these cells to properly integrate into the existing neuronal network. In short, the first few steps in making stem cells therapeutically useful are, truly, big steps indeed.

Third, safety concerns by the FDA and individual IRBs have been the primary holding up to initiation of many stem cell trials. Because hESCs universally form teratomas when injected into animals, it is unlikely that they, in their unadulterated form, will ever be used in human trials. Even the very first clinical trial of an hESC-derived progenitor was on an extended hold by the FDA until early 2009[112,113]. How real these safety concerns are is a matter of debate, but one that is sure to continue for several years.

Gene Therapy Vectors

W. French Anderson reported in the autumn of 1990 the first gene therapy trial on a patient suffering from a form of severe combined immunodeficiency (SCID). Almost three decades later, the only broadly successful application of gene therapy has been in the treatment of SCID[114]. It is hard to overstate the disappointment that, with over 1 500 approved clinical trials worldwide (many prematurely aborted), successes are so few and setbacks all too prominent[115,116]. The darker side of its major 'success' is that in the European trial, four patients who had received retroviral-based gene therapy for X-linked SCID went on to develop leukaemia. These malignancies were

Table 55.3 Most common gene therapy vectors

Vectors	*Advantages*	*Limitations*
Virus		
Retrovirus	Integrating	Dividing cells ONLY
Integrating	Broad tropism	Preferential insertion in active genes, particularly those regulating cell proliferation
	Moderate transgene size	High oncogenic potential
	Long-term expression	
Lentivirus	Integrating	Oncogenic potential
Integrating	Infects quiescent cells	Modest diffusion
	Broad tropism	
	Moderate transgene size	
	Long-term expression	
Herpes virus	Large transgene size	High inflammatory potential
Episomal		Transient expression in non-neuronal cells
AAV	High-titres	Smallest transgene capacity
Episomal (90%)	Highly-specific tropsim	Highly-specific tropsim
Integrating (10%)	Low inflammatory potential	
	Serotype-9 crosses blood–brain barrier	
Adenovirus	Large payload	High inflammatory potential
Episomal	Efficient transduction	Poor diffusion
		Short-term expression
Naked plasmid DNA-liposome[139]	Large payload	Poor transduction
	Easy to purify	
Blood-brain barrier translocators		
Carrier-mediated peptide transport	IGF-1, EGF	No carrier for most proteins
Receptor-mediated transcytosis	Highly adaptable to different proteins	Unproven in clinical trials
	RMT-BDNF entering clinical trials	
Cell-penetrating peptides	Highly adaptable to different proteins	Unproven in clinical trials
Intranasal delivery	Positive clinical improvement in clinical trials of stroke and Alzheimer's	Highly variable dosing and penetration

the result of the retrovirus preferentially inserting into the promoter of the *LMO2* gene (in two cases), a known T-cell oncogene.

Most gene therapy trials were designed to treat cancer (65%), where the goal is to arrest proliferation and foster death in the target cells. As neuropsychiatrists, our goals for gene therapy are diametrically opposite; preservation of neurons forces us to develop our own 'personalize toolbox'. To illustrate the shortcoming of applying previous trials' technique to problems of neurodegeneration, consider the following. The earliest (and only successful) trials used Moloney murine leukaemia virus (MMLV) based retroviral vectors. Like all oncoretroviruses, they only infect dividing cells, making them almost useless for treating the CNS (i.e. mature neurons do not divide). The alternative for initial trials, adenoviral vectors, can infect CNS, but have demonstrated extremely limited CNS penetration and the potential for severe inflammation. (Such inflammatory induced multi-organ failure led to the high-profile death of a relatively healthy clinical trial volunteer in 1999[117].) Together these help to explain why just 1.8% ($n = 27$) of clinical gene therapy trials have been approved for neurological disease, and only half of those for treatment of the brain (see the Gene Therapy Clinical Trials Worldwise database[118]).

These recognized shortcomings help define the requirements for the next generation of neuro-gene therapy tools. CNS gene therapy vectors must (i) possess the ability to infect non-dividing cells; (ii) carry the gene of interest to the intended target; (iii) be able to express the gene and resist the cell's natural defences, thereby preventing it from being turned off; and (iv) be safe (i.e. not induce malignancy transformation or severe inflammation, two primary causes of morbidity and mortality in previous gene therapy patients[107,117]).

Engineered viruses carrying a therapeutic gene remain the mainstay of proposed trials. Lentivirus (HIV-based) and adeno-associated virus (AAV) vectors are the two most popular viral vectors for current trials. They possess the desirable traits of low inflammatory response, good gene transduction and long-term gene expression. Table 55.3 summarizes the strengths and weaknesses of these and other gene therapy vectors (reviewed by[115,119–123]).

Interfering RNA

Until recently it was thought that most RNA transcribed from our genomes was either translated into protein or incorporated into ribsosome function (i.e. rRNA, tRNA). Now, it is believed that much, if not most, RNA is actually regulatory in nature. These short RNA species (RNAi) are able to complex with coding RNAs, thereby regulating protein production. The therapeutic potential of RNAi for treating cancer or HIV has garnered a great deal of press (and the 2006 Nobel Prize). In brief, the utility of RNAi is to reduce expression of some undesired mutant gene (a.k.a. toxic or gain-of-function mutation) like the bcr-abl fusion mutant found in chronic myeloid leukaemia. In psychiatric disease, some examples include AAV-delivered RNAi targeting the tau, and APP mutations found in

AD and frontotemporal dementia (FTD) or mutant huntingtin[124–126]. At the time of this writing no RNAi-based therapy for a CNS disorder has reached the stage of approved clinical trial; however, this is likely to change in the coming years. This subject has been reviewed extensively elsewhere[127–129].

Rethinking Clinical Trials

This section title begs the question, why do we need to change how we conduct clinical trials? Even though the mathematics behind selecting trial sample sizes is well understood[130], the psychiatry literature suffers from an unfortunately large number of studies being 'underpowered' for their purpose (power being the probability of concluding a benefit when there actually is one.) The primary culprit is not academic laziness, but arises from the fact that the statistical design of most trials requires that end-points and sample sizes must be fixed ahead of time. The more complex a trial, the more likely that these *pre hoc* assumptions will be wrong. While space limitations prevent a lengthy discussion of clinical trial design, it is important for the reader to understand that there is an alternative to designing exploratory trials around proving or disproving a null hypothesis. These Bayesian designs provide several advantages, including (i) allowing adaptive sizing of arms, midway in trial; (ii) measuring probabilities for non-directly observable events; (iii) incorporating prior knowledge; (iv) allowing smaller trials with the same statistical power; and (v) cross-arm information sharing, allowing more treatment variables. All of these will be invaluable for future gene therapy trials where such trials will require multifactor treatments and small sample sizes. For a more complete discussion of Bayesian statistics and their application to clinical trial design, the reader is referred to one of the following[131–136].

Neural Repair Finds Its Niche: Where Do We Begin Putting All the Pieces Together?

Many would begin by asking the question: what do we want to treat? However, we should ask: what are we willing to treat? It was proposed several years ago to apply gene therapy towards the treatment of anxiety/stress disorder[137]. The great philosopher (and baseball player) Yogi Berra reportedly quipped, 'In theory there is no difference between theory and practice. In practice there is.' Many illnesses we confront in geriatric psychiatry could, in theory, be treated with gene therapy or stem cells, but would we? All proposed gene- or cell-based therapy trials are invasive and present a high risk of morbidity. As with our anxiety example, when would we recommend brain surgery with gene therapy over a larger dose of diazepam? The risk versus benefit calculation has always been such that we will only consider these treatments for the worst afflicted patients (i.e. the ones with little to lose). Since these are the hardest patients to treat, we have made the already daunting task of perfecting regenerative therapy even harder.

To resolve our conundrum and bring these therapies into clinical practice, we need to complete many, many more clinical trials. Therefore, we need to make the trials less invasive, and thus less risky, thereby allowing us to treat less sick individuals. An example might be a regenerative trial in patients with early stage HD. Preclinical studies demonstrate that viral cotransduction of BDNF to promote survival and Noggin to block astrocytosis regenerates medium spiney neurons in the striatum[138]. Directly translating these animal studies into a clinical trial would be the 'sexy' approach. The theoretical grounds for such a trial are sound, but in practice it would be *extremely* difficult to obtain IRB approval for a two-gene therapy trial. A pragmatic, though less flashy, alternative is to determine whether some combination of available drugs might induce the same regeneration (see Table 55.4). For illustration purposes, we are

Table 55.4 FDA approved drugs with neuroregenerative potential

	Target	*NSC*	*NPC*	*OPC*	*Mature neurons/oligos*
Drug

I, inhibits proliferation; D, promotes differentiation; S, promotes survival; P, increases proliferation.

finalizing the Bayesian framework for such a trial comparing IGF-1 treatment paired with combinations of VPA, lithium, rosaglitazone and indomethicin.

The list of approved drugs with regenerative potential is growing, but is still quite limited. Therefore, most approaches to neuro-repair will ultimately require either gene therapy and/or cell-based therapy. The process needs to be a rational one, not relying on serendipity. In its most basic form it should entail

1. *Careful target selection*: identifying the biological target in need of correction (e.g. loss of dopaminergic nigral neurons);
2. *Payload*: design the actual treatment. A good basis for selecting these comes from our previous discussion of the neural stem cell niche, in health and disease;
3. *Vector/delivery*: engineer a means of getting it to the right place;
4. *Surveillance*: devise a way of monitoring the treatment (i.e. is it working?).

In summary, the best guide for future trials may be simply not to repeat the naïive mistakes of the past, most notable ignoring the essential role of the neurovascular niche in supporting and guiding neural regeneration. If we take such care then future editions of this text will likely contain more discussion of treatments at hand, and less hand-waving about the treatments of the future.

Vascular Dementia

Ingmar Skoog

Institute of Neuroscience and Physiology, Unit of Neuropsychiatric Epidemiology, Sahlgrenska Academy at the University of Gothenburg, Gothenburg, Sweden

BACKGROUND

Cerebrovascular disorders are generally believed to be the second most common cause of dementia, after Alzheimer's disease (AD). Dementia caused by cerebrovascular disease is often labelled vascular dementia (VaD). AD and cerebrovascular disease often co-exist in the same patient. This condition is termed mixed dementia[1]. Cerebrovascular disorders are also associated with cognitive decline which does not reach diagnostic thresholds for dementia[2–6]. The term vascular cognitive impairment was introduced by Bowler and Hachinski in 1995[7] to capture the whole range of cognitive dysfunction associated with vascular disease. This term thus includes VaD, mixed dementia and other forms of cognitive decline caused by cerebrovascular and cardiovascular diseases. It is important to recognize that cognitive impairment associated with cerebrovascular or cardiovascular disorders is potentially preventable or treatable.

DIAGNOSTIC CRITERIA AND DEFINITIONS

The most often used criteria for VaD were developed almost two decades ago. ICD-10 was published in 1993[8], DSM-IV in 1994[9], and the National Institute of Neurological Disorders and Stroke and the Association Internationale pour la Recherché et l'Enseignement en Neurosciences (NINDS-AIREN) criteria were published 1993[10]. These criteria show inconsistencies, and give rise to very different rates of VaD[11,12].

Definition of Dementia and Cognitive Decline

Cognitive function declines with increasing age. The decline may be accelerated by a range of insults to the brain, such as AD, cerebrovascular disease, other brain disorders, and various peripheral disorders such as cardiovascular diseases (CVDs). When the cognitive function reaches a certain threshold, and gives rise to difficulties in everyday life, the term dementia is used.

In criteria such as those of the ICD-10[8] and DSM-IV[9], dementia is a global decline in intellectual function involving memory, orientation, visuospatial abilities, executive function, language, thinking and often changes in personality and emotions. One problem with these criteria is that they state that memory impairment is mandatory for a diagnosis of dementia. This concept is based on the symptoms of AD, and misses a large proportion of individuals with severe cognitive dysfunction associated with impairments in activities of daily living (ADLs) and personal function, as cerebrovascular disease may cause significant cognitive dysfunction with relatively preserved memory function[7].

Definition of Cerebrovascular Disease

Many different cerebrovascular diseases may cause cognitive decline and dementia, including stroke, silent infarcts, ischaemic white matter lesions (WMLs), hereditary cerebral haemorrhage with amyloidosis, granular cortical atrophy, hypertensive encephalopathy, cerebral amyloid angiopathy and cerebral vasculitis (Table 56.1). Most cases of VaD have a mixture of cerebrovascular changes, which could be expected, as different cerebrovascular diseases share similar risk factors. The two most common causes of VaD are stroke and WMLs. However, most criteria highlight clinical strokes in their definitions of cerebrovascular disease. Thus, the definition of cerebrovascular disease is based on the presence or history of focal neurological motor symptom/signs, or brain imaging findings of cerebrovascular disease. DSM-IV lists examples of signs, while the ICD-10 specifies that at least one should be unilateral spastic weakness of the limbs, unilateral increased tendon reflexes, extensor plantar response or pseudobulbar palsy.

The DSM-IV requires that there should be signs *and* symptoms *or* laboratory evidence of cerebrovascular disease (i.e. that brain imaging reveals 'multiple infarctions in the cortex and subcortical white matter'), while ICD-10 requires evidence from history, examination *or* tests of significant cerebrovascular disease (i.e. history of stroke or evidence of cerebral infarction on brain imaging). In the NINDS-AIREN criteria[10], a diagnosis of probably VaD requires that focal signs consistent with stroke *and* relevant cerebrovascular disease by brain imaging should be present. One of the authors of the NINDS-AIREN criteria published a modified version a year later[13], in which this criterion was changed to focal signs consistent with stroke *or* relevant cerebrovascular disease by brain imaging. The first version is far too strict and underestimates the occurrence of VaD[11], since it will exclude individuals without stroke symptoms (including those with silent infarcts or white matter lesions). In a study on 85-year-olds[14], 13% of the demented had VaD based on the first version (i.e. 'focal signs consistent with stroke *and* relevant cerebrovascular disease by

brain imaging'), while 47% had VaD with the second version (i.e. 'focal signs consistent with stroke *or* relevant cerebrovascular disease by brain imaging'). In a study conducted on 100 demented patients, the prevalence of VaD was 14% using the first NINDS-AIREN criteria and 76% using DSM-III-R (which uses 'focal signs consistent with stroke *or* relevant cerebrovascular disease by brain imaging')[12]. The NINDS-AIREN criteria allow for a diagnosis of 'possible' VaD in patients with dementia and focal neurological signs in whom brain imaging is missing, and in patients with subtle onset and variable course.

Definition of an Association between Cerebrovascular Disease and Dementia

The influence of a stroke or an infarct on the cognitive symptoms is not easy to decide in the individual case, even if epidemiological studies suggest a strong statistical relationship[6,15–19]. The temporal relationship between symptoms of stroke and onset of dementia is often regarded as strengthening the possibility that the two disorders are related. The recent reports that non-symptomatic infarcts are common in the elderly and related to an increased risk for dementia and stroke[20,21] may question this statement. The NINDS-AIREN criteria suggest an arbitrary limit of three months for onset of dementia after stroke. However, a stroke which occurred years ago indicates the presence of cerebrovascular disease, including silent infarcts. The NINDS-AIREN criteria allow for a diagnosis of 'possible' VaD in the absence of a clear temporal relationship between dementia and clinical symptoms of stroke.

Both DSM-IV and ICD-10 criteria leave the clinician to decide on whether cerebrovascular disease and dementia are related, as both state that 'CVD should be (reasonably) judged to be etiologically related to the disturbance'. There are no specifications as to what this judgement should be based on.

EPIDEMIOLOGY

Almost all epidemiological studies reporting on the frequency of VaD are concerned with the subtype related to clinically manifest stroke or transitory ischaemic attacks (TIA). The proportion of vascular dementia varies widely between studies: between 15 and 45%. The variation may reflect disparities in diagnostic criteria, or differences in the rate of cerebrovascular disorders in different geographical areas[22]. It may also reflect differences in the efforts made to detect and diagnose cerebrovascular disease, and if brain imaging has been used. Although the prevalence of dementia is similar in most parts of the world, there are differences regarding the type of dementia. Stroke-related dementia is traditionally reported to be more common in Finland, the former Soviet Union and Asian countries, including Japan and China, than in Western Europe and the USA, where AD is generally reported to be the most common type of dementia. However, more recent studies report proportions of VaD in China and Japan similar to western countries[23]. Whether this is due to changes in diagnostic procedures or in risk factors for stroke is not clear.

Stroke

As mentioned, all criteria for VaD encompass history of stroke. Stroke patients typically have history of stroke or TIA including acute focal neurological symptoms and signs, such as hemiparesis or acute aphasia. Other cardiovascular manifestations, including myocardial infarction and hypertension, are common in the patients. Stroke is most often caused by cortical infarcts due to thromboembolism from extracranial arteries and the heart, and is often related to large vessel disease.

The typical clinical course of stroke-related dementia includes sudden onset, stepwise deterioration and a fluctuating course. In the early stages, the expression of cognitive impairment is variable and depends on the site of the lesions. A large proportion of patients with cerebrovascular disease have a gradual onset of dementia with a slowly progressive course[24], with or without focal signs or infarcts on brain imaging, which makes it difficult to differentiate from AD or other types of dementia. It has even been suggested that individuals with cortical strokes show less decline in cognitive function than those with subcortical cerebrovascular disease[25].

Stroke is an essential part of most criteria for VaD or vascular cognitive impairment. In line with this, most epidemiological studies report an increased frequency of dementia in individuals with stroke (Table 56.2). In the studies by Tatemichi *et al*.[15–17], relatively young individuals with ischaemic stroke had at least nine-times greater risk for dementia than stroke-free controls, and those with dementia had a higher mortality rate and worse prognosis which was independent of stroke severity. Also Pohjasvaara *et al*.[18] reported an increased prevalence of dementia in stroke victims, as well as a decrease in independent living for those with dementia. Lindén *et al*.[6] reported that stroke victims aged above 70 had an odds ratio (OR) of 4.7 for dementia. The odds for dementia were higher in those aged 70–80 (OR 6.7) than in those aged above 80 (OR 4.8), but the frequency of dementia after stroke was higher after age 80 (34% versus 18%). In addition, 60% of non-demented stroke victims had some cognitive dysfunction, showing that very few elderly stroke victims are free from cognitive disturbances. In a population study on 85-year-olds, Liebetrau *et al*.[19] reported that the odds ratio for dementia in stroke was 4.3, but the prevalence of dementia in those with stroke was

Table 56.2 Prevalence of dementia in stroke patients and in the general population

Age group	*Stroke (%)*	*Population (%)*
60–64	10	1
65–69	20	1
70–74	25	2
75–79	30	5
80+	50	20–30

57%. It may be that the increased risk for dementia with stroke decreases with age although the prevalence increases.

The most important risk factors for stroke are hypertension, diabetes mellitus, atherosclerosis, atrial fibrillation, smoking, being overweight, and hypercholesterolaemia, especially high levels of low-density lipoprotein (LDL) cholesterol[26]. All these risk factors are potentially preventable or treatable. Changing risk factor patterns (e.g. decrease in smoking, more treatment of hypertension) have decreased the incidence of stroke, and may thus decrease the frequency of VaD. On the other hand, more individuals survive after stroke, which may act in the opposite direction. It is not yet known if the prevalence or incidence of VaD is increasing or decreasing.

The pathogenesis of stroke-related dementia has not been established. The main hypothesis is that dementia is related to the location or the volume of the infarcts, but there are also other possibilities. The risk factors for VaD can be divided into stroke-related and non-stroke-related[27]. The stroke-related are similar to those in stroke, for example male sex, hypertension, diabetes mellitus, smoking and cardiac diseases. Non-stroke-related risk factors are similar to those found in sporadic AD and include higher age, lower level of formal education, family history of dementia and the presence of cerebral atrophy. This combination of risk factors supports the view that stroke-related dementia often is a consequence of both stroke and pre-existing AD pathology. According to neuropathological studies, pure VaD, without any AD brain changes, is rare[28].

Silent Cerebrovascular Disease

Most cerebrovascular disease is not related to focal symptoms, aphasia or other distinct clinical manifestation, but may be detected on brain imaging. The relevance of this silent cerebrovascular disease has been debated, but recent research has shown that it is related both to dementia and later manifestations of clinical stroke. The most common 'silent' disorders are silent infarcts and ischaemic white matter lesions.

Silent infarcts

Cerebral infarcts often occur without focal symptoms. The frequency of these so-called silent infarcts increases with age[29]. These lesions were until recently believed to be benign incidental findings on brain imaging, when researchers from the Rotterdam Study reported that individuals with silent infarcts were at increased risk of developing clinical stroke[29] and dementia[20]. Among 85-year-olds, 10% have silent infarcts on CT, and these lesions double the prevalence of dementia[21]. It is important to detect these lesions, as treatment of vascular risk factors, such as hypertension, may decrease the risk of new strokes and thus potentially delay dementia in these high-risk patients.

Subcortical white matter lesions

Another important cerebrovascular disease causing dementia and cognitive decline is subcortical white matter lesions (WMLs)[30]. These have been suggested to be the most common cause of VaD. Subcortical areas of both hemispheres are affected by marked or diffuse ischaemic demyelination and moderate loss of axons with astrogliosis and incomplete infarction. In addition, arteriosclerotic changes with hyalinization or fibrosis and thickening of the vessel walls and narrowing of the lumina of the small penetrating arteries and arterioles are also present[31,32]. The cortex, the subcortical U fibres and corpus callosum are generally well preserved, probably due to the construction of the blood supply.

The pathogenesis behind WMLs is probably that long-standing hypertension causes lipohyalinosis and thickening of the vessel walls with narrowing of the lumen of the small perforating arteries and arterioles which nourish the deep white matter[31]. Episodes of hypotension may lead to further hypoperfusion and hypoxia-ischaemia, leading to more loss of myelin in subcortical areas. The deep white matter has few collaterals, which makes it more vulnerable to ischaemia than the cortex. Furthermore, myelin is probably more vulnerable than axons to ischaemia[33].

WMLs may be detected on brain imaging. On computerised tomography (CT) scans they appear as low-density areas, and on magnetic resonance imaging (MRI) as hyperdense areas. MRI and CT may not always capture the same changes. WMLs on MRI correspond to several different histological findings, most often état criblé, and often show no correlation with cognitive decline and dementia. On the other hand, in 55 cases of WMLs on CT, the histopathological picture described in the previous paragraph was reported at autopsy in 53 of the cases[34]. Thus, MRI is more sensitive than CT for detecting changes in the white matter, but has a lower specificity.

MRI studies generally report much higher rates of WMLs than CT studies. The Rotterdam population study[3] reported that 11% in the age strata 65–69 years, 21% in those aged 70–74 years, 27% in 70–79-year-olds and 54% in those aged 80–84 years had WMLs, and the Helsinki Aging Brain Study[35] reported periventricular hyperintensities in 21% of those aged 55–75 years, and 65% in those above that age. A recent population-based neuropathological study reported that 94% of demented subjects had WMLs[30].

The cognitive decline related to WMLs is suggested to be due to disconnection of subcortical–cortical pathways, producing a decline in abilities related to subcortical or frontal lobe structures. Subcortical symptoms in individuals with WMLs include psychomotor slowness and retardation[4,5] and extrapyramidal signs. Frontal lobe symptoms[36] include executive dysfunction, apathy, loss of drive and emotional blunting. Other symptoms are bilateral or unilateral pyramidal tract signs, and hemi- or motor anaesthesia, pseudobulbar palsy, depression, early urinary incontinence and early gait dysfunction. Memory dysfunction is often mild.

The dementia often has an insidious onset and a slowly progressive course[25,31], which makes it difficult to distinguish from AD. Initially, there may be transient and fleeting attacks of focal neurological symptoms, with a subacute accumulation of deficits. WMLs seldom occur as the sole cause of dementia, and the clinical picture may vary depending on what other causes contribute to the dementia. Punctate WMLs on MRI do not progress, while confluent white matter abnormalities are progressive, and thus more malignant in the long term[37].

The main risk factors for WMLs are high age, hypertension, and hypertension clustering factors. It has been suggested that the arterial changes are due to exposure of vessel walls to increased pressure over time. The greater the pressure and/or life span, the more likely are these changes to be present. This may be one reason for the observed increase with age reported in most studies.

It was recently shown that diastolic blood pressure and mean arterial pressure in midlife was related to the presence of white matter lesions in late life, supporting both the theory that long-standing high blood pressure is important and that resistance of the smaller arteries and microvascular network is important[38].

Mixed Dementias

The common co-occurrence of AD and VaD is becoming increasingly recognized[1,30]. This may even be the most common cause of dementia, especially in the oldest ages. As already mentioned, cerebrovascular disease increases the risk of developing dementia[6,15–19,34,], but to evaluate the relative contribution of cerebrovascular disease towards the dementia symptoms in the individual patient is almost impossible. Cerebrovascular disease may be the sole cause of dementia in an individual; it may be the event that finally overcomes the brain's compensatory capacity in a subject whose brain is already affected by not-yet clinically manifest Alzheimer pathology, and in many instances minor manifestations of both disorders which individually would not be enough to produce dementia may produce it together[39,40]. On a clinical basis, it is often almost impossible to differentiate mixed dementia from pure VaD. Cerebrovascular disease as a contributing cause of dementia may be overlooked as onset is sometimes insidious, the course gradual, and the infarctions clinically silent or not detectable by brain imaging. Pure VAD may also be overdiagnosed, as the presence of stroke, WMLs or other cardiovascular disease does not mean that they caused the dementia.

Even the histopathological diagnoses of AD and VaD are uncertain. Extensive AD encephalopathy[41–43] and cerebrovascular disease[41,44] are reported in individuals with no signs of dementia during life. The MRC-FAS study[43], and the Nun Study[45] both found that only about half of those fulfilling neuropathological criteria for AD were demented during life. Similar results are reported in PET (positron emission tomography) studies using the PiB (Pittsburgh compound B) to detect amyloid deposition[46]. This shows that presence of extensive AD in the brain does not always result in dementia. A substantial proportion of individuals fulfilling the NINCDS-ADRDA (National Institute of Neurological and Communicative Disorders and Stroke, and the Alzheimer's Disease and Related Disorders Association) criteria for probable AD or NINDS-AIREN criteria for probable VaD have mixed pathologies[28,47,48]. Also, WMLs have been described on both brain imaging and at autopsy in about two-thirds of cases of Alzheimer's disease[32,34,49]. The Nun study[45] showed that presence of cerebrovascular disease increased the risk that individuals with AD lesions in their brains would express a dementia syndrome, from 57% in those without cerebrovascular disease to 93% in those with 1–2 lacunar infarcts and 75% in those with large infarcts[45]. In addition, patients with VaD may have cholinergic deficits similar to those seen in AD, caused by ischaemia of basal forebrain nuclei and of cholinergic pathways[50,51]. Also other markers of AD, such as high tau[52] and low beta-amyloid[53] in cerebrospinal fluid may appear in VaD. Finally, similar vascular risk factors have been reported both for AD and VaD[54], which also may explain the common co-occurrence of these disorders.

DIAGNOSIS

The first step in the diagnostic work-up is to determine the extent of cognitive dysfunction, the nature of this dysfunction, and its consequences. This should be done in all elderly patients with a recent stroke, or other cerebrovascular disease. A simple screening instrument may be used, for example the Mini-Mental State Examination. Other tests include examinations of executive function, the Clock Test, word fluency, naming ability and five-item memory test. It needs to be emphasized that patients with dementia related to CVD are often difficult to test due to language dysfunction.

The second step aims to identify cerebrovascular and other causes of the dementia. In the elderly, there are often multiple causes of dementia, and every contributing treatable cause that can be diagnosed may be important in the treatment of the patient. Besides cerebrovascular disease, other conditions that might contribute to cognitive decline include, for example, cardiovascular diseases, deficiency states, infections and depression. Brain imaging is necessary in this step, not only to identify cerebrovascular disease (white matter lesions and cerebral infarcts), but also to diagnose low pressure hydrocephalus, subdural haematoma, and brain tumours. The examinations should also include careful history-taking, interview of a close informant, neurological, psychiatric and physical examinations, chest X-ray, ECG and biochemical screening. This last includes cholesterol (total cholesterol, s-high-density lipoprotein cholesterol, s-low-density lipoprotein, triglycerides), screening for diabetes mellitus (fasting P-glucose, B-HbA1c), P-homocystein, vitamin B12, a thyroid function test and thrombocytes, leukocytes and haemoglobin. Cerebrospinal fluid (CSF) examinations should be performed for analyses of beta-amyloid, tau protein, inflammation and CSF/blood ratio (for blood–brain barrier function).

An ECG should be performed to detect arrhythmias and other cardiac diseases. A carotis Doppler should be done to detect atherosclerosis in this vessel.

Traditionally AD has been a diagnosis of exclusion and VaD has often been assigned if the patient has a history of stroke thought to be etiologically related to dementia. From a clinical standpoint, it is neither important nor possible to differentiate between AD and VaD in most cases with cerebrovascular disease. Most cases of VaD are probably of a mixed aetiology, and older patients with AD may often have concomitant cerebrovascular disease, which needs treatment. Therefore the diagnostic procedure should detect evidence for AD and cerebrovascular disease and direct the treatment to both disorders.

TREATMENT POSSIBILITIES

The general strategy in the treatment of VaD is to prevent new strokes or infarcts. Detection and treatment of risk factors is essential. Some risk factors are listed in Table 56.3. Treatment of cardiac arrhythmias, diabetes mellitus, hypertension and hypercholesterolaemia is also essential. Regarding white matter dementia, antihypertensive treatment may potentially prevent the changes in the small vessels. Recently it was shown that treatment of hypertension prevented stroke also in individuals above the age of 80[55]. Although no formal studies have been performed, the use of anticoagulant agents, for

example low-dose treatment with salicylates, is often used. Patients with VaD often have concomitant AD. In these cases, one should initiate treatment with an acetylcholinesterase inhibitor[50,56].

The Frontotemporal Dementia Syndromes

Mario F. Mendez

VA Greater Los Angeles Healthcare System and David Geffen School of Medicine at UCLA, Los Angeles, USA

INTRODUCTION

The frontotemporal dementia (FTD) syndromes are related disorders resulting from neurodegeneration of the frontal and anterior temporal lobes. In 1892, Arnold Pick, a Prague neuropsychiatrist, described the first known patient and subsequently published a series of three patients with left anterior temporal atrophy[1,2]. In 1911, Alois Alzheimer, a German neuropathologist, described the characteristic inclusion bodies of what came to be known as 'Pick's disease.' The field was nearly quiescent until the late 1980s when investigators in Lund, Sweden reported on an autopsy series of 158 patients with dementia[3,4], 20 (13%) of whom proved to have frontal lobe degeneration. In the past two to three decades, progress has been rapid. In the 1990s, there were several clinicopathological studies of FTD[5,6] and the eventual demonstration of a linkage of some cases to the tau gene region on chromosome 17[7]. Finally, in the past few years, researchers discovered an association of FTD with mutations in the progranulin gene (*PGRN*) and identified one of the major ubiquitinated proteins in FTD as the TAR DNA-binding protein 43 (TDP-43)[8–11].

The three principal FTD syndromes are the behavioural variant (bvFTD), which comprises over half of these patients, and the language-predominant syndromes of progressive non-fluent aphasia (PNFA) and semantic dementia (SD). Although often underdiagnosed[12,13], these three FTD syndromes comprise the third most common neurodegenerative dementia after Alzheimer's disease (AD) and dementia with Lewy bodies (DLB). Clinical reports describe frequencies of FTD of 5–13% among dementia outpatients[14,15]. In possibly the best population-based series, there was a calculated annual (1990–1994) incidence of FTD in Rochester, MN, of 2.2 per 100 000 in the age group 40–49 years, 3.3 for 50–59, and 8.9 for 60–69[15].

On average, the FTD syndromes have a presenile age of onset, are equally common among men and women, and lack a proven ethnic predisposition. The age of onset of bvFTD averages around 57 years with a usual range of 51–63 years, but patients have presented from the 20s to the 80s[16–18]. The age of onset of SD is similar to that of bvFTD, but PNFA patients are often slightly older[17]. FTD syndromes are common among dementia patients with an age of onset of less than 65 years, accounting for approximately 15–20% of young-onset dementias[18–20], with prevalences in the 45–64 year age group of 15 per 100 000 in the UK and 6.7 per 100 000 in the Netherlands[20–22].

CLINICAL PRESENTATIONS

Behavioural Variant FTD

The clinical syndrome of FTD presents with several 'core' and 'supportive' behavioural changes in mid-life (Table 57.1)[23–26]. The most common behavioural changes are apathy or decreased spontaneity and interest, and disinhibition or impulsivity[25,27,28]. Second, bvFTD patients violate social and moral norms, conventions or rules[25,26]. They may inappropriately touch others or violate their personal space, talk to strangers or children that they do not know, make sexual comments, forgo tact or table manners, and even manifest sociopathic behaviour such as theft. Third, they have 'emotional blunting' with a loss of empathy and awareness of the needs of others. Basic emotional appreciation is decreased, particularly for negative facial or vocal emotions[29,30]. Fourth, patients lose insight into their behavioural changes and lack self-referential behaviours such as embarrassability or shame. Fifth, they frequently have changes in dietary or eating behaviour, most commonly a carbohydrate craving[25]. Sixth, bvFTD patients have a range of repetitive behaviours from simple motor stereotypies to complex compulsive-like acts[25]. Finally, a supportive criterion is neglect or loss of interest in personal hygiene with failure to wash, bathe, groom or dress appropriately. In comparison, psychotic symptoms such as delusions and hallucinations are much less common among bvFTD patients compared to other dementia syndromes[25,31].

Cognitive functions

Patients with bvFTD develop frontal-executive deficits. This is reflected in their lack of insight and loss of awareness or distress at their disability or the consequences of their behaviour. Their judgement is abnormal, and they are often concrete on idiom and proverb interpretation. Occasionally, patients have stimulus-bound behaviour such as echolalia and utilization behaviour (grasping and repeatedly using objects that they see or tending to read aloud anything they see). On language examination, bvFTD patients often have progressively decreased verbal output and mutism in advanced stages. They also manifest reiterative speech or verbal stereotypies. In contrast, early bvFTD patients have relatively spared memory with better free recall, cued recall and recognition than

Table 57.1 Behavioural variant frontotemporal dementia

I. Core diagnostic features
- A. Progressive deterioration of behaviour, cognition or both
- B. Early apathy or inertia
- C. Early behavioural disinhibition with abnormal sociomoral behaviour
- D. Early 'emotional blunting' or loss of sympathy or empathy
- E. Loss insight or and self-referential behaviours

II. Supportive diagnostic features
- A. Dietary or eating behaviour, most commonly a carbohydrate craving
- B. Repetitive (stereotypic or compulsive) behaviour
- C. Executive deficits with relative sparing of memory and visuo-spatial functions
- D. Decline in personal hygiene and grooming
- E. Brain imaging: predominant frontal and/or anterior temporal abnormality

Source: Modified from Neary *et al.*[61]

Table 57.2 Progressive non-fluent aphasia

I. Core diagnostic features
- A. Insidious onset and gradual progression
- B. Agrammatism
  1. Grammatical morpheme and functor word omission
  2. Reduced mean length of utterance
  3. Phonemic paraphasias
- C. Motor speech abnormalities
  1. Articulatory struggle and stuttering
  2. Dyarthria and/or dysprosody
  3. Apraxia of speech

II. Supportive diagnostic features
- A. Impaired syntactical comprehension
- B. Impaired repetition
- C. Alexia and agraphia
- D. Brain imaging: asymmetric abnormality predominantly affecting left hemisphere

Source: Modified from Neary *et al.*[61]

do AD patients[18,32,33]. Furthermore, they have preserved visuo-spatial skills such as spatial localization and orientation in familiar surroundings[34,35]. Rare bvFTD patients even have a facilitation of artistic and musical ability[36].

On neurological examination, bvFTD patients are usually normal early in their course but can develop primitive reflexes and motor changes as the disease progresses. A major subgroup of bvFTD patients develops parkinsonism, dystonia and ideomotor apraxia, or fasciculations and muscle wasting. Many of those who develop parkinsonism eventually evolve to the related syndromes of progressive supranuclear palsy (PSP) and corticobasal syndrome (CBS)[37–43]. A second major subgroup of about 10–15% of bvFTD patients develop motor neuron disease (MND), primarily with bulbar and proximal upper extremity impairment[44–47].

On neuropsychological testing, bvFTD patients perform particularly poorly on tests of executive functions[48–52]. They are often impaired on digit span backwards, verbal fluency, Trail Making Test B, and the Tower Test. They do poorly on the Iowa Gambling Task, where they fail to improve when offered monetary rewards[53]. Patients with bvFTD cannot do tasks of abstraction and have poor verb comprehension relative to nouns[54–56]. They may be impaired on paradigms where they must infer other people's mental states, thoughts and feelings, referred to as 'theory of mind'[57], and the ability to process social rule violations is impaired along with their sense of 'personal' morality[30,58]. In comparison, as previously noted, there is relative preservation of amnesia or visuo-spatial impairments on neuropsychological measures.

Progressive Nonfluent Aphasia

PNFA is characterized by an initial two or more year period of relatively isolated difficulty in verbal expression with agrammatism, difficulty with sentence syntax, shortened phrase length, and motor speech difficulties in the presence of relatively preserved comprehension (Table 57.2)[59–62]. Patients have difficulty with verbs and with sentence processing[63]. They also have apraxia of speech, with hesitant, broken and effortful output and phonologic (phonemic paraphasic) errors, particularly in repetition of polysyllabic words. Speech changes include progressive dysarthria with stuttering and oral apraxia[64]. Reading and writing is correspondingly impaired, and patients with PNFA are aware of their language and speech deficits.

In PNFA, there is asymmetric atrophy of the left frontotemporal lobes[61]. Magnetic resonance imaging (MRI) with voxel-based morphometry (VBM) and functional imaging reveal marked atrophic changes or hypometabolism and decreased blood flow in the left perisylvian, inferior frontal and anterior insular areas[59,65]. Most patients with PNFA have frontotemporal neuropathology, but some patients have a language variant of AD at postmortem[62,66].

Semantic Dementia

This FTD syndrome produces a multimodal loss of conceptual knowledge, particularly in word comprehension and facial recognition (Table 57.3). In contrast to PNFA, patients with SD have fluent speech and normal grammar but cannot understand words[67]. They have relative preservation of repetition, phonology, syntax, the ability to read aloud and the ability to write orthographically regular words. Their speech output becomes progressively empty, however, as they lose substantive words and their meanings. On testing, they have problems with single word comprehension on pointing commands, word definitions and matching of objects or pictures with words. On reading, there is a characteristic disorder termed 'surface dyslexia' with inability to read irregularly spelled words but preserved ability to sound them out[68]. The rest of their cognitive profile reflects semantic loss in other domains. There may be an impairment in the recognition of familiar faces (prosopagnosia) and impairment of object meaning or identity (object agnosia) that cannot be attributed to naming difficulties. Despite these deficits, SD patients can continue to learn (episodic memory) and have intact visuo-spatial skills[69].

In SD there is circumscribed atrophy of the anterior inferior temporal gyri[70]. The cortical atrophy involves the left inferolateral temporal lobe and fusiform gyrus, right temporal pole, bilateral ventromedial frontal cortex, and the amygdaloid complex with sparing of the hippocampus[70]. Most SD patients have greater atrophy in the left anterior temporal region compared to the right. The asymmetric involvement is often evident on MRI imaging and correlates

Table 57.3 Semantic dementia: consensus criteria

I. Core diagnostic features
A. Insidious onset and gradual progression
B. Poor confrontational naming, particularly for unfamiliar items
C. Loss of word comprehension, particularly for unfamiliar items
D. Intact word repetition
E. Intact motor speech
AND/OR
A. Perceptual disorder characterized by
1. Prosopagnosia: impaired recognition of identity of familiar faces
2. Object agnosia: impaired recognition of object identity
B. Preserved perceptual matching and drawing reproduction
Supportive diagnostic feature
Brain imaging: predominant anterior temporal abnormality-bilaterally or asymmetric

Source: Modified from Neary *et al.*[61]

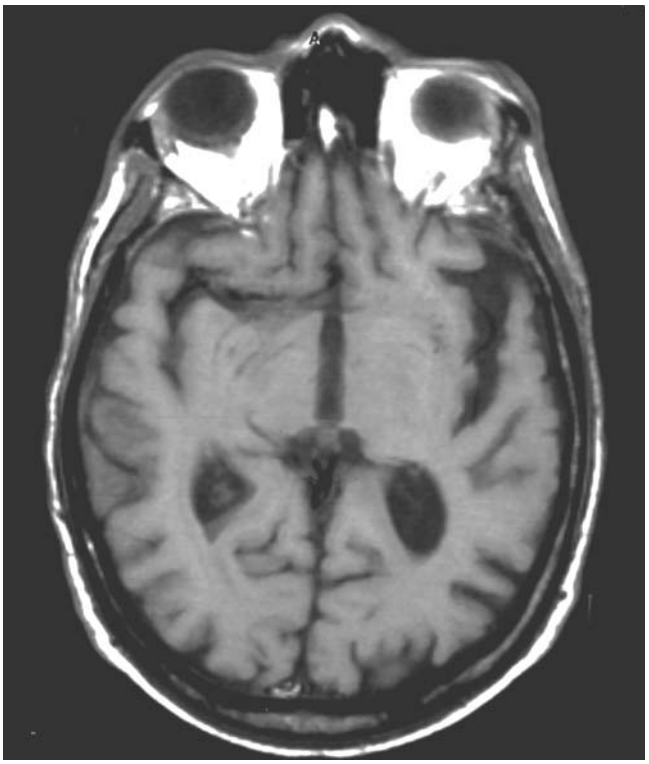
with relative impairments for word meaning (left temporal lobe) versus prosopagnosia or object recognition (right temporal lobe)[71]. The function of the anterior inferior temporal region appears to be to bind information together.

CLINICAL EVALUATION AND DIAGNOSIS

With the exception of the identifiable mutations, there are as yet no definitive tests for the FTD syndromes. In bvFTD, the behavioural changes outlined above usually precede or overshadow any cognitive deficits[6,18,19,72]. Suspicion for bvFTD arises when there is a change in personality, usually in mid-life[19,73,74]. Suspicion for PNFA or SD arises when there is new speech or word-finding difficulty in mid-life. Clinical criteria for diagnosing the three main FTD syndromes are the FTD Consensus Criteria (see Tables 57.1–57.3)[61]. These criteria have proven imperfect, with about 33–56% of bvFTD patients failing to meet Core Consensus Criteria on presentation (see Table 57.1)[12,13,75]. They are particularly deficient when it comes to a subgroup of bvFTD patients who lack changes on neuroimaging and who fail to progress after years of follow-up[50,51,76]. Currently, the FTD Consensus Criteria are undergoing revision by an international team of experts in the field.

Brain MRI can help confirm the presence of an FTD syndrome (Figure 57.1)[77]. Although often normal in early stages[78,79], MRI scans eventually show frontal and anterior temporal atrophy, enlargement of the Sylvian fissures, and anterior callosal atrophy[80–86]. There is temporal polar, amygdalar and lateral temporal and fusiform gyral involvement but relative sparing of the hippocampi[83,87–90]. FTD patients may have additional MRI evidence of bilateral caudate atrophy, and others have changes in the substantia nigra and putamen or high signal changes in white matter[91]. VBM studies in autopsy-confirmed patients have confirmed the mesial frontal, anterior insular and anterior temporal regional atrophy[92–96]. Finally, recent studies suggest that the neuropathological variants of FTD may have different patterns of frontotemporal atrophy on neuroimaging[95,97].

Functional imaging may be more sensitive than MRI for the diagnosis of FTD. Positron emission tomography (PET) and single-photon emission tomography scans show decreased regional



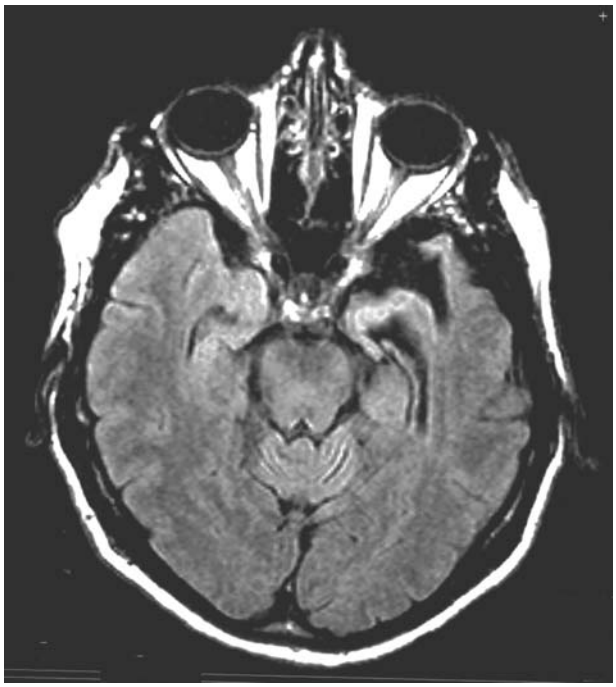


Figure 57.1 MRI (T2-weighted) image of progressive non-fluent aphasia (PNFA). Asymmetric atrophy of the left Sylvian fissure with reciprocal enlargement of the left frontal horn

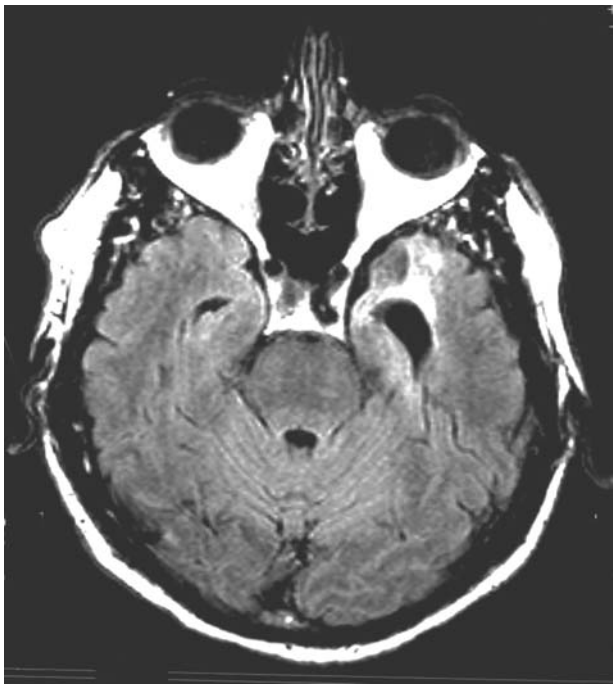

metabolism and cerebral blood flow in the frontal cortex and anterior temporal lobes (Figure 57.2)[72,82,98,99]. On fluorodeoxyglucose (FDG) PET, glucose uptake is reduced primarily in dorsolateral and ventrolateral prefrontal cortices and in frontopolar and anterior cingulate regions[100]. Although PET scan changes are not specific for FTD syndromes[101], worsening functional changes over time favour the diagnosis of a neurodegenerative dementia such as FTD[102,103]. Furthermore, new functional imaging technologies, such as Pittsburgh Compound-B (PIB), hold great promise for distinguishing FTD syndromes from AD and other neurodegenerative disorders with amyloid-related pathology[104,105].

There are important brain–behaviour relationships between symptoms and specific regions of involvement in FTD. Patients with bvFTD have greater right than left-sided atrophy[106,107]. The initial pathology in bvFTD involves the ventromedial frontal cortex, orbitofrontal region and anterior insula[108,109]. Abnormalities in social and moral conduct correlate with changes in these regions on functional neuroimaging[26]. Apathy correlates with mesial frontal atrophy on both MRI VBM and on FDG-PET[28,110]. Disinhibition correlates with atrophy of the subcallosal part of the frontal lobe, orbitofrontal region and adjacent temporal areas[28,106,110]. PFNA and apraxia of speech correlate with left peri-Sylvian and anterior insular involvement[92]. SD correlates with anterior temporal atrophy[88,111]. Moreover, in SD, impaired word comprehension corresponds to left anterior temporal atrophy, and right temporal atrophy corresponds to impaired recognition of faces (Figure 57.3).

Most other biomarkers, such as plasma TDP-43 or tau levels, have not yet proven to be clinically useful for the diagnosis of FTD syndromes. Cerebrospinal (CSF) biomarkers hold the most promise for

(a)

(b)

Figure 57.2 FDG-PET imaging of FTD patient. (a) Horizontal and (b) saggital views demonstrate frontal and anterior temporal hypometabolism

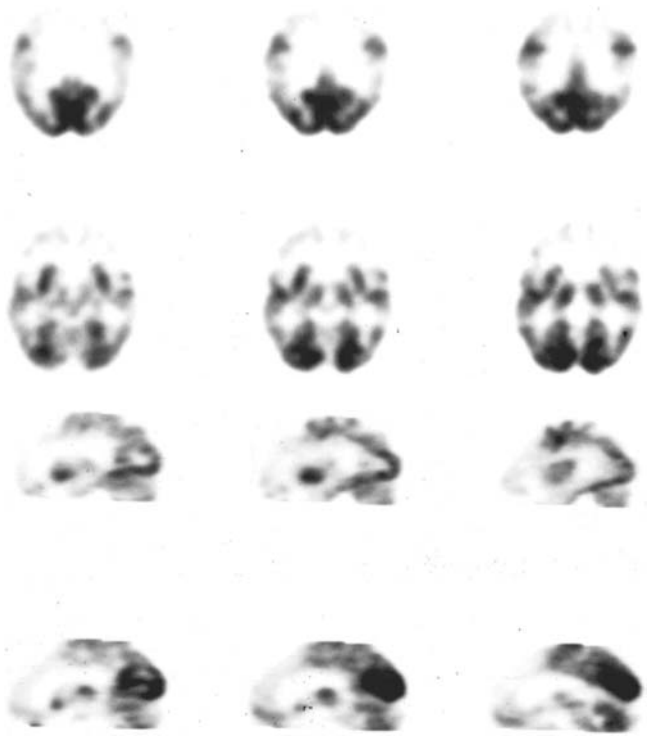

Figure 57.3 MRI (T2-weighted) images from patient with semantic dementia (SD). There is bilateral anterior temporal atrophy disproportionately affecting the left temporal lobe and associated with impaired word comprehension

eventually helping distinguish FTD from AD[112]. Among patients with bvFTD, some have found a significant decrease of CSF tau protein[113], but most report normal or only slightly increased CSF total tau and phospho-tau levels[114–120]. Overall, the literature indicates significantly lower total tau and tau/Aβ42 amyloid ratios in FTD compared to AD. In addition, decreased plasma levels of the PRGN protein in FTD patients with these mutations may be useful in screening for this specific genetic form of FTD (see below)[121].

PATHOLOGY AND NEUROGENETICS

There is frontotemporal lobar degeneration on gross pathology. The ventromedial frontal region and the anterior temporal areas have the most severe atrophic changes. Initially, the cortical degeneration is usually asymmetric and involves the mesial frontal regions including the anterior cingulate gyrus and the anterior insula. The frontotemporal cortex has neuronal and synaptic loss and astrogliosis with spongiosis (minute cavities or microvacuolation) of the outer, supragranular (II–III) layers, with variable involvement of subcortical and limbic structures[122–124]. Specific loss of von Economo neurons occurs in the anterior cingulate and anterior insulae[124]. Finally, the serotoninergic and dopaminergic systems are decreased with relative sparing of cholinergic systems[125,126].

The FTD syndromes include pathological variants that have intraneuronal inclusions that are either tau-positive or tau-negative, ubiquitin-positive (Table 57.4)[127]. FTD is most commonly due to tau protein, with tau-positive inclusions, or to the neuronal accumulation of TAR DNA-binding protein-43 (TDP-43) protein, with tau-negative, ubiquitin-positive inclusions. Among a cohort of 26 bvFTD patients, there were equal numbers with tau-positive and tau-negative pathology[128], and among another 74 bvFTD patients, 55% were associated with a TDP-43 proteinopathy[60,129]. Tau is a microtubule-associated protein (MAPT) that stabilizes microtubules and promotes microtubule assembly by binding to tubulin[130].

Table 57.4 Frontotemporal lobar degeneration (FTLD) neuropathology[127,141]

Histopathology		*Clinical syndromes*	*Genetic association*
Tau-positive			
FTLD-tau	Intranuclear tau-positive inclusions, e.g. Pick bodies	bvFTD, PNFA, PSP, CBS	*MAPT* gene abnormities
Tau-negative, ubiquitin-positive			
FTLD-TDP			
U1	Dystrophic neurites (elongated, long); neuronal cytoplasmic inclusions (few)	SD	None known
U2	Dystrophic neurites (few, short); neuronal cytoplasmic inclusions	FTD-MND, MND	Intraflagellar transport 74
U3	Dystrophic neurites (short); neuronal cytoplasmic inclusions; neuronal intranuclear inclusions	bvFTD, PNFA	*PRGN*
U4	Dystrophic neurites; few neuronal cytoplasmic inclusions; neuronal intranuclear inclusions	bvFTD	*VCP*
FTDP-UPS	Ubiquitin proteosome system	bvFTD	*CHMP2B*
FTDP-U 'atypical'		Very young onset bvFTD	
Tau-negative, ubiquitin-negative			
FTDP-IF	Neuronal intermediate filament inclusion disease		
FTDP-ni	No inclusions	bvFTD	
BIBD	Basophilic inclusion body disease	bvFTD	

It is abnormal if hyperphosphorylated, resulting in a breakdown of microtubules and an impairment of axonal transport. TDP-43 is a nuclear protein whose function is not entirely clear, but appears to have a role in the regulation of transcription and mRNA splicing[131]. It is normal for TDP-43 to be ubiquinated, but it is abnormal when phosphorylated[131].

Many patients with FTD syndromes have the intraneuronal accumulation of MAPT with tau-positive inclusions[132–134]. Six different isoforms of this tau protein result from alternative splicing, particularly of exon 10, which affects the number of carboxyl-terminal repeats[135,136]. An FTD 'tauopathy' may result from tau-positive inclusions due to either an imbalance in the ratio of tau isoforms with 3 or 4 microtubular binding repeats or to the abnormal hyperphosphorylation of tau. A tauopathy underlies nearly half of those with bvFTD, most of those with the PNFA variant, and all who develop parkinsonism, including the related disorders of PSP and CBS[60,92,128,129,137].

More than half of patients with FTD syndromes have tau-negative, ubiquitin-positive inclusions which contain TDP-43 (Figure 57.4)[127,138–140]. TDP-43 is expressed when there is neuronal injury, resulting in caspase-dependent cleavage of TDP-43 and its deposition in insoluble neuronal inclusions. These ubiquitin-positive inclusions include different ubiquitin subtypes (U1–U4) depending on the distribution of ubiquitin positivity (Table 57.4)[141–144]. About

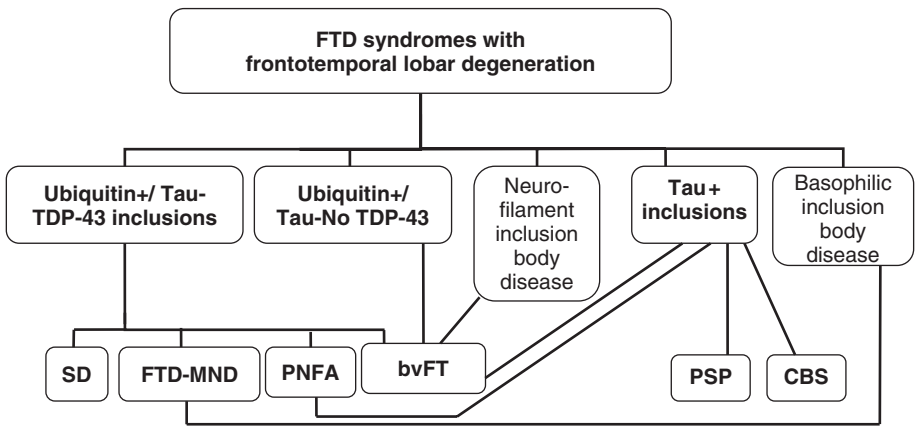

Figure 57.4 The relationships among the different pathologic and clinical variants of FTD syndromes with frontotemporal lobar degeneration

a quarter of FTLD-TDP cases are U1, half are U2, a quarter are U3, and a very small number are U4. A ubiquitin-positive, TDP-43 proteinopathy underlies over half of those with bvFTD, most of those with the SD variant, and FTD patients who develop MND[60,128,129,145]. In addition, abnormal TDP-43 immunoreactivity also occurs in other neurodegenerative disorders including AD[94,146].

A small proportion of FTD cases are associated with pathologies other than a tauopathy or a TDP-43 proteinopathy (Table 57.4). Some patients have ubiquitin-positive inclusions without TDP-43. A subset of these shows immunostaining against proteins of the ubiquitin proteosome system (FTDP-UPS). Another subset is ubiquitin-positive, TDP-43-negative without any positive immunostaining to an identified target protein. These 'atypical' FTLD-U patients have a very early age of onset and lack a clear family history for the disorder[127]. Other patients are both tau-negative and ubiquitin-negative. One, known as neuronal intermediate filament inclusion body disease, results from an accumulation of intraneuronal inclusions that are immunoreactive to neurofilament and α-internexin (FTDP-IF)[127,147,148]. Another has no inclusions whatsoever evident on immunohistochemistry (FTDP-ni). This term replaces the formerly described FTD cases of 'dementia lacking distinctive histology'[139,140,149,150]. A further subset associated with FTD-MND is basophilic inclusion body disease, which results in the identification of basophilic round neuronal inclusions that show variable immunoreactivity to ubiquitin but are unreactive to other stains (BIBD)[151,152].

Some estimates state that 38–50% of patients with FTD may have a positive family history[153,154], but direct autosomal dominant inheritance is present in only about 15%[155]. These autosomal dominant cases are due to *MAPT* mutations in 7–21% and *PGRN* mutations in 5–26%, both linked to chromosome 17[10,156–158].

MAPT mutations may result in neurodegeneration from tau aggregation in neurons and glia resulting in interference with axonal transport[159,160]. This aggregation often follows from missplicing of exon 10 and the surrounding intronic 'stem-loop'. There are over 40 known potential pathogenic *MAPT* mutations including 27 missense mutations, 4 silent mutations, 2 in-frame single codon deletions and 8 intronic mutations[161].

In 2006, researchers reported mutations in the *PGRN* gene in association with FTD and ubiquitin-positive (FTLD-TDP U3) inclusions[9,10,140,162]. Since then, researchers have found 40 to 50 different *PGRN* mutations that lead to degradation of mutant RNA[9,156,161]. Progranulin is a 593-amino acid, secreted glycosolated protein. It has many roles, including in brain development, as a growth factor and as an anti-inflammatory agent with functions in wound healing. The relationship between *PRGN* and TDP-43 remains to be elucidated. Paradoxically, investigators have identified mutations in the gene encoding for TDP-43 in familial amyotrophic lateral sclerosis, but not in FTD or FTD-MND families[163,164].

In addition to *MAPT* and *PGRN*, there are rare genetic mutations associated with FTD syndromes. Mutations in the valosin-containing protein linked to chromosome 9 result in bvFTD with inclusion body myopathy or Paget's disease (VCP)[165]. VCP is an ATPase associated with multiple cellular activity, and, at autopsy, there are widespread ubiquitin- and TDP-43-positive intranuclear inclusions (FTLD-TDP U4)[141,166]. Mutations in the charged multivesicular body protein 2B (CHMP2B) linked to chromosome 3 result in early onset bvFTD with severe cognitive deficits[167]. CHMP2B plays a role in efficient autophagy, and, at autopsy, there are ubiquitin-positive inclusions that are not immunoreactive to TDP-43 but that appear to stain for other ubiquitin proteosome system proteins (FTLD-UPS)[168]. Finally, the clinical bvFTD-like syndrome may result from an alternative transcription of the presenilin 1 mutation associated with familial AD[169].

COURSE AND MANAGEMENT

The duration of FTD syndromes can be quite variable, depending on subtype and the presence or absence of complications, such as parkinsonism or MND. The usual duration of the three uncomplicated syndromes, bvFTD, PNFA and SD, is about 8–11 years with death resulting from terminal pulmonary, urinary tract or decubitus infections or complications[6,170]. Those with FTD-MND have a much shorter, more malignant course of about 1–3 years[18]. There may be a decreased survival if there is an underlying tauopathy, as opposed to a TDP43 proteinopathy[171]. As FTD syndromes progress, syndromes may transform and evolve. For example, bvFTD or PNFA patients with an underlying tauopathy may evolve to parkinsonism and PSP or CBS. Regardless of phenotypic evolution, all, except for a subgroup of non-progressors ('phenocopies'), eventually accumulate cognitive deficits, develop profound dementia, and have a tendency to late mutism. The non-progressive phenocopies are an enigmatic group of patients who fulfil criteria for bvFTD but show little change in their symptoms over time[50,51,172].

The treatment of bvFTD primarily involves managing the behavioural symptoms with psychoactive medications. Selective serontonin-receptor inhibitors, such as sertraline, paroxetine or fluoxetine, can decrease disinhibition–impulsivity, repetitive behaviours and eating disorders[173]. Trazodone or an atypical antipsychotic such as aripriprazole can also help manage significantly disturbed or agitated behaviour, disinhibition or verbal outbursts. Antipsychotics, however, carry some risk in dementia and in bvFTD, and the US Food and Drug Administration has required warning labels because these medications may increase mortality in elderly patients. Moreover, similar to patients with dementia with Lewy bodies, some patients with bvFTD can have an unusual neuroleptic hypersensitivity[12,174]. The acetylcholinesterase inhibitors, such as donepezil, galantamine or rivastigmine, have not had significant efficacy for patients with bvFTD and can worsen disinhibition or compulsions[169]. Memantine, another dementia medication, is under investigation for the treatment of this disorder, but has not yet shown clinically significant efficacy[175,176]. Most recently, investigators have developed measures for monitoring of clinical drug trials and rational drug treatment for FTD syndromes[177]. This approach holds great promise for an eventual treatment that targets the underlying pathophysiology of FTD, particularly the abnormalities in tau protein and TDP-43[176].

The non-pharmacological management of patients with FTD syndromes focuses on behavioural interventions and care of the caregivers. Behavioural disturbances are particularly distressing to caregivers, who are prone to significant depression[27,178,179]. Family support and education is critical, including the availability of psychosocial counselling and community resources. Some behavioural disturbances may respond to retraining or to rehabilitation techniques[180,181], and speech therapy may benefit PNFA and SD patients. Special attention is needed for safety issues among FTD patients[182], and, when hyperorality is present, restrictions are necessary to prevent lethal ingestion behaviours[183]. As immobility occurs, FTD patients, like all advanced dementia patients, become susceptible to pulmonary emboli, aspiration pneumonia, urinary tract infections and decubitus ulcers.

CONCLUSIONS

The FTD syndromes are neurodegenerative disorders that are rapidly being elucidated. Research has now shown that they are clinical, pathological and genetically heterogeneous conditions. The three classic syndromes are bvFTD, with apathy, disinhibition and other behavioural changes, and PNFA and SD, with early predominant language or word comprehension difficulty. These FTD syndromes can be associated or evolve into the parkinsonian syndromes of PSP and CBS or into FTD with MND. In recent years, basic science research has also made great strides in uncovering the underlying neuropathology and neurogenetics of these syndromes. We now know that they are primarily due to abnormalities in tau or in TDP-43 protein and that these may result from mutations of the *MAPT, PRGN* or other genes. The future looks extremely promising for the discovery of pathophysiological mechanisms and disease-modifying therapies for the FTD syndromes.

The Lewy Body Dementia Spectrum (Alpha Synucleinopathies)

J.-P. Taylor and I. G. McKeith

Wolfson Research Centre, Newcastle General Hospital, Newcastle upon Tyne, UK

INTRODUCTION

The alpha synucleinopathies encompass a diverse range of neurodegenerative entities with the common neuropathological hallmark of abnormal accumulation in the brain of aggregates of insoluble alpha-synuclein. Major members of this club include Parkinson's disease (PD), the associated Parkinson's disease dementia (PDD), dementia with Lewy bodies (DLB), multisystem atrophy (MSA), pure autonomic failure and rapid eye movement (REM) sleep behaviour disorder. The clinico-pathological manifestation of each of these conditions appears to depend upon the pattern of insoluble alpha-synuclein deposition in specific neuronal and glial populations[1].

Of particular relevance to geriatric practitioners, and the focus of the present chapter, are the Lewy body dementias (LBDs) PDD and DLB, given that, combined, these diseases represent the second commonest cause of dementia in the elderly[2].

NEUROPATHOLOGY OF LEWY BODY DEMENTIAS

As intimated by their appellation, the common histopathological feature of LBDs is Lewy bodies (LBs). These spherical neural inclusions were first described by Friederich Lewy in 1912 in the substantia nigra, locus coerulus and dorsal nucleus of vagus as well as in the hypothalamus, nucleus basalis of Meynert and sympathetic ganglia of PD patients[3,4]. However, interest in the role of LB formation in dementia did not arise until the latter half of the twentieth century when Japanese neuropathologists described a number of cases of dementia with severe extrapyramidal signs, who on autopsy had significant cortical LB deposition[5–8]. These cortical LBs can now be relatively easily visualized by the use of advanced neuropathological techniques including antiubiquitin and, more recently, specific alpha-synuclein immunohistochemical staining.

Histopathologically, LBs are eosinophilic neuronal inclusion bodies whose major constituent is aggregated alpha-synuclein bound together with ubiquitin and neurofilament. Cortical LBs tend to be smaller and less eosinophilic than LBs seen in the brainstem. It has been proposed by Braak and colleagues[9] that in PD, LBs appear initially in the brainstem and then ascend progressively along the neuroaxis, with this pattern corresponding to the clinical development of parkinsonism. Later cognitive and neuropsychiatric symptoms emerge then as a consequence of LB cortical involvement. The temporal order of progression appears to be less clear in DLB although neuropathologically three categories, based on LB deposition, have been proposed[3]: a brainstem-predominant DLB, a limbic (or transitional) DLB, and a predominantly cortical DLB. Correlation of these categories or the distribution of alpha-synuclein with dementia development, extrapyramidal signs or neuropsychiatric symptoms, however, is lacking[10]. In addition, current pathological criteria probably do not explain the full range of potential pathological distributions that can occur, as up to 20% of older patients with LBs at autopsy have a cortical predominant pattern of distribution that does not conform to either the Braak or DLB Consortium schemas[11].

Neuropathological assessments of DLB are further complicated by the presence of co-existent Alzheimer's disease (AD) pathology as high senile plaque counts are found in 80–90% of DLB cases; this is a comparable level to that found in pure AD. Conversely, LB pathology has been found in the amygdalae of individuals who have widespread AD pathology[12] although these cases seldom display any clinical characteristics of DLB and thus should be regarded separately from LBDs[3]. These observations have, however, contributed to the sustained belief that AD and LBDs are caused by the same underlying disease as reflected in the use of terms such as 'the Lewy body variant of AD' for these mixed pathology cases[13]. This is inappropriate, since 80–90% of DLB cases neuropathologically do not have the typical AD-associated neocortical neurofibrillary tangles which are now known to be integral to the pathophysiology of AD[14]. More recently clinico-pathological data have suggested that the expression of a DLB clinical phenotype is related to the severity of LB pathology and inversely related to the severity of Alzheimer type pathology[3,15].

CLASSIFICATION OF LEWY BODY DEMENTIAS

Existing nosological systems such as DSM-IVR have been poorly operationalized with regard to PDD and DLB. PDD in DSM-IV-R is only briefly referenced and its syndromal definition is imprecise requiring the presence of PD with associated cognitive and motoric deficits, executive dysfunction and impairment in memory retrieval, which may be exacerbated by depression. DLB as a disease entity is not even listed in DSM-IV-R and this probably reflects the presumed association with AD as well as the various and confusing diagnostic labels which have been attached to this condition over the years, including Lewy body dementia, Lewy body variant of AD, senile dementia of Lewy body type and diffuse cortical Lewy body disease.

Principles and Practice of Geriatric Psychiatry, 3rd edn. Edited by Mohammed T. Abou-Saleh, Cornelius Katona and Anand Kumar
© 2011 John Wiley & Sons, Ltd

An important step forward to address these issues has been the formulation of operationalized criteria for both PDD[16] and DLB[5,6] (see Tables 58.1, 58.2 and 58.3), with the latter undergoing a revision in 2005[3]. These have allowed clinicians to make more precise diagnoses and develop clearer management strategies. From the perspective of research, operational criteria have begun to facilitate in a systemized manner a better understanding of the natural history of these conditions and improved clinico-pathological correlations, as well as allowing clinical trials to be conducted to standards accepted by drug regulatory authorities. Overall, however, it is important to recognize that the criteria for DLB and PDD are still under development and will require further refinement (e.g. neuropathological criteria), as well as being complemented by effective disease biomarkers to improve early detection (see later discussion).

As presented in Tables 58.1 and 58.2, the diagnosis of probable or possible PDD depends primarily upon the presence of core symptoms of (i) diagnosis of parkinsonism, (ii) a dementia with an insidious onset and slow progression in the context of established PD and (iii) the absence of features which could suggest other conditions as the cause of mental impairment[16]. The diagnosis of probable PDD depends upon the presence of the core symptoms as well as a cognitive profile typical for PDD (e.g. attention, visuo-spatial) and at least one behavioural symptom (e.g. visual hallucinations). The diagnosis of possible PDD is less rigorous; while still requiring the core features, the associated cognitive impairment may be, for example, atypical; behavioural symptoms may or may not be present and there may be features which make the diagnosis less robust, e.g. evidence for vascular disease on imaging. For a diagnosis of probable or

Table 58.1 Features of dementia associated with Parkinson's disease

I. **Core features**
   1. Diagnosis of Parkinson's disease according to Queen Square Brain Bank criteria
   2. A dementia syndrome with insidious onset and slow progression, developing within the context of established Parkinson's disease and diagnosed by history, clinical, and mental examination, defined as:
      - Impairment in more than one cognitive domain
      - Representing a decline from premorbid level
      - Deficits severe enough to impair daily life (social, occupational, or personal care), independent of the impairment ascribable to motor or autonomic symptoms

II. **Associated clinical features**
   1. Cognitive features:
      - Attention: Impaired. Impairment in spontaneous and focused attention, poor performance in attentional tasks; performance may fluctuate during the day and from day to day
      - Executive functions: Impaired. Impairment in tasks requiring initiation, planning, concept formation, rule finding, set shifting or set maintenance; impaired mental speed (bradyphrenia)
      - Visuo-spatial functions: Impaired. Impairment in tasks requiring visual-spatial orientation, perception, or construction
      - Memory: Impaired. Impairment in free recall of recent events or in tasks requiring learning new material, memory usually improves with cueing, recognition is usually better than free recall
      - Language: Core functions largely preserved. Word finding difficulties and impaired comprehension of complex sentences may be present
   2. Behavioral features:
      - Apathy: decreased spontaneity; loss of motivation, interest, and effortful behaviour
      - Changes in personality and mood including depressive features and anxiety
      - Hallucinations: mostly visual, usually complex, formed visions of people, animals or objects
      - Delusions: usually paranoid, such as infidelity, or phantom boarder (unwelcome guests living in the home) delusions
      - Excessive daytime sleepiness

III. **Features which do not exclude PD-D, but make the diagnosis uncertain**
   - Co-existence of any other abnormality which may by itself cause cognitive impairment, but judged not to be the cause of dementia, e.g. presence of relevant vascular disease in imaging
   - Time interval between the development of motor and cognitive symptoms not known

IV. **Features suggesting other conditions or diseases as cause of mental impairment, which, when present make it impossible to reliably diagnose PD-D**
   - Cognitive and behavioral symptoms appearing solely in the context of other conditions such as:
     Acute confusion due to
     a. Systemic diseases or abnormalities
     b. Drug intoxication
     Major Depression according to DSM IV
   - Features compatible with "Probable Vascular dementia" criteria according to NINDS-AIREN (dementia in the context of cerebrovascular disease as indicated by focal signs in neurological exam such as hemiparesis, sensory deficits, and evidence of relevant cerebrovascular disease by brain imaging AND a relationship between the two as indicated by the presence of one or more of the following: onset of dementia within 3 months after a recognized stroke, abrupt deterioration in cognitive functions, and fluctuating, stepwise progression of cognitive deficits)

Table 58.2 Criteria for the diagnosis of probable and possible PD-D

Probable PD-D

A. Core features: Both must be present

B. Associated clinical features:

- Typical profile of cognitive deficits including impairment in at least two of the four core cognitive domains (impaired attention which may fluctuate, impaired executive functions, impairment in visuo-spatial functions, and impaired free recall memory which usually improves with cueing)
- The presence of at least one behavioral symptom (apathy, depressed or anxious mood, hallucinations, delusions, excessive daytime sleepiness) supports the diagnosis of Probable PD-D, lack of behavioral symptoms, however, does not exclude the diagnosis

C. None of the group III features present

D. None of the group IV features present

Possible PD-D

A. Core features: Both must be present

B. Associated clinical features:

- Atypical profile of cognitive impairment in one or more domains, such as prominent or receptive-type (fluent) aphasia, or pure storage-failure type amnesia (memory does not improve with cueing or in recognition tasks) with preserved attention
- Behavioral symptoms may or may not be present

OR

C. One or more of the group III features present

D. None of the group IV features present

Table 58.3 Consensus criteria for the clinical diagnosis of probable and possible DLB

1. Central feature (essential for a diagnosis of possible or probable DLB): Dementia defined as a progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention, executive function and visuo-spatial ability may be especially prominent.
2. Core features (two core features are sufficient for a diagnosis of probable DLB, one for possible DLB):
   - Fluctuating cognition with pronounced variations in attention and alertness
   - Recurrent visual hallucinations that are typically well formed and detailed
   - Spontaneous features of parkinsonism.
3. Suggestive features (if one or more of these is present in the presence of one or more core features, a diagnosis of probable DLB can be made. In the absence of any core features, one or more suggestive features is sufficient for the diagnosis of possible DLB. Probable DLB should not be diagnosed on the basis of suggestive features alone):
   - REM sleep behaviour disorder
   - Severe neuroleptic sensitivity
   - Low dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET imaging.
4. Supportive features (commonly present but not proven to have diagnostic specificity):
   - Repeated falls and syncope
   - Transient, unexplained loss of consciousness
   - Severe autonomic dysfunction, e.g. orthostatic hypotension, urinary incontinence
   - Hallucinations in other modalities
   - Systematized delusions
   - Depression
   - Relative preservation of medial temporal lobe structures on structural imaging
   - Generalized low uptake on SPECT/PET perfusion scan with reduced occipital activity
   - Abnormal (low uptake) MIBG myocardial scintigraphy
   - Prominent slow wave activity on EEG with temporal lobe sharp waves.
5. A diagnosis of DLB is less likely:
   - In the presence of cerebrovascular disease evident as focal neurological signs or on brain imaging
   - In the presence of any other physical illness or brain disorder sufficient to account in part or in total for the clinical picture
   - If parkinsonism only appears for the first time at a stage of severe dementia.
6. Temporal sequence of symptoms:
   DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism (if present). In research studies, when a distinction needs to be made between DLB and PDD, the one-year rule between the onset of dementia and parkinsonism should be applied.

Source: Adapted from McKeith *et al*. Diagnosis and management of dementia with Lewy bodies. Third report of the DLB consortium, *Neurology* 2005; **65**: 1863–72. Reprinted with permission from Wolters Kluwer Health.

possible DLB (Table 58.3), consensus criteria demand that the core features of fluctuating cognitive impairment, recurrent visual hallucinations and parkinsonism should be present (two or more core features for a diagnosis of probable DLB and one core feature for a diagnosis of possible DLB). DLB criteria also provide supportive and suggestive features that may make the diagnosis more likely. Clinical assessment of these features is discussed in more detail later.

The development of these criteria has, however, not been without difficulties:

Deciding if it is DLB or PDD

The diagnostic separation of DLB from PDD, on the basis of when the motor features occur relative to the dementia has caused controversy[17–20]. Currently both the consensus criteria for DLB and PDD recommend that for a diagnosis of PDD, the extrapyramidal motor features need to be present for at least 12 months or more before the onset of the dementia, but if the dementia precedes the motor symptoms or occurred within 12 months of the motor features then the diagnosis should be DLB. This boundary delineation has been considered useful in research for determining the epidemiology and natural history of these conditions as well as providing clinicians with clear categorical labels for diagnosis. However, separation of PDD and DLB on a temporal arbitrariness has no strong clinical or pathological basis. Indeed, as will be discussed below, while minor differences do exist between DLB and PDD, they demonstrate remarkably similar cognitive profiles as well as similar neuropsychiatric features, neuroleptic sensitivities, sleep symptoms, autonomic dysfunction and responsiveness to cholinesterase inhibitors[21]. Overall unitary approaches have proven useful for study of common neurobiological and genetic processes in these conditions, and, indeed, the term Lewy body disease, which encompasses PD, PDD and DLB, and the term Lewy body dementias, which includes PDD and DLB, have been particularly helpful in this regard (see Figure 58.1). Therefore, while separating the dementias, PDD from DLB, avoids confusion clinically and helps stream patients depending upon the clinical setting in which they are first diagnosed (e.g. movement disorder clinics for PDD and dementia clinics for DLB), in certain cases, particularly when the temporal ordering of motor to cognitive symptoms is not clear, the umbrella term LBDs is likely to be more useful (Table 58.4).

Problems with Validation of DLB Consensus Criteria

Neuropathological validation studies using the 1996 DLB consensus criteria[6] suggested that while the specificity of the clinical diagnosis of probable DLB, i.e. LB pathology found at autopsy, is high at >80%, the sensitivity ≈60%, which suggests that many LB pathology cases do not present with the typical features of fluctuations, visual hallucinations or parkinsonism. Difficulties in clinically discerning core symptoms in certain individuals, particularly when the dementia is severe, the fact that significant LB pathology may occur later in the disease course such that its clinical effects are limited, or the co-occurrence of Alzheimer pathology, which modifies the clinical presentation, are all possible explanations for this reduced sensitivity in DLB detection. Importantly, it means that a significant proportion of potential DLB cases are missed; however, biomarkers and, in particular imaging techniques (see below), which enhance sensitivity in atypical/uncertain cases, may help overcome this problem.

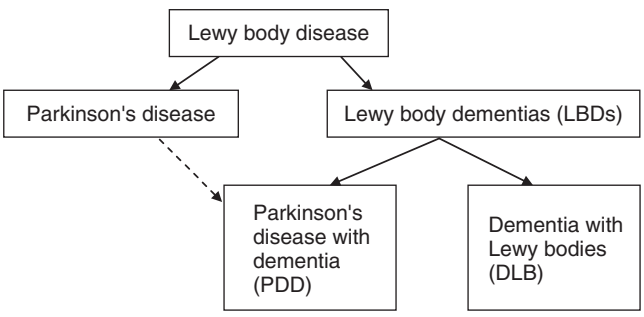

Figure 58.1 Classification of Lewy body diseases

Table 58.4 Key points in classification

- Parkinson's disease with dementia (PDD) should be used to describe dementia that occurs in well-defined Parkinson's
- Dementia with Lewy bodies (DLB) should be diagnosed when the dementia occurs before or concurrently with parkinsonism
- In research, the parkinsonism needs to be present for at least one year before the onset of dementia to make a diagnosis of PDD, but if the dementia occurs within 12 months of the motor symptoms, or indeed precedes it, then the diagnosis should be DLB
- Lewy body disease includes PD, PDD and DLB
- Lewy body dementias (LBDs) are part of the Lewy body disease spectrum and include PDD and DLB

When it is difficult to diagnostically separate PDD from DLB, the generic term LBDs might be more helpful clinically.

AETIOLOGY

The aetiology of LBDs remains unclear. However, a number of biological candidates have been proffered, including LB formation, alpha-synuclein pathology and neurochemical deficits.

LB and Alpha-Synuclein Pathology

Initially LBs were hypothesized as the core neurotoxic lesion involved in the aetiology of LBDs given their association in PD with nigro-striatal dopaminergic cell loss. However LBs are only sparsely distributed in the cortex in LBDs and their density does not appear to correlate strongly with disease duration or symptom[22]. More recent thinking has been to view LBs as a neuroprotective response by vulnerable neurons attempting to sequester toxic alpha-synuclein species. An earlier stage in the neurodegenerative process appears to be the accumulation of small aggregates of alpha-synuclein. These aggregates, which are enormous in number, appear to be more widely distributed in the brains of patients with PDD and DLB than LBs and their presence in presynaptic terminals is thought to severely impair synaptic function[23]. The presence of amyloid beta in the neocortex has also been associated with more extensive alpha-synuclein lesions and thus it has been speculated that amyloid beta may have a role in the genesis of alpha-synuclein deposition in LBDs. This is an intriguing finding as it may provide evidence of a link between LBDs and AD pathology but further work is required to clarify this interaction[24].

Recently, a great deal of interest has been focused on the role of the enzyme glucocebebrosidase (GBA) in LBDs. GBA deficiency as a result of an autosomal recessive mutation has long been known to be associated with Gaucher's disease, where there is marked cellular accumulation of the GBA lipid substrate, glucocerebroside. However, it has become evident that while the severe manifestations of Gaucher's occur when there is less than 20% GBD activity, milder heterozygous mutant variants can have little deleterious effect in early life but can cause the later development of PD or DLB (see below for further discussion)[25]. Currently it is unclear in what way GBA mutations are related to PD and LBDs although it has been speculated that impaired ceramide metabolism (in which GBA is involved) and lysosomal recycling interact with the process of alpha-synuclein formation.

Neurochemical Changes

In addition to the neuropathological changes, there are severe deficits in monoaminergic and cholinergic systems in LBDs (see O'Brien *et al*. for further elaboration[2]). While the link between nigro-striatal dopaminergic neuronal degeneration and parkinsonism is established, it is also speculated that abnormal dopamine transmission, particularly in the striatum and frontal areas, contributes to the executive dysfunction[26]. Cell loss in raphe nuclei (serotonin) and locus coerulus (norepinephrine) may explain the mood symptoms, apathy and attentional dysfunction evident in LBDs. Cholinergic deficits in LBDs have been suggested to contribute to the global cognitive impairment and attentional dysfunction as well as hallucinosis; amelioration of these symptoms by cholinesterase inhibitors (ChEis) strongly supports the involvement of cholinergic dysfunction in LBDs pathology.

EPIDEMIOLOGY

Parkinson's Disease Dementia

The prevalence of dementia in PD has been estimated at between 24% and 31%, and the incidence rate is at least four to six times that of the rate of dementia in age-matched controls[27,28]. It is becoming increasingly recognized that cognitive impairment is present even in the earliest stages of PD; in two recent studies it was estimated that between 19% and 24% of newly diagnosed PD patients appear to have some degree of cognitive impairment[29,30]. The nature of these deficits varies, but subtle deficits in executive function, including attention shifting and working memory, as well as deficits in visuospatial function and episodic memory, have been noted. With time there appears to be a broadening and exacerbation of these deficits and it has been suggested that the mean duration from onset of PD to the development of PDD is around ten years; indeed one longitudinal study suggested that the cumulative prevalence was up to 78% after eight years of follow-up[31]. Risk factors for the development of PDD include older age, mild cognitive and attentional impairments at the initial diagnosis of PD, the severity of motor manifestations, and, in particular, the presence of rigidity, postural instability and gait disturbance[32–35]. While PD incidence is twice as common in men as women it is not clear if male gender predisposes PD patients to the development of PDD. Smoking may also be a risk factor but the presence of apolipoprotein E4 (*APOE4*) genotype, unlike AD, does not appear to be a risk factor for PDD[36–39]. Recent large-scale autopsy studies have demonstrated that between 4% and 10% of PD patients have evidence for GBA mutations. These individuals tend to display early-onset parkinsonism and at least half had hallucinations and cognitive decline; it has recently been suggested that GBA mutations represent the most common genetic risk factor for the development of PD or LBDs[40].

Dementia with Lewy Bodies

Community prevalence figures for DLB have ranged from 0% to 30.5% of dementia cases depending on the sample cohort[41]. This wide range can be explained by a small number of studies with low patient numbers, differences in case criteria used and the presence of significant sampling biases. However, studies have suggested approximately 15–30% of all dementia cases meet neuropathological criteria for DLB at autopsy, emphasizing that a significant proportion of DLB cases are probably being missed clinically[42]. There are very few studies examining the incidence of DLB; two longitudinal studies, one US-based and the other Japanese-based, estimated the incidence as 0.57 per 1 000 person years and 1.4 per 1 000 person years, respectively[43,44]. Risk factors for DLB are unclear as prevalence studies have been too small. It has, however, been suggested that *APOE4* status reduces survival rate in DLB (as with AD) although its presence has little effect on disease onset or duration[45]. With regard to GBA, an autopsy study that included 95 patients with pathological confirmed DLB noted that 28% of subjects had GBA mutations. Those patients with AD co-pathology had substantially less at 10%, suggesting that GBA mutations tend to lead to more pathologically pure forms of LBDs[46]. There may be an increased prevalence of DLB with older age and some case series have suggested a male preponderance although more recent studies have refuted this. Of note, however, is a recent neuropathological study suggesting that while the prevalence of LBs is almost the same between the sexes, the severity of LB pathology may differ, with males having a more brainstem/limbic pattern compared to a more diffuse neocortical pattern seen in women[15].

CLINICAL FEATURES

LBDs have a distinctive constellation of symptoms and signs, including progressive cognitive impairment, neuropsychiatric alterations, parkinsonism, sleep behaviour disturbances and autonomic dysfunction. In PDD, parkinsonism is the initial complaint with the subsequent development over many years of an insidiously progressive cognitive impairment. Neuropsychiatric symptoms such as visual hallucinations are often initially viewed as a side effect of dopamine replacement therapy, but later, particularly as the cognitive impairment advances, they often arise independent of any anti-parkinson treatment. DLB patients, on the other hand, often have less prominent parkinsonism at initial presentation; instead, they tend to present with an evolving dementia that is often associated with attentional/cognitive fluctuations as well as visual hallucinations. These differences in the clinical presentation of the PDD versus DLB, particularly earlier in the disease course, are likely to relate to the differences in pathological spread and distribution of LBs and alpha-synuclein between the two conditions, as previously discussed. However, symptom and feature convergence occur between PDD and DLB later in the disease course, reflecting the commonality at this point in terms of neuropathology.

Cognitive and Attentional Impairment

Clinicians with experience in LBDs often state that they get an inherent 'feel' of how the cognitive profile of patients with LBDs

differs from that of patients with AD. Patients with LBDs have been suggested to display 'subcortical' features such as bradyphrenia and attentional deficits as well as visuo-perceptual problems (disproportionate to the global cognitive impairment), and this contrasts with the more 'cortical' feel of AD, where language and memory deficits predominant. Thus on the Mini-Mental State Examination, a patient with DLB or PDD might be well orientated to time and place, score two out of three points on the delayed recall, but be unable to perform the serial sevens or copy the double pentagons.

This clinical impression of a difference is certainly supported by detailed neuropsychological testing. Patients with LBDs tend to perform better on verbal memory tests; indeed, in the early stages of the disease, episodic recall tends to be preserved, in contrast to AD, where short-term memory deficits are the presenting complaint. However, psychomotor speed is much slower in patients with LBDs compared to AD patients. In addition, patients with LBDs tend to have much more marked executive and attentional dysfunction[47,48] and this appears to be associated with fluctuations in cognitive function. These fluctuations, which may vary in duration in terms of minutes, hours or days, occur in up to 85% of patients with LBDs[49]. Fluctuations in cognition can occur in other dementias, such as AD and vascular dementia, but they appear qualitatively distinct in LBDs, where there appears to be an interruption of awareness that is often associated with transient episodes of confusion and communicative difficulties. Remission of near-normal cognitive function can then occur spontaneously in the absence of clear environmental triggers, suggesting that the fluctuations in LBDs are internally driven. A major problem, however, which has affected the accurate diagnosis of LBDs, is how to clinically define what cognitive fluctuations actually are. In DLB, various caregiver/observer inventories have been created to answer this issue. Importantly, Ferman *et al*.[49] found that four characteristics of the fluctuations appear to be particularly useful in reliably distinguishing DLB from AD:

- daytime drowiness and lethargy
- daytime sleep of two or more hours
- staring into space for long periods
- episodes of disorganized speech.

Patients with LBDs also display more marked visuo-perceptual impairments on testing than AD patients, and this may tie in with the finding that there is marked parietal and occipital hypoperfusion in LBDs on functional neuroimaging. Within LBDs, the profile of cognitive deficits is broadly similar in PDD and DLB although it has been suggested that DLB patients suffer more severe executive and attentional dysfunction than PDD patients[50].

Neuropsychiatric Symptoms

Visual hallucinations are a common symptom in LBDs: 45–65% of PDD patients have visual hallucinations; their occurrence is higher in DLB with 60–80% displaying visual hallucinations[16]. These rates contrast with the low rates of visual hallucinations reported in AD (less than 10%) and hence the importance which is attached to the presence of visual hallucinations in the diagnostic criteria for both PDD and DLB. Visual hallucinations also tend to be persistent in LBDs, which helps differentiate them from those which occur in AD or delirium. In terms of phenomenology, the majority of hallucinations tend to be complex and formed, and are typically of people (often children), animals and body parts that are either animate or static. The hallucinations can provoke emotional responses ranging from amusement through to indifference and outright fear. Insight is often variable and dependent upon the severity of the concurrent dementia although patients often have better insight into the unreality of the episode when it is over. Auditory hallucinations can also occur, but less frequently than visual hallucinations, in about 20% of patients with LBDs. Delusions are very common in DLB patients (rates of up to 78% have been reported) although their prevalence in PDD patients is lower at about 20–25%[16]. They are often based around experienced hallucinations and visuo-perceptual disturbances. They are typically complex and bizarre and their content often includes persecutory, spouse infidelity and 'phantom boarder' themes. Misidentification syndromes such as Capgras appear to occur almost exclusively in DLB compared to PDD[16].

Depressive symptoms also appear to be common in PDD and DLB patients although prevalence estimates vary considerably from 7% up to 76% depending upon the population studied and the definition used[42]. It can be difficult to make the diagnosis of depression as the clinical picture is often complicated by associated apathy, bradykinesia and attentional dysfunction.

Sleep disorders, in particular REM sleep behaviour disorder, are frequently associated with LBDs. This parasomnia is characterized by a loss of skeletal muscle atonia during REM sleep and its onset often precedes the onset of LBDs by many years. With associated daytime somnolence and noctural restlessness, it has been suggested that REM sleep behaviour disorder may contribute to the cognitive fluctuations and hallucinations seen in LBDs[49].

Parkinsonism

PD is a prerequisite for the diagnosis of PDD; in contrast, in DLB, parkinsonism is only present in about 25–50% of patients at time of diagnosis, although the majority (75–80%) will go on to develop motor features sometime during their disease course. Postural gait instability with less tremor dominance appears to be the typical presenting motor phenotype in both PDD and DLB[51]. Symmetric extrapyramidal symptoms, greater axial rigidity and suboptimal levodopa responsivity (especially evident in DLB) in comparison to PD are also features[52].

Autonomic Dysfunction

Autonomic dysfunction that affects both sympathetic and parasympathetic systems is a significant and common feature of PD through to PDD and DLB. The dysfunction leads to a variety of clinical manifestation including orthostatic hypotension, carotid sinus hypersensitivity, reduced secretions (lacrimal, mouth, sweat), urinary retention, erectile dysfunction and bowel problems (both constipation and diarrhoea). Orthostatic hypotension and carotid sinus sensitivity occur more commonly in LBDs than AD or age-matched controls[53,54] and are likely to contribute to the high rates of syncope and falls that occur in this population.

Alpha-synuclein and LB deposition appear to be widespread within the autonomic system. This and the associated acetylcholine deficiency, which impairs effective preganglionic and parasympathetic synaptic neurotransmission, have been speculated as possible causes of the autonomic dysfunction[53].

Neuroleptic Sensitivity

Neuroleptics can provoke a severe adverse reaction in 30–50% of patients with LBDs[55] even when low doses are used. These reactions

can either be acute or subacute and they generally manifest as an abrupt worsening of parkinsonism with associated increased sedation and confusion. The severity of these reactions is such that they can prove fatal within days or weeks. Acute D2 blockade is thought to mediate these effects and they can occur with the use of both typical and atypical antipsychotics[56].

Gait Instability, Falls and Loss of Consciousness
